So far as etiology is concerned, there are a number of things one need not consider because of the extreme duration of the congestive failure. The patient had some degree of congestive failure for thirteen years without any remissions. It is only necessary to mention congenital heart disease in passing. He might possibly have had an interventricular septal defect that ultimately led to left ventricular hypertrophy and failure; but it is unusual for congenital heart disease to wait for forty-two years to manifest itself. Also, the complete absence of cyanosis anywhere in the story is very much against a septal defect, because if the left ventricle fails the pressure in it falls below that on the right and unoxygenated blood is forced into the peripheral circulation to produce cyanosis. The same argument holds for cor pulmonale. The absence of cyanosis, polycythemia and evidence of right ventricular preponderance makes it unnecessary to give this diagnosis more than passing consideration. Again, the duration is too long for syphilis. Also there is no characteristic murmur of aortic regurgitation, and the serologic tests for syphilis were negative.

At the time of the first admission the patient had a blood pressure of 160 systolic, 110 diastolic, which represents true hypertension, and, as often happens, the first thing that drew attention to the high blood pressure was the presence of congestive failure. However, I do not believe that hypertension alone could account for this degree of failure extending over thirteen years, but it doubtless was a contributing factor.

Arteriosclerosis and coronary heart disease must also be considered. The presence of bundle-branch

block favors this diagnosis. The absence of characteristic T-wave changes in the electrocardiogram, and particularly the complete absence of mention of anginal pain anywhere in this long abstract, make the diagnosis of coronary heart disease untenable as the explanation for twelve years of congestive failure. I think the presence of pain in the joints is of significance in the etiology of the type of heart disease. In the first place, the way the attacks of joint pain are described is characteristic of rheumatic fever; it is much more like that than like rheumatoid arthritis. He had two distinct attacks of rheumatic fever and probably some activity between the attacks, as evidenced by the intermittent joint pains. Since it is well known that few people have two attacks of rheumatic fever without some heart disease, it is probable that he at least had myocarditis. Another thing in favor of rheumatic heart disease is the duration, for on the law of averages people who stay in congestive failure for prolonged periods of time have rheumatic heart disease oftener than any other type of heart disease. That, of course, is just on the basis of statistics and may mean nothing in this particular case.

Another thing in favor of rheumatic heart disease is the conduction difficulty, which ended in auricular fibrillation. Auricular fibrillation is one of the common features of rheumatic heart disease, particularly in cases in which there is mitral stenosis. Another thing that might be explained on the basis of rheumatic heart disease is the development of pericarditis. The patient may have had pericardial effusion at the time of the second admission, judging from the x-ray film. Later on during the admission he developed a definite friction rub, which seemed to be pericardial and not pleuro-pericardial. All this is in favor of rheumatic heart disease. Regardless of whether that was the fundamental thing, he doubtless had some residual myocardial fibrosis as the result of the previous attacks of rheumatic fever.

Strongly against the presence of rheumatic heart disease, however, is the complete absence of murmurs throughout the twelve years that the patient was followed, except for one occasion, at the time of his first admission, when they mentioned an apical systolic murmur to which no one attached significance. However, for no heart murmurs to have been heard is not incompatible with rheumatic heart disease, because all the reported examinations in this record were done when the man was in severe congestive failure. Frequently, in failure, one does not hear a murmur even though there is valvular disease. In favor of rheu-

matic heart disease is the x-ray evidence of an extremely large left auricle. The roentgenologists say that that is very good evidence for mitral stenosis. However, he did not show anything except two elevated white-cell counts to suggest true rheumatic activity during the twelve years. There was no prolongation of the PR interval, no joint pain or anything else that suggests rheumatic activity.

Against the whole thing's being on the basis of congestive failure is the fact that pleural effusion was always on the left side. We are taught that, if unilateral effusion is present as a part of heart failure, it is on the right side rather than the left. It was always on the left in this case. The fact that the fluid was bloody and xanthochromic is highly unusual for fluid in congestive failure, and suggests that some other process was present. However, it is known that the patient had had three chest taps shortly before that admission, and at the time of admission there was air in the chest, which may have indicated that previous taps had damaged the lung and had allowed blood to escape into the pleural space. We therefore cannot put too much weight on the bloody fluid.

I cannot fit two factors very well into the diagnosis of rheumatic fever. One is the fact that the patient showed a thickened pleura in all the films. Another thing is the bulge that developed on the right ventricle, as seen by x-ray. I think that this is a good time to have the x-ray films exhibited, because I need a lot of help from them.

DR. MILFORD SCHULZ: These are the films taken at the first and second admissions. They are all anteroposterior views. There are also a good many oblique views that we might have use for later.

DR. BECKMAN: Can you be sure that the left auricle was enlarged, or must you rely on the fluoroscopist?

DR. SCHULZ: In the right antero-oblique view there seems to be definite enlargement posteriorly in the region of the left auricle.

DR. BECKMAN: You are quite sure that it is the left auricle?

DR. SCHULZ: It is in the position that the auricle usually occupies. I think that the patient was undoubtedly fluoroscoped and that the person who interpreted the examination took the fluoroscopist's opinion into consideration.

DR. BECKMAN: Where is the bulge on the right ventricle?

DR. SCHULZ: This is the right antero-oblique film, and I believe that this represents the bulge in the area of the right ventricle anteriorly.

DR. BECKMAN: Do you suppose it could be an aneurysm?

DR. SCHULZ: It was not present previously. How frequently does an aneurysm occur in the right ventricle?

DR. BECKMAN: Almost never, but I have to explain it some way.

How about the prominence of the left auricle in the earlier films? Is it really the left auricle, or has it some connection with the later shadow in the ventricle?

DR. SCHULZ: I should say that it was the left auricle. This homogeneous increase in density may be fluid in the left chest. You can see it extending along the lateral chest wall. Or perhaps it is thickened pleura.

DR. BECKMAN: That was said to be present in all films, although they mentioned it only at the end.

DR. SCHULZ: It had been present since the time of the pneumothorax.

DR. BECKMAN: I do not know whether it is possible to say that the thickened pleura was due simply to the fact that the lung was traumatized and blood went into the thorax to cause sufficient irritation to give thickening. It may have been due to some other process, although I am at a loss to explain it.

I shall have to guess concerning the bulge in the right ventricle. As I have said, an aneurysm in this region is very uncommon. Aneurysms are usually the result of coronary heart disease with a cardiac infarct. At the admission prior to the one when the bulge in the right ventricle was noted, a friction rub was heard. This might possibly have been the result of infarct, perhaps even in the right ventricle, which thereafter led to weakening and subsequent development of an aneurysm. However, I do not believe that it is possible to make a diagnosis of coronary disease in the complete absence of precordial pain throughout the history, particularly at the time the rub appeared. There would have to be more evidence of coronary disease than he had to lead to the diagnosis of coronary occlusion.

The only other thing I can think of is a tumor in the right side of the heart. There are a wide variety of primary tumors, and every kind of metastatic tumor has been seen in the heart. I do not know how one can differentiate primary tumors of the heart, but I shall "stick out my neck" and say that this patient had a benign tumor in the right ventricle. I presume that he had mitral stenosis on the basis of the previous attack of rheumatic fever and the x-ray evidence of mitral

stenosis, although a murmur was never heard. I believe that the lungs will show pulmonary edema. The white-cell count of 32,000 terminally means that he had some acute infection, probably bronchopneumonia. He might have had acute bacterial endocarditis, but there is no evidence for that, and I think pneumonia is far commoner in occurrence. I also think that there was cardiac cirrhosis of the liver on the basis of the fact that the liver was so large at the onset and was not palpable at the final admission.

DR. BENJAMIN CASTLEMAN: Dr. Williams, would you like to comment?

DR. CONGER WILLIAMS: I know the answer. There is just one thing that I should like to say. I remember seeing this patient on the ward when I was a house officer several years ago. At that time the diagnosis of coronary heart disease was questioned because of the duration of symptoms. It was also pointed out that the electrocardiogram, which then showed bundle-branch block, could very well conceal any underlying difference in preponderance of the ventricles. As soon as bundle-branch block appears, axis deviation is no longer significant. The new pattern bears no relation to ventricular preponderance and may conceal a high degree of right or left preponderance.

CLINICAL DIAGNOSES

Arteriosclerotic heart disease, with right and left congestive heart failure.

Pleural effusion, left.

DR. BECKMAN'S DIAGNOSES

Rheumatic heart disease, with mitral stenosis.

Congestive heart failure.

Thickened pleura, possibly due to hemothorax.

Bronchopneumonia.

Cardiac cirrhosis.

Benign tumor of right ventricle?

ANATOMICAL DIAGNOSES

Pulmonary arteriosclerosis, severe, arterial and arteriolar.

Ayerza's disease.

Pulmonary embolism, old, left (? thrombosis).

Mural thrombus of right atrium.

Cor pulmonale.

Organizing blood clot, left pleural cavity.

Mural endocarditis, fibrous.

Pericarditis, fibrous.

Bronchopneumonia.

Peripheral edema.

Passive congestion of liver, spleen and kidneys.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: This man had an enormous heart, weighing 750 gm. The enlargement for the most part was on the right side. The right auricle was tremendously enlarged, and there was

FIGURE 1. Photomicrograph of Lung Showing Arteriosclerosis.

a mural thrombus in the appendage. The right ventricle was tremendously dilated and thickened, measuring 7 mm. in thickness, which is at least twice normal. The left auricle was not enlarged; neither was the left ventricle. We were unable to find any abnormalities in the valves. The ring of the tricuspid valve was greatly dilated, measuring 16 cm. in circumference. The pulmonary valve was also somewhat dilated, and the conus below it was markedly dilated, forming an aneurysmal outpocketing approximately 1 cm. deep. The endocardium over it was thickened and fibrous, but the underlying myocardium was normal. The appearance of the endocardium was similar to that seen below the aortic valve in the left ventricle in cases of long-standing aortic regurgitation. The coronary arteries showed only slight sclerosis. Grossly we were fairly certain that the etiology of the enlargement of the heart was in the lungs and not in the heart.

On examination of the pleural cavities we were amazed to find a large mass, about 9 by 8 by 8 cm., in the lower part of the left pleural cavity extending from the diaphragm up to the fourth rib. It was adherent to the pleura and pushed the left lower lobe medially and anteriorly; it also pushed the heart over a bit. This proved to be an organizing hematoma, which apparently must have occurred at the time of one of the chest taps

before the second admission, as Dr. Beckman suggested. There was no fluid in the left pleural cavity. The lungs in gross showed a moderate degree of arteriosclerosis of the main vessels, but microscopically there was severe arteriolarsclerosis. This slide (Fig. 1) is a low-power view of a section of the lung showing three arteries with markedly thickened walls and intimal hyalinization. The intervening lung is normal. The next slide (Fig. 2) is a high-power view showing the luminal narrowing. The findings are those of the Ayerza syndrome and explain the right-sided cardiac hypertrophy. There was, in addition, a terminal

FIGURE 2. Photomicrograph of High Magnification Showing a Vessel with Marked Luminal Narrowing.

bronchopneumonia and a large, laminated, old, adherent embolus in the left main pulmonary artery and its two major branches, apparently arising from the mural thrombus in the right auricle. It may have originated in situ as a thrombus, but I believe that most cases of thrombosis of the large pulmonary arteries begin as emboli and build up by superimposed thrombosis. It was an old affair and had nothing to do with the terminal event; but it certainly added to the burden of the right heart. The liver showed moderate congestion but no cirrhosis.

I think the suggestion by Dr. Williams that the bundle-branch block disturbed the axis deviation certainly held here. If he not had it, there certainly would have been a marked right-axis deviation.

CASE 29352

PRESENTATION OF CASE

A seventy-seven-year-old baker entered the hospital because of severe dyspnea.

Approximately twenty or thirty years prior to admission the patient began to suffer with mild dyspnea on exertion that became progressively worse. About four and a half years before entry he was seen in the Out Patient Department, where a few wheezes and rales were heard in his chest. The heart sounds were distant. The aortic second sound was greater than the pulmonic; there were no murmurs. The blood pressure was 140 systolic, 85 diastolic. He complained of moderate urinary frequency. The diagnoses of pulmonary emphysema, arteriosclerotic heart disease and early decompensation were made. He was digitalized, with improvement of his symptoms. After that he was quite well, except for a chronic cough productive of small amounts of gray sputum daily, until one month prior to admission, when he developed epigastric pain, gas and constipation. Because of the constipation his physician stopped digitalis and referred him for gastrointestinal studies. He rapidly became dyspneic and orthopneic. He had no nocturnal attacks or chest pain. The chronic cough became worse, and the patient raised one cupful of gray sputum daily. There was no nausea, vomiting, anorexia or tarry, bloody or clay-colored stools. There was no fever, hemoptysis, weight loss or chills.

The family and past histories were noncontributory.

Physical examination revealed a well-preserved old man who sat up in bed because of moderate dyspnea. He coughed frequently and brought up small amounts of foul-smelling, yellow sputum. The chest was hyperresonant. The heart was percussed 10.5 cm. to the left of the midsternal line in the fifth intercostal space. The sounds were distant and there were many extrasystoles. There was a soft, blowing systolic murmur over the entire precordium and in the left axilla but best heard at the apex. The neck veins were slightly distended. There was slight dullness at the base of the left chest posteriorly, and in that area the voice and breath sounds were slightly suppressed. The abdomen was soft; no masses were felt, and no tenderness elicited. There was pitting edema at the ankles.

The blood pressure was 120 systolic, 70 diastolic. The temperature was 99°F., the pulse 90, and the respirations 25.

Examination of the blood revealed a red-cell count of 4,500,000, with a hemoglobin of 14.5 gm.,

and a white-cell count of 7500, with 75 per cent neutrophils. The urine and stools were negative. A blood Hinton test was negative. The serum protein was 6.3 gm., and the nonprotein nitrogen 70 mg. per 100 cc.; the carbon dioxide combining power was 21.0 millimols, and the chloride 975 milliequiv. per liter.

A gastrointestinal series was negative. Chest roentgenograms showed haziness over almost all of both lung fields consisting of strand-like infiltration following the pathway of the bronchovascular tree. In addition, in the right lower lobe there was an area of increased density 5 cm. wide and 3 cm. high, with indefinite margins. There was calcification of some of the hilar lymph nodes on the right. There was a small amount of fluid in the left pleural cavity, and probably some in the right. The heart was enlarged, especially in the region of the left ventricle, and the aorta was tortuous.

An electrocardiogram showed a normal sinus rhythm of 75. The PR interval was 0.16 second. The ST segment was depressed in Leads 1, 2 and 4. The T wave was low in Leads 1, 3 and 4, and there was slight left-axis deviation.

The patient was digitalized and given mercurial diuretics, following which the edema lessened. On the ninth hospital day oliguria developed and the nonprotein nitrogen was found to be 116 mg. per 100 cc. The nonprotein nitrogen gradually rose, and complete urinary suppression developed on the eleventh hospital day. Catheterization yielded only 2 cc. of urine. He was given Mercupurin and 50 cc. of 50 per cent glucose solution. On the thirteenth hospital day the nonprotein nitrogen was 160 mg. per 100 cc., the carbon dioxide combining power 19.7 millimols per liter and the chloride 93.2 milliequiv. per liter. The patient showed increasing signs of uremia, remained anuric for four days and died on the fifteenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. JACOB LERMAN: I should like to know what the urine showed, even though it was said to be negative.

DR. BENJAMIN CASTLEMAN: At the first examination it was amber and alkaline, with a specific gravity of 1.025, and showed no albumin or sugar. The Sulkowitch test for urinary calcium was ++. On the following day the specific gravity was 1.010, and on the fifth day 1.007; there were no other changes.

DR. LERMAN: The diagnoses made in the Out Patient Department—arteriosclerotic heart disease, cardiac failure and pulmonary emphysema—seem justified on the basis of the findings at

that time. The patient's condition remained unchanged until he developed evidence of pulmonary infection. At that point we may say that, as so commonly happens in people with long-standing congestive failure, chronic bronchitis developed. Later he developed epigastric pain, which suggested to the doctor the need for gastrointestinal studies.

The physical findings indicate a dilated heart with congestive failure and fluid in the left chest. The electrocardiogram suggests obvious digitalis effect and slight coronary disease. The blood findings are normal. To me the striking laboratory findings are the retention of nitrogen and the mild acidosis in the presence of an apparently normal urine. The specific gravity was 1.025, indicating fairly good concentration, at least in the beginning. X-ray study confirmed congestive failure and showed something else, which may have been a pulmonary tumor.

DR. MILFORD SCHULZ: These films show a somewhat enlarged heart with particular prominence in the left ventricular area. There is some fluid at both bases, and the hilar and pulmonary markings are increased. In addition, this area of infiltration apparently lies in the midportion of the right lower lobe.

DR. LERMAN: Is the area in the right lower lobe consistent with bronchiectasis, or is it not too extensive enough?

DR. SCHULZ: Some of the markings at the bases are consistent with bronchiectasis. I think the area of infiltration is something more recent—perhaps an infarct.

DR. LERMAN: The x-ray findings are consistent with congestive failure plus the additional shadow in the right lower lobe, which Dr. Schulz suggests may be a pulmonary infarct. It may be a tumor. Certainly the clinical findings are consistent with bronchiectasis at both bases in a man with long-standing congestive failure.

The point I must explain is why this patient had renal failure in the presence of a normal urinary picture. It seems difficult. I cannot see any connection between the shadow in the right lower lobe and the renal involvement. The x-ray findings of an apparently prominent left ventricle and the accentuated aortic second sound noted in the record suggest the existence of hypertensive heart disease. We have no evidence from the record that he had hypertension, and it does not seem likely that a slight degree of congestive failure existing four and a half years before entry could have dropped the blood pressure from a hypertensive to a normal level. Therefore, I doubt that he had hypertensive heart disease. Arteriosclerotic heart disease is the more likely explanation of the cardiac picture.

I should like to consider chronic glomerulonephritis as an explanation of renal failure. It is most unlikely that he would not have albuminuria or show slight evidence of nephritis in the sediment. Furthermore, the concentration of the urine to 1.025 is hardly consistent with chronic glomerulonephritis. There is no obvious evidence of arteriolar nephrosclerosis or of pyelonephritis. The absence of hypertension certainly argues against glomerulonephritis, nephrosclerosis and pyelonephritis.

The final episode of oliguria and anuria could have been due to the natural course of uremia, but we must remember that he was taking mercurial diuretics and that these may have caused additional irritation of the kidneys and contributed to their final shutdown. I am inclined to believe that at autopsy there was evidence of irritation of the kidneys due to the diuretics. This, however, does not help to explain the discrepancy between renal failure and normal urinary findings. Cardiac failure alone does not explain it. Cardiac failure plus pulmonary infection in the presence of arteriosclerotic kidneys might explain the picture.

Other mechanisms, extrarenal in origin, may produce renal failure without actual injury of the kidneys. Dehydration is one of them, but it obviously does not play any role here. Adrenal failure sometimes causes marked nitrogen retention without renal damage. I have never seen this degree of renal failure—a nonprotein nitrogen of 70 mg. per 100 cc. and a carbon dioxide combining power of 21 millimols per liter—in adrenal disease. Moreover, the blood chloride was within normal range, and there was no hypotension.

One should consider some process involving both ureters simultaneously. Infection may do it, but there is no evidence of it here. I cannot conjure up anything else,—malignant disease or any other pathologic process,—that would involve both ureters uniformly. One would have to assume that the patient had congenital absence of one kidney or of one ureter with involvement of the remaining kidney or ureter by a malignant process, such as retroperitoneal lymphoma. This seems somewhat farfetched.

One must also consider bilateral ischemia of the kidneys. Among the possible causes of this condition is some disturbance of the aorta itself. Aneurysms, in the proper location, have been described that produce progressive ischemia of the kidney with renal failure and eventual shutdown. This patient had pain in the epigastrium. He may have had a dissecting aneurysm of the thoracic aorta that worked its way down to both renal arteries and then caused progressive shutdown. Against this diagnosis is the fact that the pain

was not excruciating and did not persist. Furthermore, there was no evidence of arterial involvement elsewhere: there is no mention of obstruction of the iliac arteries.

One might consider a horseshoe kidney as a cause of progressive renal failure without much in the way of urinary findings. However, since there is no mention of an abdominal mass we need not consider it further.

It seems to me that the most likely diagnosis is arteriosclerotic heart disease with congestive failure, and arteriosclerotic kidneys with renal failure resulting from congestion plus the toxic effect of chronic pulmonary infection. I meekly add the possibility of an aortic aneurysm producing bilateral renal ischemia.

CLINICAL DIAGNOSIS

Arteriosclerotic heart disease, with decompensation.

DR. LERMAN'S DIAGNOSES

Arteriosclerotic heart disease, with congestive failure.

Uremia due to congestion of arteriosclerotic kidneys plus toxic effect of chronic pulmonary infection.

Bilateral renal ischemia due to aneurysm of aorta?

ANATOMICAL DIAGNOSES

Undifferentiated malignant tumor involving retroperitoneal lymph nodes, lungs, pleura, spleen, peritoneum and vertebral bone marrow.

Compression of both ureters by tumor.

Hydroureter, right.

Hydronephrosis, right.

Cardiac hypertrophy, moderate.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: At autopsy this man showed perfectly normal-looking kidneys, except for slight scarring such as one might expect to find in a man of his age. The right pelvis was dilated, but the left was not. The retroperitoneal nodes all along the aorta were enlarged, were replaced by tumor and compressed both ureters, the right more than the left. We were unable to get a probe into the right ureter at a point about 6 cm. below the ureteropelvic junction. A similar process was present on the left, but the occlusion was not so complete because it was easily probed. However, with the probe out, the walls of the ureter closed down on the lumen, so that during life there was probably complete obstruction. It is possible that the complete occlusion on the right side produced so-called "reflex anuria" on the other side so that no urine reached the bladder, but the urologists inform me that this rarely, if ever, occurs.

The shadow in the right lower lobe was a markedly thickened pleura infiltrated with neoplasm. There were nodules of tumor in the lung parenchyma, in the spleen, in the omentum and in the mesentery; and microscopically they were present in the vertebral bone marrow. The strand-like infiltration observed on the roentgenogram was due to tumor infiltration of the lymphatics.

The exact classification of the tumor is difficult. The cells are large, many with two or three nuclei, and although it suggests in a few places an embryonal form of carcinoma, such as is seen in the testis, it is probably some form of undifferentiated sarcoma. The testes were normal, and we were unable to find any other primary source, so that we shall have to leave it as an undifferentiated malignant tumor.

The heart was moderately enlarged and showed minimal coronary disease. There was no evidence of disease within the kidney itself.

INFECTIOUS DISEASE IN WARTIME

THE current educational campaign of the Metropolitan Life Insurance Company has for its subject, suitably enough under present conditions, rheumatic fever. To achieve the objectives of an earlier recognition of rheumatic fever, better care of the child ill with the disease, and an appreciation of the increased dangers resulting from overcrowding and the unsanitary conditions following in the wake of our organization for war, the company has planned a most comprehensive program. This includes the distributing of suitable material to policyholders and others, the enlisting of the interest of local physicians and school officials and

the arranging of discussions at parent teacher associations, service clubs and so forth. In addition, an excellent pamphlet on the clinical considerations of rheumatic fever has been prepared for distribution to physicians. In this country the best approach to any public problem is still the education of the public.

Rheumatic fever remains a major health problem today. Between the ages of five and nine years it causes more deaths than any other single disease, and is exceeded in mortality only by a combination of the four principal communicable diseases of childhood. Between the ages of ten and fourteen years it is also outranked by none, and between fifteen and twenty-four years it is led only by tuberculosis. It is fair to say, however, since the inference may be drawn that rheumatic fever is actually on the increase, that its relative growth in importance is due to the fact that deaths from other diseases have declined even more rapidly. Actually the death rate from chronic heart disease among the company's policyholders between the ages of five and twenty-four has fallen two-thirds in the last thirty years, and that due to acute rheumatic fever at approximately the same rate—from 7.2 to 1.7 per 100,000.

The disease rheumatic fever has richly earned the significance that is being attached to it and the efforts that are being made to defeat it. There is, however, reason to doubt that at the present time any important infectious disease is undergoing a drop in its morbidity rate. In the armed forces, composed largely of men under thirty and including such a large proportion of the group in the later years of adolescence, rheumatic fever constitutes a constant and relatively serious medical problem. Everyone is aware of the increase in communicable diseases, particularly of scarlet fever,—fortunately in a mild form,—of meningitis and of pulmonary infections.

The same general experience obtained during World War I, and it is, of course, common knowledge that war with its mass movements of population, its mobilization in close quarters of large

numbers of susceptible individuals and its tendency to break down the usually well-organized civilian health facilities, carries with it an inevitable increase in the microscopic enemies of man, regardless of the justice of the cause to which the Nation is committed.

For some time to come the acute infectious diseases must be combated—as they have been for years; and it is hoped that more effective weapons will be available than have ever before been possessed. There is every indication, also, that outbreaks of malaria and other tropical and semi-tropical diseases must be faced when the troops return from their far-flung battle lines.

A NURSE ON BATAAN AND CORREGIDOR

LIEUTENANT REDMOND,* formerly an American Red Cross nurse, now an officer in the Army Nurse Corps, went to Manila in September, 1940, after three years of service in the Army and Navy Hospital at Hot Springs, Arkansas. Little did she realize what her experiences would be when, after a year, she found herself in the Sternberg General Hospital in the fall of 1941. Her wards were going like clockwork at seven o'clock in the morning of December 8 when she came off duty, and she had planned a morning of sleep and an afternoon of golf. The attack on Pearl Harbor, when reported over the telephone by a friend, was at first taken as a joke, but by some sensible instinct she rushed to the bank and cabled her savings home. No sleep came that day and for many days to come. Soon hundreds of casualties arrived in trucks, ambulances, buses, carts and anything that had wheels. Many were dead when they reached the hospital. Operating tables were empty hardly a moment at a time. The morale was magnificent. The wounded were quiet. Often one would say, "Take my buddy, he's hurt worse than me."

The bombing continued. Nurse Redmond

watched some dogfights in the sky and saw three enemy planes brought down. The pilots, dead, were brought to the hospital; one was a German. Cavite was burning. Soon rumors spread, only to be followed by Japanese troops marching on Manila. By December 23, Nurse Redmond and her associates had been moved to Bataan. There she remained, conscious of the slowly approaching danger but always doing her full duty. Supplies grew short, the field hospitals were bombed, the dust and heat were indescribable. With a hospital full of dysentery patients, they had no lime for the latrines. Serum for gas gangrene ran out, and Colonel Adamo's patients had to be transferred to a hill away from the hospital sheds. Finally came the air raids, blowing some of the wards to bits. Foxholes were dug outside each building and used by all who could get to them; others crawled under the beds in the orthopedic ward after the traction ropes had been cut. Then came the care of the twice wounded. Fortunately Nurse Redmond was uninjured, although knocked down and buried in debris. Little work could be done for a day or two, except to bury the dead.

Like most persons in a crisis, one begins to think "long thoughts," and Nurse Redmond was no exception.

That night we stayed in our fox holes. I didn't sleep. We hadn't eaten since breakfast, but I wasn't hungry. We were like hunted animals, waiting for the kill, almost hoping it would happen quickly so that the torment of waiting would end. But stronger than that was anger; anger and hate and a hot desire to fight back, to avenge our dead.

What kind of human beings would deliberately bomb a hospital, defenseless, openly marked for what it was, filled with the wounded and the sick?

I don't know. The only answer I had found when I crawled out of my hole in the morning, my head aching, a crick in my back, my legs cramped, was not an answer but a conviction. This isn't a war in which anybody—anybody—is let off. Each single individual of us is in it and each must give everything he has to give. An enemy that will bomb hospitals and undefended cities—sick and injured men, or women and children and helpless old people—isn't an enemy you can ever come to terms with; not in the usual meaning of the phrase. The war must end without compromise.

After more horrors, Bataan fell, and on April 7, Nurse Redmond was moved to Corregidor. There

*Redmond, J. *I Served on Bataan*. 167 pp. Philadelphia and New York J. B. Lippincott Company, 1943.

she worked in a hospital tunnel, always cheerful, always doing what she could to serve her patients. There were some amusing moments. Food was better at first than on Bataan. A cleaning woman found some soap and nail polish, so the nurses had shampoos, finger waves and manicures. Some dresses were discovered, and they had a rummage sale. A Chinese tailor who had taken refuge in the tunnel proved to be a great find. He fashioned suits out of discarded officers' clothes, so the nurses had streamlined coveralls, skirts and blouses. Finally came the shelling of Corregidor, and even Nurse Redmond found it hard to face great numbers of people torn and bleeding and dying in masses. "When one patient dies it is agonizing enough, when you are faced by such mass suffering and death something cracks inside you, you can't even be quite the same again."

At last came the trip by air to Melbourne, Australia, leaving Corregidor on a strangely quiet night when the Japanese were celebrating the Emperor's birthday. General Wainwright's car led the small procession to the docks. The flight to Australia was as smooth and peaceful as if there were no war.

MEDICAL EPONYM

CLUTTON'S JOINTS

This disease is described by H. H. Clutton in a paper "Symmetrical Synovitis of the Knee in Hereditary Syphilis" appearing in the *Lancet* (1: 391-393, 1886), from which the following is quoted:

To recapitulate, one would say that the synovitis was symmetrical, affecting only the knees, that it was of a chronic and painless character, and that all the patients were the subjects of hereditary syphilis. It is probable that, with further observation, the knees will not be found to occupy this solitary distinction, and that other joints will be seen to be affected in a similar manner.

R W B

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

BLAKE—JOHN B. BLAKE, M.D., of Brattleboro, Vermont, died August 17. He was in his seventy-eighth year.

Dr. Blake received his degree from Harvard Medical School in 1891. He taught there for a number of years and wrote on medical subjects. He was formerly surgeon in chief of the Boston City Hospital, visiting surgeon for the Long Island Hospital and consulting surgeon for the Boston Insane Hospital. He had been retired since 1920. He was a member of the Massachusetts Medical Society, American Medical Association, Boston Society for Medical Improvement, Boston Medical Library, Boston Surgical Society, Boston Obstetrical Society and American Surgical Association.

Two daughters and four sons survive.

SEED—RAYMOND C. SEED, M.D., of Lawrence, died June 6. He was in his forty-sixth year.

Dr. Seed graduated from Dartmouth College and received his degree from Jefferson Medical College of Philadelphia in 1921. He was a member of the Massachusetts Medical Society and the American Medical Association.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

TONSILLECTOMY AND POLIOMYELITIS

The Massachusetts Department of Public Health recommends the temporary postponement of tonsillectomies until an estimate can be made of the probable prevalence of poliomyelitis during the present season. Early indications pointed to a light year, but with cases on the increase in Connecticut and Rhode Island and a few cases in Massachusetts, some increase in prevalence in this state may occur. In epidemic years, numerous cases are usually reported before the middle of August. Because only a single case was recorded in the first two weeks of August, making a total of only 17 cases for the year, a large outbreak is not expected.

There is definite evidence that the bulbar form of poliomyelitis is likely to occur following tonsillectomy. The additional threat to life from this form justifies the postponement of such operations.

CHANGE IN PREMARITAL BLOOD TEST LAW

As of June 12, 1943, a new premarital blood test law became effective in Massachusetts. The underlined portions of the following copy of the law are called to the special attention of all physicians:

Section 28A. Except as hereinafter provided a certificate shall not be issued by the clerk or registrar under Section 28 until he has received from each party to the intended marriage a medical certificate signed by a qualified physician registered and practicing in the commonwealth, a physician registered or licensed to practice in any other state of the United States or a

commissioned medical officer on active service in the armed forces of the United States who has examined such party as hereinafter provided. *Such examination shall be made only to ascertain the presence or absence of evidence of syphilis, and shall include a serological test for syphilis.* Said test shall be made by a laboratory of the state department of public health or by a laboratory meeting standards approved by said department, or, if not located within the Commonwealth, approved by the United States Public Health Service. *The examination by such physician and the laboratory test shall be made not more than thirty days before a certificate is issued under Section 28.* If such physician, in making such examination, discovers evidence of any such disease, he shall inform both parties to the intended marriage of the nature of such disease and of the possibilities of transmitting the same to his or her marital partner or to their children. . . . Blank forms of medical certificates required under this section shall be furnished to city and town clerks by the Department of Public Health. . . . In emergency cases where the death of either party to the intended marriage is imminent or where the female is near the termination of her pregnancy, upon the authoritative request of a minister, clergyman, priest, rabbi or attending physician, the clerk or registrar may issue a certificate under Section 28 without having received the medical certificate, or having endorsed on his certificate a statement of such receipt, as provided by this section. Whoever, being subject to the laws of the commonwealth fails to comply with any provision of this section shall be punished by a fine of not less than ten nor more than one hundred dollars.

If the parties to the intended marriage reside in different communities in Massachusetts, the certificates should be made out in duplicate. In all other cases one certificate for each party is adequate.

DISTRICT OFFICES

With the opening of three new offices, all the eight districts of the Massachusetts Department of Public Health now have facilities where personnel assigned to the districts can meet for conferences and have a common repository for their records. Each district health officer now has a staff composed of nurses, engineers, nutritionists, social-service workers and others, and is equipped to assist physicians, boards of health and other agencies in solving problems connected with public health.

The location of these district officers and the names of the district health officers are as follows:

Southeastern District:

Dr. Harold W. Stevens
105 William Street, New Bedford
Tel. New Bedford 3-7081

South Metropolitan District:

Dr. Henry M. DeWolfe
1245 Hancock Street, Quincy
Tel. GRANite 5006

North Metropolitan District:

Dr. A. Daniel Rubenstein
519 State House, Boston
Tel. CAPitol 4600 (Line 312)

Northeastern District:

Dr. Robert E. Archibald
367 Main Street, Wakefield
Tel. CRYstal 1118

South Central District:

Dr. Oscar A. Dudley
476 Main Street, Worcester
Tel. Worcester 2-8805

North Central District:

Dr. Arthur E. Burke
Central Avenue, Ayer
Tel. Ayer 2305

Connecticut Valley District:

Dr. Walter W. Lee
278 Main Street, Greenfield
Tel. Greenfield 3061

Berkshire District:

Dr. Walter W. Lee
184 North Street, Pittsfield
Tel. Pittsfield 2-1929

COMMUNICABLE DISEASES IN MASSACHUSETTS FOR JULY, 1943

RÉSUMÉ

DISEASES	JULY 1943	JULY 1942	SEVEN-YEAR MEDIAN
Anterior poliomyelitis	1	9	4
Chicken pox	398	436	402
Diphtheria	7	21	14
Dog bite	1150	1227	1199
Dysentery, bacillary	2	0	11
German measles	469	212	60
Gonorrhea	355	413	389
Measles	1468	1159	1152
Meningitis, meningococcal	62	13	5
Meningitis, other forms	7	7	•
Meningitis, undetermined	3	0	•
Mumps	244	555	431
Pneumonia, lobar	93	100	155
Salmonella infections	19	9	9
Scarlet fever	440	330	257
Syphilis	363	427	424
Tuberculosis, pulmonary	214	314	292
Tuberculosis, other forms	19	22	28
Typhoid fever	6	4	5
Undulant fever	7	4	4
Whooping cough	317	882	521

*Pfeiffer-bacillus meningitis only other form reportable previous to 1941

COMMENT

The outstanding feature of the July communicable disease picture is the poliomyelitis figure, with only 1 case reported for the month; hence the chances of a sizable outbreak seem rather remote. Incidentally, this is the lowest number of recorded cases for July so far as this disease is concerned. Meningococcus meningitis, although still at a point twelve times as high as that of the seven-year median, has experienced a 33 per cent drop since June. Scarlet fever, which reached epidemic proportions during the previous months, is now well on its way down to more satisfactory levels.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anterior poliomyelitis was reported from Wakefield, 1; total, 1.

Diphtheria was reported from Boston, 1, Cambridge, 1, Dennis, 1, Everett, 1, Fall River, 2, Woburn, 1, total, 7
Dysentery, bacillary, was reported from Boston, 2 total, 2

Encephalitis, infectious, was reported from Barnstable 1, Brockton, 1, Cambridge, 1, Everett, 1, total, 4

Malaria was reported from Camp Edwards, 1, Fort Banks, 6, Fort Devens, 4, Millbury, 1, Whately, 1, total, 13

Meningitis, meningococcal, was reported from Ashland 1, Auburn, 1, Barnstable, 1, Boston, 16, Bourne, 1, Brookline, 1, Cambridge, 3, Camp Edwards, 2, Canton 1, Fall River, 3, Fitchburg, 1, Fort Banks, 1, Fort Devens, 2, Haverhill, 3, Holyoke, 3, Longmeadow, 1, Lowell, 1, Lynn, 1, Malden, 2, Methuen, 2, Pittsfield, 2, Quincy, 1, Rockland, 1, Somerville, 1, Springfield, 2, Stoughton, 1, Templeton, 1, Wakefield, 1, Watertown, 1, Weymouth, 1, Wilmington, 1, Worcester, 2, total, 62

Meningitis, other forms, was reported from Boston 3, Chelsea, 1, Fall River, 1, Melrose, 2, total, 7

Meningitis, undetermined, was reported from Braintree, 1, Cambridge, 1, Worcester, 1, total, 3

Salmonella infections were reported from Boston, 2, Braintree, 1, Brookline, 2, Cambridge, 1, Grafton 1, Lawrence, 2, Methuen, 1, Norwood, 1, Peabody, 2, Pittsfield 1, Salem, 4, Spencer, 1, total, 19

Septic sore throat was reported from Beverly, 1, Boston, 5, Williamstown, 1, total, 7

Tetanus was reported from Brockton, 1, total, 1

Trachoma was reported from Boston, 1, total, 1

Trichinosis was reported from Boston, 2, Dover 1 total, 3

Tularemia was reported from Falmouth, 1, Walham, 1, total, 2

Typhoid fever was reported from Boston, 1, Fall River, 1, Holyoke, 1, North Attleboro, 1, Salisbury, 1, Saugus, 1, total, 6

Undulant fever was reported from Adams, 1, Boston 1, Gloucester, 1, Hawley, 1, Merrimac, 1, Spencer 1, Sudbury, 1, total, 7

BOOK REVIEWS

Changes in the Knee Joint at Various Ages with Particular Reference to the Nature and Development of Degenerative Joint Disease By Granville A. Bennett, MD, Hans Wayne, MD, and Walter Bauer, MD 4°, cloth, 128 pp, with 9 illustrations and 31 plates New York: The Commonwealth Fund, 1942 \$2.50

As the authors state in their preface, the rheumatic disorders rank foremost among the crippling diseases and are a frequent cause of prolonged morbidity. The origin and exact characteristics of these disorders are imperfectly understood. Barring the chance discovery of a specific substance or some special method of treatment, it seems that the most promising approach to the problems that these disorders present is the one chosen by the authors. It is a fundamental necessity to know what goes on in apparently normal joints as age advances before one can even make shrewd guesses concerning the exact causes and the exact nature of the pathologic changes that are responsible for abnormal joints affected by any chronic progressive disease of uncertain etiology. The authors of this clearly written and beautifully printed and illustrated volume speak with authority de-

rived from a complete familiarity with the extensive literature of the rheumatic disorders for the last one hundred years, a sound pathological training and a long clinical experience in the treatment of these disorders.

Investigation of the changes in the human knee joint at various ages was initiated by Bauer and Bennett in 1933. Their purpose was to familiarize themselves with the appearance of and the changes in the so-called normal joint as life goes on by studying these joints at each decade of life. The material was obtained post mortem or from amputations and was limited to those joints in which, so far as they could establish the fact, there had been no history or clinical evidence of arthritic disease. They found that all the joints obtained from individuals beyond the second decade of life exhibited alterations similar to those observed in hypertrophic arthritis (degenerative joint disease). The authors concluded that the articulations remain normal for only a very short time after maturation. They state 'Why this is so remains a riddle, as does the whole process of aging. Because of the wide distribution of degenerative joint disease, it is evident that the disease is not climatically limited nor confined to the human species.'

Their material consisted of sixty three knee joints from persons ranging in age from one month to ninety years. In none of these joints in life had there been any symptoms of joint disease, and no abnormalities had been noted in clinical examinations. However, in every subject beyond the age of fifteen some degeneration was found in one or more tissues of the joints.

In the sixth decade the loss of all articular cartilage from an eburnated epiphysis was observed. Apparently the degree of villous hypertrophy and of synovial fibrosis was not proportional to the degree of change in the cartilaginous surfaces of the joints. In several specimens the synovial membranes were practically normal. In the seventh decade it was rare to find any one of the articular structures entirely normal. Typical marginalipping was very frequent and the semilunar cartilages were badly damaged. In the eighth decade large areas of complete absence of articular cartilage were found on the weight bearing surfaces of the femur and of the tibia. These changes were still out of proportion to the changes in the synovial membrane but the semilunar cartilages showed more fraying and partial calcification. In the ninth and tenth decades all these changes were more advanced.

Chapter IV, in which the authors give their interpretation of these articular findings, does not lend itself to abstract and should be read in toto. It is evident that they have become convinced that the reparative powers of hyaline articular cartilage are extremely limited and that if necrosis occurs it is replaced by imperfectly formed fibrocartilage. The subchondral bone suffers in like manner and concomitantly with the articular cartilage.

In Chapter V the authors' concepts of pathogenesis are given. They were arrived at not only as a result of this detailed visual study of the changes in normal joints but from their previous sound research work and their wide clinical experience. The authors appear to have assumed an entirely dispassionate attitude which is admirable and rather rare. They have presented the evidence and carefully weighed its value especially in relation to etiology. It is unfortunate that war service has made it temporarily

impossible for this brilliant teamwork to follow closely the elusive but fresh scent that certain unpublished research has already provided.

The Biological Action of the Vitamins. A symposium edited by E. A. Evans, Jr., Ph.D. 8°, cloth, 227 pp., with 36 illustrations and 8 tables. Chicago: The University Press, 1942. \$3.00.

This is an outstanding collection of papers on recent fundamental investigations regarding the vitamins. The fourteen contributions included were presented at the University of Chicago in September, 1941, in co-operation with the University of Wisconsin, and a like symposium was given at Madison on respiratory enzymes. The volume contains papers on the biologic action of the vitamins in general, including cocarboxylase, thiamine, riboflavin, nicotinic acid, pyridoxine, pantothenic acid, biotin and vitamin K. The contributors include some of the most eminent workers in their fields, notably C. A. Elvehjem, Paul György, Norman Jolliffe, D. W. MacCorquodale and Vincent du Vigneaud.

In general outlook these papers consider not only the chemistry of the vitamins and their ration to experimental and clinical deficiency states, but also their rapidly unfolding roles in the field of the respiratory enzymes, in carbohydrate metabolism and in promoting the growth of yeasts and bacteria. For example, they point out that riboflavin is a prosthetic group in coenzyme II, which aids in catalyzing the oxidation of hexose monophosphate, and that it is essential for the growth of lactic acid bacteria; that the enzyme cocarboxylase, concerned in the decarboxylation of alpha keto acids, is an ester of thiamine; and that biotin has been found identical with coenzyme R, a compound necessary for the growth of certain nitrogen-fixing bacteria, and also with protective factor X or vitamin H, which inhibits the harmful effects of feeding raw egg white to certain animals.

Perhaps the most fascinating paper is that of du Vigneaud on biotin, which recounts the most recent chemical triumph in the field of vitamins. All are well worth reading, however, and this book is highly to be recommended.

The Hemorrhagic Diseases and the Physiology of Hemostasis. By Armand J. Quick, Ph.D., M.D. 8°, cloth, 340 pp., with 24 illustrations and 9 tables. Springfield, Illinois: Charles C Thomas, 1942. \$5.00.

The past five years have witnessed great clarification in the mysteries surrounding the various problems relating to blood clotting. In this period a number of seemingly unrelated investigations have converged: new knowledge regarding prothrombin and methods for its detection, the discovery of the antihemorrhagic vitamin K, the purification and therapeutic use of heparin, and the discovery in sweet-clover disease of cattle of the hemorrhagic factor dicoumarol. In these investigations the name of Quick has constantly loomed large, and it is therefore fitting that the first authoritative monograph on the physiology and clinical manifestations of normal and abnormal hemostasis should have been written by this Marquette University investigator.

The book is distinguished by its thoroughness and clarity, and above all by its wisdom. Well and simply written, it fulfils a long-felt need in grouping together in separate chapters the many accumulated bits of knowl-

edge regarding thrombin, prothrombin, thromboplastin, fibrinogen, platelets and anticoagulants. The references, which are unusually complete, are alphabetically grouped at the end of each chapter.

Discussions of physiologic principles are followed by chapters dealing with such clinical conditions as thrombopenic purpura, hemophilia and hypoprothrombinemia, and with the uses of heparin and dicoumarol. Although a thorough discussion and painstaking review of the literature distinguish these chapters, they suffer somewhat from the author's primary concern with the laboratory rather than with the clinic. Particularly with thrombopenic purpura and hemophilia there is too much reliance on the literature and on some of the author's "pet" theories, for example, a histamine disturbance in purpura and a simple thromboplastin defect in hemophilia. There is increasing evidence that idiopathic thrombopenic purpura is primarily a splenic dysfunction with remote, possibly hormonal, inhibition of platelet formation from megakaryocytes in the bone marrow. As regards hemophilia, the clearcut experiments of F. H. L. Taylor and his associates at the Thorndike Memorial Laboratory of the Boston City Hospital are dismissed with scant notice. Whether hemophilia is primarily a thromboplastin deficiency or an abnormality in the euglobulin fraction of the plasma is still not entirely settled; perhaps both groups of investigators are correct.

These criticisms are possibly captious, for the book is not only authoritative and thorough but respectful of the extensive literature and not unmindful of the historical roots of each particular subject. The format, typography and printing are quite in keeping with the general excellence of the work, which is completed by an appendix containing methods for determination of the coagulation time, bleeding time, clot retraction, platelet count, and levels of prothrombin and fibrinogen, together with methods for the assay of thromboplastin, thrombin and heparin.

The book is highly recommended for use in general hospitals and clinical laboratories. Collaboration with a clinical investigator might be desirable in a second edition.

First Aid to the Injured and Sick: An advanced ambulance handbook. Edited by Major Norman Hammer, M.R.C.S. Eighteenth edition. 16°, paper, 336 pp., with 313 illustrations. Baltimore: The Williams and Wilkins Company, 1941. \$2.00.

The fact that this little volume is its eighteenth edition speaks well for its popularity. The first part of the book is devoted to the form and functions of the body. This section gives a clear and remarkably well-illustrated account of body structures in an extremely simple and concise manner.

The author states that air-raid first aid has been his special interest for the past five years, and the numerous illustrations of and directions for first aid show how well he has accomplished his task of explaining sound methods clearly and graphically to the students of this subject. The chapter on sprains, dislocations and fractures is particularly commended, as is the section on the first-aid treatment of hemorrhage and wounds. The newer treatments of burns and injuries from gassing are given careful attention.

The book will be of great value to all who would familiarize themselves with first-aid treatment.

NUMBER 11

ACUTE PERICARDITIS WITH SPECIAL REFERENCE TO CHANGES IN HEART SIZE*

LOUIS WOLFE, MD†

BOSTON

THE 5 cases that form the basis of this report have certain features in common. The patients were young or middle aged men with normal hearts. During an acute respiratory infection acute pericarditis supervened. The most remarkable feature was a rapid, conspicuous enlargement in the size of the heart, followed by a slower reversion toward normal and recovery without any demonstrable cardiac abnormality. Similar cases have been seen but are not included in this report because in them the opportunity for x-ray confirmation of heart size was not available.

Of particular interest at the present time are 3 cases in which the pericarditis complicated atypical primary pneumonia.

CASE REPORTS

CASE 1. L. R., a 37 year old, married man, with negative family and marital histories, entered the Beth Israel Hospital for the third time on September 19, 1929. The past history was negative except for thyrotoxicosis. During each of the previous two admissions (December 1928 and March, 1929), subtotal thyroidectomy was performed for hyperthyroidism. The patient had had repeated paroxysms of auricular fibrillation, but there was no demonstrable structural abnormality of the heart by physical, roentgenographic or electrocardiographic examination. The blood pressure was normal. Following the second thyroidectomy he gained weight and felt well enough to return to work. However, the basal metabolic rate remained elevated, so that he was given Lugol's solution, and just prior to the third admission was subjected to three weekly roentgen-ray exposures over the thyroid gland, the basal metabolic rate being +18 per cent. The patient was readmitted several days after the onset of pain in the neck and across the upper chest, stiffness of all the muscles and general malaise. Examination on admission revealed slight injection of the pharynx, auricular fibrillation and fever.

The temperature varied between 98° and 102°F until the 37th day after admission, remaining normal thereafter.

except as noted below. The pulse showed marked fluctuations, due to frequent short paroxysms of auricular fibrillation. The respirations averaged 20. During the febrile period general malaise, slight cough, a feeling of substernal constriction, sharp precordial pain and anorexia were the outstanding symptoms. The physical signs in the lungs were variable, consisting of slight dullness, diminished breath sounds and fremitus at the right base crepi-

FIGURE 1. Case 1 (September 27, 1929)

This film shows considerable enlargement of the heart shadow compared with that in a previous film. Normal cardiac landmarks are preserved.

tant rates under the angle of the right scapula and a pleural friction rub in the right axilla. Examination of the heart on admission revealed no abnormalities except in rhythm, but from the 22nd to 38th hospital days a pericardial friction rub was constantly audible over the entire precordium. It was not possible to demonstrate T wave signs, and distended neck veins, evidence of a congested

*27s and all subsequent figures are reproductions of x-ray films taken at a distance of seven feet. They were reproduced to show the cardiac outline as clearly as possible without regard for the details of the pulmonary lesions.

†Instructor, Courses for Graduates, Harvard Medical School, associate visiting physician and chief of Cardiac Clinic, Beth Israel Hospital.

liver, edema and blood pressure changes were not observed.

On the 57th day, the patient having recovered from the acute illness, thyroidectomy was performed for the third time. Convalescence was uneventful except for the re-

FIGURE 2. Case 1 (December 10, 1929).

The heart size is normal, and the configuration and measurements are identical with those in films taken prior to this patient's illness and subsequent to his recovery, a period of thirteen years.

currence of the precordial pain, the pericardial friction rub and a temperature of 102°F. on the 74th day. The patient was discharged in excellent condition 9 days later.

The hemoglobin level and red-cell count were 85 per cent and 4,090,000, respectively. The white-cell counts varied between 6800 and 14,600 but were usually normal. Five vital-capacity determinations ranged between 2450 and 2800 cc. Teleroentgenographic measurements showed a total transverse diameter of 17 cm. on the 8th day (Fig. 1), and 14.2 cm. on the 82nd day (Fig. 2), the internal diameter of the chest being 28.5 cm. on both occasions. There was diminished radiance of both lung bases, especially on the right, and slight haziness in the right costophrenic angle. An electrocardiogram on admission showed auricular fibrillation and normal RST segments and T waves. Four days later, the RST segments were displaced upward in Leads 1 and 2, and the ascending limb of the T waves rose in a straight line; T₃ was inverted. All subsequent electrocardiograms displayed inverted T waves in all leads.

The patient developed diabetes in 1930, requiring insulin. Paroxysms of auricular fibrillation continued, but there was no demonstrable structural abnormality of the heart. Electrocardiograms and x-ray examinations were identical to those taken prior to the third hospital admission. He was last seen in 1942.

CASE 2. J. M., a 50-year-old pharmacist, entered the Beth Israel Hospital on January 29, 1941, and was discharged on February 12. His father died of cancer of the bowel, his mother of diabetes. Two sisters had diabetes, and four sisters and one brother were living and well. The marital and past histories were irrelevant.

The present illness began 12 days before entry with a feeling of malaise and feverishness. Finding his temperature elevated, the patient immediately went to bed. His physician found a few rales at both lung bases, a normal heart and a temperature of 100°F. Five days before entry, a pericardial friction rub was heard for the first time, and 2 days before entry the temperature rose to 102°F, after which it remained normal until entry. There was no chest pain at any time. The patient perspired a great deal and had an occasional dry cough. A diagnosis of bronchopneumonia was made.

The temperature on admission was 100.4°F. (rectal), rising to 101 on the 2nd day, after which it was normal. The pulse was 100 and respirations 22. The blood pressure was 120/80. A few fine crepitant rales were heard at both lung bases. A loud pericardial friction rub was audible all over the precordium, and persisted until January 30.

The hemoglobin level and red-cell count were normal. Three white-cell counts were 12,200, 7500 and 6600. A tuberculin skin test was positive in a dilution of 1:10,000.

FIGURE 3. Case 2 (January 29, 1941).

There is considerable cardiac enlargement, especially to the left. The silhouette is not suggestive of effusion, and the normal landmarks are preserved. The pulsations observed under fluoroscopic screen were of fair amplitude.

Sputum examinations for tubercle bacilli were negative. The corrected sedimentation rates were 2.3, 1.9, 1.1 and 0.7 mm.

A teleroentgenogram taken on the day of admission (Fig. 3) showed the total transverse diameter of the heart to be 15.8 cm. The roentgenologist reported the pulsations to be of fair quality, and there was no evidence of pericardial fluid. On February 10, the total transverse diameter of the heart was 13.5 cm. (Fig. 4).

Electrocardiograms showed the typical changes of acute fibrinous pericarditis; the last one, taken on February 11, still showed inverted T waves in Leads 2 and 3, but the T waves in Leads 1 and 4 had become upright. One month after discharge all leads were normal.

CASE 3. H. W., a 23-year-old man, was seen at home on July 29, 1933. He had never been robust, but led an active life and worked hard. Three years previously he had had a carbuncle on the upper lip. There was a history of diabetes in the mother and of rheumatic heart

was held tensely. The blood pressure was 120/70. The temperature fluctuated between 98 and 103°F. for the first 3 days, and was normal thereafter.

The white cell count on admission was 19,800, rising to 23,800 on the following day, and thereafter quickly falling to a normal level. Two blood cultures were negative. Electrocardiograms revealed the classic pattern of early acute fibrinous pericarditis.

The roentgenologist's report is of particular interest. There was a remarkable change in the size of the heart in 9 days, with an increase of 2.4 cm. Pulsations of the heart were fairly distinct, but the shape of the heart was that of pericardial effusion. There was no evidence of undrained fluid in the left pleural cavity or new areas of dullness in either lung. The diaphragm moved fairly well on both sides.

Although there was no clinical evidence of pericardial effusion, several pericardial taps were attempted, yielding 1 cc. of sanguineous fluid, which proved negative on culture. By the 10th hospital day the heart size had returned to normal, and the patient was discharged. He has remained completely well to the present time.

CASE 4. S. B., a 30-year-old, married man, was seen in another hospital on September 19, 1942. The present ill-

FIGURE 4. Case 2 (February 10, 1941).

The heart size is within normal limits. The silhouette corresponds to that seen in Figure 3.

disease in a brother. The present illness began 6 days before the first examination, with a slight unproductive cough and precordial pain. Three days later the patient felt chilly and the temperature rose to 101°F., reaching 102 on the following day. An insect bite above the right eye, sustained a week before, resulted in a purulent discharge, but this rapidly healed.

Examination showed consolidation of the left lower lobe. The heart and blood pressure were normal. On August 4, the signs were suggestive of fluid at the left base. From August 2 until admission to a hospital on August 8, a loud pericardial friction rub was constantly audible over the entire precordial area.

The white-cell count on admission was 25,400, falling gradually to 8700. X-ray examination of the chest disclosed fluid in the left pleural cavity, displacing the heart to the right.

A trocar thoracotomy was performed on the 2nd hospital day, and a free flow of pus was obtained. Culture yielded a pure growth of *Staphylococcus aureus*. The temperature fell sharply, but throughout the rest of the hospital stay there were slight rises above normal. X-ray films of the chest showed considerable improvement, and the patient was discharged on August 31, completely relieved except for slight pain in the left shoulder.

Two days later severe, sharp precordial pain recurred, followed in 2 or 3 days by sharp pain in both axillae, feverishness and profuse sweating. The patient remained up and about, but was readmitted 5 days following his discharge.

Examination revealed increased cardiac dullness, both to the right and to the left. The cardiac impulse was easily identified, and was not forceful but rather diffuse. The rate was rapid and the sounds were vigorous. There was a pleural friction rub at the left base. The abdomen

FIGURE 5. Case 4 (September 19, 1942).

The heart shadow is considerably enlarged, which is suggestive of pericardial effusion.

ness began on September 5 with headache, slight cough, profuse sweating, feverishness and generalized aching. When the patient was seen by his physician 5 days later the headache was still severe and the cough was unproductive and harassing. There were small pin-point areas of inflammation in the throat and crepitant rales in both lungs. The heart was normal. The patient was examined every day from then on, nothing unusual being found in the heart. On September 18 he felt well enough to shave himself. At 1:30 a.m. on the following day he was awakened by sharp precordial pain and a constricting pain in the anterior chest of great severity, requiring morphine. A pericardial friction rub was heard a few hours later. On arrival at the hospital an x-ray film was taken (Fig. 5), which showed considerable car-

diac enlargement. The white-cell count was normal and the temperature was 101°F.

Physical examination showed a well-looking young man in no apparent discomfort, but complaining of occasional precordial pain. The area of cardiac dullness was increased. The palpable cardiac impulse was diffuse and corresponded with the left border of dullness. The rate was moderately rapid and the rhythm regular. A loud pericardial friction rub was audible over the entire precordial area. The heart sounds were distinctly and easily heard but were of rather poor quality. The only pulmonary finding was diminished respiratory excursion of the left lower chest. The blood pressure was 142/76. The pulse was of good quality; a paradoxical pulse could not be demonstrated. There was no distention of neck veins or liver, no Ewart sign and no edema or respiratory embarrassment.

Daily swings in temperature up to 104°F. were recorded until October 1, after which the temperature remained normal. The pulse averaged 85 and respirations

FIGURE 6. Case 4 (October 2, 1942).

There is still considerable enlargement of the heart shadow, but the landmarks are visible, and there is no suggestion of pericardial effusion.

20. Sulfadiazine was administered in adequate doses both before and after admission, but no benefit resulted and the drug was therefore discontinued. By September 22, the heart sounds had considerably improved, but the size of the heart was unchanged. The friction rub remained loud over the entire precordium until October 2, when it was limited to the region of the aortic valve. At that time the heart was much smaller (Fig. 6). An x-ray film taken on October 16 (Fig. 7) showed that the heart size was almost within normal limits. The blood pressure remained unaltered during the entire illness, and at no time were clinical signs of pericardial effusion elicited. Slight dullness and rales at both lung bases appeared, and finally a small area of bronchial breathing with increased spoken voice at the right base was detected. The cough gradually subsided, and the patient was well enough to leave the hospital on Octo-

ber 21. At no time was there dysphagia. Three weeks later there were no abnormal physical findings and the blood pressure was 142/90.

The white-cell count was normal except on September 20, when it reached 14,300, thereafter rapidly return-

FIGURE 7. Case 4 (October 16, 1942).

The heart size is almost within normal limits. Comparison of the supracardiac shadow with that in Figure 5 shows an almost identical contour in both instances, indicating that, if fluid was present early in the course of the disease, the amount was very small.

ing to normal. Several electrocardiograms showed the characteristic pattern of acute fibrinous pericarditis. An electrocardiogram on November 14 revealed entirely normal curves.

CASE 5.* A.R., a 42-year-old, married salesman, entered the Beth Israel Hospital on August 21, 1942. The past history was negative except for tonsillectomy 25 years previously and influenza 24 years previously. The mother had hypertension.

The present illness began 2 weeks before admission with the onset of diarrhea, which lasted for 3 days. The patient continued to work as a traveling salesman, but 1 or 2 days after the diarrhea stopped he noted general malaise, loss of appetite and feverishness, and several days later a nonproductive cough. His physician made a diagnosis of "grippe" and advised rest in bed. The temperature fluctuated from normal to 103°F. up to the time of admission. The cough became progressively worse.

On August 21, the patient complained of stabbing precordial pain and sharp pain in the right anterior chest, aggravated by inspiration and causing some difficulty in breathing. He became aware of sudden rapid beating of the heart, together with great weakness. The family physician was unable to measure the blood pressure, and sent him to the hospital after administering morphine and Paredrine.

*Reported through the courtesy of Dr. Hyman Morrison.

Physical examination revealed a cold and clammy skin, respiratory difficulty owing to pleuritic pain, slight cyanosis and marked weakness. The temperature was 103°F (rectal), the heart rate 214 (electrocardiogram), and the respirations 24. The posterior pharyngeal wall was in

was of a normal pattern, and a teleroentgenogram (Fig 9) showed the heart to be of normal size and the lung fields clear.

CAUSE OF THE CHANGES IN HEART SIZE

The differential diagnosis between dilatation of the heart and pericardial effusion is, as most clinicians agree, often a difficult and sometimes an insoluble problem. It is necessary to consider all the information obtained by examination of the heart and chest, a general and detailed study of the circulation, x-ray examination and fluoroscopy, electrocardiography and paracentesis. No one of these methods, including paracentesis, is infallible,

FIGURE 8 Case 5 (August 26 1942)

There is considerable increase of the heart size. The normal landmarks are preserved, and there is nothing to suggest effusion.

FIGURE 9 Case 5 (December 5 1942)

This shows a normal cardiac silhouette. The general contour is similar to that in Figure 8.

jected. The heart appeared to be enlarged and extremely rapid and the sounds were of poor quality. There were scattered crepitant rales over both lung bases, but no areas of dullness and no bronchial breathing or other abnormal signs. The examination was otherwise negative.

The white-cell count on admission was 15,000, rising to 16,400 on the 4th hospital day and falling to 12,000 on the day of discharge. A heart film taken on August 26 (Fig 8) showed enlargement of the heart and a pneumonic process at the right base.

The admission electrocardiogram showed a supraventricular type of tachycardia with a rate of 214. There was slight elevation of the RST segment in Leads 2, 3 and 4 without any displacement in Lead 1. The following day the rhythm was normal, and the rate 105; there was slight inversion of T_1 , and the RST segments were still elevated in Leads 2, 3 and 4, with an upper concavity of the ascending limb of the T waves. The final electrocardiogram, taken the day before discharge, showed inverted T waves in all four leads.

Three tenths of a gram of quinidine hydrochloride was injected intramuscularly on admission, and 2½ hours later the heart rate was 100. The blood pressure was unobtainable at first, but rose slowly to 110/80 after the restoration of normal rhythm. Clinical improvement was rapid in spite of the continuance of cough, but the rales at the bases increased, and slight dullness to percussion and suppressed breath sounds appeared over the right base. After the 3rd hospital day the temperature remained normal, and on the 8th day the patient insisted on going home.

He was next seen on December 5. Recovery was complete. The patient was working full time and attending gymnasium twice a week. Examination revealed no abnormalities of the heart or lungs, the electrocardiogram

but the collective data obtained by all of them may permit an accurate evaluation.

Nowadays, few clinicians cling to the idea that the presence of a pericardial friction rub is incompatible with an effusion in the pericardial sac. The location and distribution of the rub, however, is of some significance, since in most cases when excess fluid accumulates in the pericardial cavity the friction sound disappears in the region of the apex while persisting over the base of the heart and sternum.

The heart sounds are much more apt to be muffled, distant or absent in cases of effusion than in cases of dilatation, although in the latter the quality of the sounds may change and gallop rhythm may be present.

Increase in the area of absolute dullness on percussion may be striking in cases of pericardial effusion, and the abrupt transition from absolute dullness to normal resonance may help in the diagnosis. The area of supracardiac dullness may be increased.¹

A paradoxical pulse is often found when fluid is present.

The cardiac impulse is usually absent when the pericardial sac contains a large amount of fluid, but is not obliterated in cases of cardiac dilatation. In the latter it may be noted as a diffuse, wavy impulse, and with few exceptions the left border of cardiac dullness corresponds to it. Should the cardiac impulse be detectable in a case of effusion, the left border of dullness may extend far to the left and below its location.

There has been considerable controversy regarding the presence and significance of physical signs over the posterior aspects of the lungs in pericardial effusion.² These signs include almost all those known to occur, but whether they correspond to those described by Bamberger-Ewart or present some less characteristic pattern, or are similar to the findings in pleural effusion, most observers agree that they are indicative of fluid in the pericardial cavity. Such signs may be elicited on the right as well as on the left side, or may be limited to the right side. In evaluating signs that are suggestive of pleural effusion, the latter may be excluded by x-ray examination. Posterior signs are never produced by heart enlargement alone.

Dilatation of the heart may occur without necessarily resulting in circulatory disturbances. It is well known, however, that pericardial effusion, even when not large, may cause profound alterations in the circulation. Dyspnea, cyanosis, markedly distended neck veins, a fall in arterial blood pressure with decreasing pulse pressure, a rise in venous pressure, an acutely distended and depressed liver and so forth are too well known to require comment. Yet in some cases large collections of fluid are compatible with an apparently normal circulation. The critical factor is the speed with which fluid accumulates in the pericardial sac.³⁻⁶

Reliance on x-ray examination in the differentiation of cardiac dilatation from pericardial effusion has been the cause of many errors in diagnosis. Nevertheless, this method of examination is of considerable value. The water-bottle configuration is not conclusive evidence of fluid and may be seen in cases of dilatation. The absence of pulsations on fluoroscopy may indicate fluid, but feeble pulsations may be misleading. Vigorous pulsation of the aortic knob and decreased pulsation of the left ventricular border suggest fluid (Freedman⁷). This author is also of the opinion that the most reliable diagnostic procedure is daily roentgen-ray examination of the heart. The finding of considerable change in its size within short periods of time he considers the best sign of fluid. A change in the outline of the cardiac silhouette with a change in position of the patient has been stressed by many observers.

Low voltage in the electrogram may be found when excess fluid is present.

The vital capacity is diminished with effusion.³

The final proof of the existence of excess fluid depends on its actual demonstration by paracentesis, operation or autopsy. The failure to withdraw fluid with a needle does not prove its absence, for fluid may be encapsulated or the technic of paracentesis may be at fault.

The differential diagnosis between pericardial effusion and cardiac dilatation was carefully considered in each case in this series, and since the primary purpose of this paper is to report the rapid enlargement of the heart in acute fibrinous pericarditis, it will be necessary to state the reason for considering the change in heart size as due to dilatation, and not to effusion in the pericardial cavity.

In Case 1, the first evidence of pericarditis was furnished by the electrocardiogram. The pattern observed was pathognomonic of early acute pericarditis, so that the diagnosis could be made with confidence in the absence of other evidence.⁸ Four days later a teleroentgenogram (Fig. 1) showed a great increase in the size of the heart compared to the previous plate, in which the measurements were within normal limits. The configuration of the heart shadow was not considered to be at all suggestive of effusion; the normal landmarks were preserved. An increase of such magnitude in so short a time, if due to effusion would in all probability have given rise to clinical manifestations of circulatory embarrassment. Yet these were singularly absent and the vital capacity was constant throughout the illness. The heart sounds remained normal; the friction rub during the period of its audibility, could be heard at the apex, and there was a complete absence of characteristic posterior lung signs, distended neck veins, an enlarged tender liver, a change in blood pressure and so forth.

The diagnosis of pericarditis in Case 2 was first made on the basis of a friction rub. Five days later a teleroentgenogram (Fig. 3) showed considerable cardiac enlargement. The heart contour was not suggestive of fluid, and under the fluoroscope the cardiac pulsations were seen to be of fair amplitude. As in the previous case, there were none of the numerous signs or symptoms that are associated with a large or rapidly accumulating pericardial effusion. A second teleroentgenogram (Fig. 4), taken twelve days after the first one, showed the heart measurements to be within normal limits, and the total transverse diameter had decreased 2.3 cm.

In Case 3, the roentgenologist was so impressed by the remarkable increase in heart size in nine days that, although the cardiac pulsations were

distinct, it was his opinion that pericardial effusion was present. The electrocardiogram was pathognomonic of early acute fibrinous pericarditis. Clinically the heart was enlarged to the right and to the left. The cardiac impulse was easily felt and was not forceful but rather diffuse. The heart sounds were loud and there were no signs of compression. Nevertheless, in view of the recent empyema, the roentgenologist's opinion and the high white-cell count, several pericardial taps were attempted, but no fluid was found.

The cardiac silhouette in Case 4 suggested the presence of pericardial fluid. However, if it was present the amount was very small and was responsible for but little enlargement of the cardiac shadow. The teleroentgenogram taken several hours after the onset of pericarditis (Fig. 5) revealed a degree of enlargement that, if due entirely or for the most part to effusion, indicated an extremely rapid accumulation of fluid. This would in all probability have given rise to obvious circulatory disturbances. After seeing the x-ray film, every attempt was made to elicit clinical symptoms or signs of effusion, but these were consistently absent. The increase in cardiac dullness was inconspicuous, the apex impulse remained palpable, the friction rub was constantly audible over the apex of the heart as well as over the base, there was no change in cardiac outline with change of position, and the heart sounds were good. As the size of the heart decreased, even though there was still considerable enlargement, the contour no longer suggested the presence of fluid (Figs. 6 and 7).

The diagnosis of pericarditis in Case 5 was made solely on the basis of the electrocardiograms. The first two showed RST elevations without reciprocal depressions, and without changes in the QRS waves, which may be considered pathognomonic of early acute pericarditis. The third electrocardiogram showed inverted T waves in all the leads. The first x-ray film (Fig. 8) was taken five days after the onset of pericarditis and showed considerable enlargement of the heart without any of the features that are helpful in making a diagnosis of pericardial effusion. Clinically, as in the cases cited above, there was nothing to indicate a rapidly forming effusion.

In none of the cases was a decrease in amplitude of the QRS waves in the electrocardiogram, such as may be seen with pericardial effusion, observed.

The opinion appears warranted, in all these cases, that the rapid and striking increase in the size of the contents of the pericardial sac was due to an increase in the size of the heart itself and not to an increase of pericardial fluid. It is unlikely that fibrin deposits could have contrib-

uted materially to the rapid and striking changes in size that were seen. The same may be said in regard to swelling or edema or diffuse inflammatory infiltration of the heart muscle, particularly in view of the fact that circulatory efficiency did not appear to be impaired in the slightest degree. Simple dilatation of the heart, it would seem, was responsible for the phenomenon observed. Yet these patients appeared to be extremely well, and in none of them were symptoms or signs of circulatory disturbances observed.

MECHANISM OF ACUTE DILATATION

The anatomical structure of the pericardium and its ligaments¹⁰ suggests that one of its functions is to restrain dilatation of the heart. Although there is no uniformity of opinion concerning this point, most of the clinical and experimental evidence favors this view.¹¹⁻²⁵ If one were to ascribe the dilatation observed in our cases to pericarditis alone, it would be necessary to assume that the restraining function of the pericardium is lost when pericarditis occurs. There is no evidence to support this assumption; dilatation, moreover, does not occur in all cases of pericarditis. In suppurative pericarditis and in tuberculosis, a small heart is the rule. But in these two conditions an outpouring of fluid takes place that, together with the pericardium, which has yielded to the maximum extent conditioned by the inflammatory process and effusion, acts to restrain cardiac dilatation. It appears that in some cases, when the pericardium is inflamed, either effusion or cardiac dilatation follows.

It has been shown that, when the characteristic electrocardiographic pattern of acute pericarditis occurs, diffuse subepicardial myocarditis is present.^{8, 9, 27-29} Since this pattern was observed in our cases, the additional factor of myocardial inflammation in causing dilatation must be considered.

Finally, the relatively slow heart rate, sinus arrhythmia and paroxysmal auricular fibrillation observed in our cases suggest that preponderant vagal tone may occur in the presence of pericardial inflammation and act as additional factors favoring cardiac dilatation. Van Liere and Crisler²⁶ have shown experimentally that vagal stimulation causes dilatation of the heart, and that the dilatation is greater, sometimes considerably so, if the pericardium is slit so that it loses its restraining function. Observations on the heart rhythm and electrocardiographic patterns following injection or removal of the stellate ganglions in dogs offer further suggestive evidence that the neurogenic mechanism may be disturbed following pericardial injury.⁸

The clinical evidence in the cases under discussion does not favor the view that impaired circulation in the pneumonic lung, anoxemia and toxemia were effective in producing cardiac dilatation.³⁰

It is possible that paroxysmal tachycardia in Case 5 played some part in producing cardiac dilatation. It should be noted, however, that the paroxysm lasted only a few hours, and that the teleroentgenogram showing enlargement was taken five days after the paroxysm had ended. Cardiac dilatation does not often occur as a result of tachycardia, even with rates approaching 200,³¹ and the available precise information³¹⁻³³ concerning the time of appearance of dilatation during paroxysmal tachycardia and its subsequent disappearance after the paroxysm has ended makes it extremely unlikely that the dilatation observed was related to the rapid heart action. Furthermore, in the accurately observed cases of dilatation associated with tachycardia, congestive failure was present; the cardiac silhouette, when the latter is present, may give a misleading impression of heart size.³⁴ These considerations make it even less likely that the paroxysms of auricular fibrillation had any bearing on the dilatation observed in Case 1.

Cardiac enlargement may occur in hyperthyroidism. In many if not all these cases, however, hypertension, coronary artery disease, valvular disease, congestive failure and so forth, are complicating factors.³⁵⁻³⁷ For these reasons, as well as the mildness of the hyperthyroidism and reversal of the heart size toward normal before the hyperthyroidism was corrected, thyroid disease is excluded as the cause of dilatation in Case 1.

DISCUSSION

Röntgenologic and orthodiagraphic demonstration of cardiac enlargement during acute infections has been reported by various observers.^{30, 38, 39} A careful search of the literature failed to disclose similar studies showing cardiac enlargement in acute pericarditis, such as occurred in the cases here reported. Aside from its interest as a feature of pericarditis, the importance of not mistaking the heart enlargement for pericardial effusion is obvious, as emphasized by Barnes and Burchell⁴⁰:

I have seen many cases of pericarditis in which the heart became large very rapidly, and I am convinced that in some of these cases we are dealing with the finest examples of acute dilatation of the heart which are known to clinical medicine. The enlargement is ordinarily ascribed to the accumulation of fluid in the pericardial sac, but I have had occasion to tap the pericardial sac as many as three times without obtaining any fluid whatsoever. Therefore, I believe that dilatation of the heart may occasionally be an important feature of acute pericarditis.

The clinical features of pericarditis were similar in all the cases. The pericarditis occurred in the course of an acute respiratory infection, having its onset after the first week, or in some cases when the original infection, which varied in severity from mild to severe, had about run its course. Evidence of active pericardial inflammation then persisted for as long as two or three weeks or, as in 1 case, for a much shorter time. A loud pericardial friction rub over the entire precordial area was usually audible during this entire period. Pericardial involvement was characterized by recurring sharp precordial pain, and in 2 cases by severe crushing anterior chest pain similar to that which occurs in acute myocardial infarction. Pleuritic pain was also usually present. The temperature chart may reveal but slight elevation, or a widely swinging temperature up to 104 or 105°F., while the pulse rate remains relatively slow and may show sinus arrhythmia. One patient had paroxysmal auricular fibrillation, and another paroxysmal auricular tachycardia. With the advent of pericarditis the white-cell count usually remains within normal limits or becomes slightly elevated. The corrected sedimentation rate is elevated. Once recovery sets in progress is rapid and without sequelae, and normal activity is soon possible. None of the patients have manifested residual cardiac defects; one of them has been followed for thirteen years, and another for nine years.

Cases 2, 4 and 5 occurred during a period when primary atypical pneumonia^{41, 42} was prevalent and was recognized and differentiated from the usual bacterial types of pneumonia. The clinical and x-ray features in these cases were similar to those described as occurring in primary atypical pneumonia, and the presence of ordinary bacterial agents could not be demonstrated. Although staphylococcal empyema was present in Case 3, the pulmonary infection was unlike the cases of staphylococcal pneumonia that have been described,^{43, 44} and its nature must remain in doubt. In this period (1933), 2 other cases of pericarditis that complicated pneumonia following a "grippe-like" infection were seen. The nature of the respiratory infection in Case 1 is also uncertain, except that the onset was like "grippe," which diagnosis, in fact, was originally made. The illness had none of the features suggesting that it might have been rheumatic carditis without valvular involvement.⁴⁵ Although pericarditis may occur as a postoperative complication,⁴⁶ including thyroidectomy,⁴⁷ the long lapse of time between thyroidectomy and the onset of pericarditis makes any causal relation extremely unlikely.

SUMMARY

Five cases of acute pericarditis complicating respiratory infections are described. In 3 cases the characteristics of the respiratory infection were similar to those occurring in primary atypical pneumonia.

Acute cardiac dilatation was demonstrated by teleroentgenograms and was unaccompanied by evidence of disturbed cardiac function. Complete cardiac recovery occurred in every case.

Acute cardiac dilatation is not identical with acute heart failure or with any symptoms or signs of altered cardiac function. Within certain limits of time and degree it may be regarded as physiologic.

The mechanism of acute cardiac dilatation associated with pericarditis is discussed.

THE INTRAPERITONEAL USE OF SULFANILAMIDE IN GASTROINTESTINAL RESECTIONS

THOMAS J. ANGLEM, M.D.,* AND HOWARD M. CLUTE, M.D.†

BOSTON

THE present concept of the mode of action of the sulfonamide compounds provides a rational basis for their prophylactic intraperitoneal use in gastrointestinal surgery, and gives good reason to believe that this may be one of the most fruitful and advantageous fields for the employment of these drugs. A brief summary of the steps leading to the present knowledge of the action of these drugs will make clear the basis for this opinion.

Lockwood¹ in 1938 demonstrated that peptones resulting from the proteolytic action of bacteria exercise an inhibitory effect on the action of sulfanilamide, and suggested that the latter prevents the specialized metabolic activity required of invasive organisms. He offered evidence that this effect may be achieved by the prevention of utilization of protein metabolites by the organism. Fildes,² in a study of the mechanism of the antibacterial action of mercury, found that it is specifically neutralized by sulfhydryl (SH) compounds and concluded that mercury combines with them, thus depriving the bacteria of SH groups. This conclusion, he believed, accords with the view that antibacterial substances may operate by interfering with essential metabolites necessary for the growth of bacteria. Stamp,³ working on a similar hypothesis, found that extracts of streptococci contain a substance that antagonizes the action of sulfanilamide. Green⁴ noted that under certain conditions *Brucella abortus* is capable of releasing some factor into the culture medium that inhibits the action of sulfanilamide. He showed that the yield of the antisulfanilamide factor is greater when the *Br. abortus* is allowed to autolyze. He also demonstrated that this factor has a powerful growth-promoting effect, not only on *Br. abortus* but on other organisms as well.

Previously, McIntosh and Whitby⁵ and others had called attention to the fact that a particular concentration of sulfanilamide is not bactericidal to more than a certain number of bacteria, varying with the species. This observation was confirmed by Green, who noted, for example, that an inoculum of 2000 organisms in a 1:10,000 concentration of sulfanilamide showed, after a preliminary growth phase, progressive bacteriostasis and final

sterilization, whereas an inoculum of 3000 organisms finally grew out. This relation was precise and constant and could be accurately predicted. Green's observations all pointed to the conclusion that the antisulfanilamide factor responsible for overcoming the bacteriostatic effect is produced by the autolysis of dead and living cells. Finally, he pointed out a fact frequently overlooked—namely, that whereas it is generally considered that sulfanilamide is bacteriostatic to relatively few organisms, it tends to be forgotten that the sensitivity to it varies only in degree, though often very widely. Not one of many organisms tested by him was completely insensitive to 1:100 concentrations of sulfanilamide. He found, for example, that a small inoculum of the almost insensitive *Bacillus subtilis* was killed by a high concentration.

Finally, Woods⁶ found that yeast extracts contain a substance that, like those of Stamp and Green, reverses the inhibitory effect of sulfanilamide. The behavior and chemical properties of this substance suggested to him that it might be chemically related to sulfanilamide. Following this lead, he tested various substances having a chemical structure similar to that of sulfanilamide. One of these, *p*-aminobenzoic acid, was discovered to have a high antisulfanilamide activity. Woods found a constant relation between the concentration of sulfanilamide used and the concentration of *p*-aminobenzoic acid required to reverse its inhibitory effect. He believed that his findings provided strong confirmation of Lockwood's suggestion that the inhibitory effect of sulfanilamide on bacterial growth is based on an inactivation of bacterial enzymes, and that the inactivation is due to the competition for the enzyme between the metabolite essential for bacterial growth and the structurally similar sulfanilamide. Woods further suggested that the differences in sensitivity of different organisms to sulfanilamide inhibition are correlated with quantitative differences in ability to synthesize *p*-aminobenzoic acid.

The significance of the foregoing with respect to the prophylactic intraperitoneal application of sulfanilamide in gastrointestinal surgery will be clear when the following points are considered. Immediately after the construction of an anastomosis, whether done by an open or by a so-called "aseptic" technic, conditions exist that are most favorable for the effective action of sulfanilamide.

*Assistant professor of surgery, Boston University School of Medicine; surgeon, Massachusetts Memorial Hospitals.

†Professor of surgery, Boston University School of Medicine; surgeon-in-chief, Massachusetts Memorial Hospitals.

The inoculum of bacteria along the suture line is small. If infection can be considered to exist at this time, it is presumably in a preinvasive stage and there is little or no protein digestion, and it may reasonably be assumed that antisulfonamide substances are not present in high concentration. By the local application of sulfanilamide along the suture line, an overwhelming concentration of the drug can be brought to bear on the small number of bacteria.

It has long been known that in the healing of anastomosed hollow viscera the first essential is the agglutination of the opposed serosal surfaces by a fibrin seal. In the absence of any gross technical error, secondary leakage of a suture line may occur as a result of bacterial action along it, causing interference with agglutination of the opposed serosal surfaces or lysis of the fibrin seal that has begun to form. If local bacteriostasis along the suture line can be maintained long enough to permit the formation of a firm fibrin seal, which requires only a few hours to take place, the danger of secondary leakage and peritonitis can be greatly diminished.

That the local implantation of sulfanilamide is effective in bringing about this result has been dramatically shown by Varco, Hay and Stevens.⁷ By this method they were able to reduce to zero the mortality from peritonitis in a series of complicated experimental gastrointestinal surgical procedures on 37 dogs—procedures that had hitherto carried a discouragingly high mortality from leakage at the suture line and subsequent peritonitis. They observed further that in the few dogs in the series that died of other causes, there was found at post mortem a firm fibrin seal between the opposed serosal surfaces, which contrasted sharply with the picture observed when dogs that had not been treated with sulfanilamide died of peritonitis in this interval, where there was little fibrin sealing and, hence, gross contamination from the stitch holes.

We have to date used sulfanilamide as a prophylactic agent by local implantation within the peritoneal cavity in 75 cases of gastrointestinal anastomosis or other operative procedures requiring the opening and closure of hollow viscera within the peritoneal cavity, excluding obstructive or Mikulicz resections. These cases are summarized in Table 1.

Sulfanilamide was used as the chemotherapeutic agent in all cases. The chemotherapy was limited to the intraperitoneal dose, with the single exception of a case of carcinoma of the sigmoid in which sulfaguanidine was given orally both preoperatively and postoperatively. We believe that this point is of major significance with respect to the incidence of toxic reactions. This has been

emphasized by Jackson and Collier,⁸ who observed no toxic reaction in a series of 33 cases in which sulfanilamide was given only intraperitoneally. In contrast with this, they report 9 cases of toxic hepatitis with jaundice in a series of 29 cases in

TABLE 1. Data on Cases.

which additional sulfanilamide was given. In our series, there was but one clear-cut toxic reaction, a toxic hepatitis occurring four days after a gastric resection. Complete recovery followed a stormy convalescence.

In the case in which sulfaguanidine was given preoperatively and postoperatively, mentioned above, a toxic hemolytic anemia was suspected on the second postoperative day, when the red-cell count and hemoglobin suddenly dropped from preoperative levels of 4,510,000 and 90 per cent, respectively, to 2,600,000 and 54 per cent. However, on the same day there was a discharge of dark blood from the wound, and subsequently large quantities of dark blood were passed rectally. We are inclined to believe that this represented a straightforward case of postoperative hemorrhage, rather than a reaction to the drug.

We are convinced that the danger of serious toxic reaction is slight when a single intraperitoneal dose of sulfanilamide is used, even when this dose is large.

The intraperitoneal doses of sulfanilamide employed in our series varied from 4 to 16 gm., with an average of 7.8 gm., and in 10 cases an additional amount (2 to 4 gm.) was left in the wound. When this study was first begun, we were influenced in favor of relatively large doses by the experience and recommendations of Thompson, Brabson and Walker⁹ in the intraperitoneal use of sulfanilamide in appendicitis. In the more recent cases, the usual intraperitoneal dose has been 6 to 8 gm.

Whereas sulfanilamide alone was used in all our cases, it seems likely that a mixture of sulfanilamide and sulfathiazole, as advocated by Key¹⁰ in orthopedic conditions, offers certain advantages. Throckmorton^{11, 12} has shown that in experimental animals some sulfathiazole remains visible within the peritoneal cavity for three to six days after implantation, whereas sulfanilamide remains visible for only six to twelve hours. The prolongation of the local effect that would be attained by the use of the more slowly absorbed sulfathiazole, its wider range of bacteriostatic activity and its more effective mobilization of cellular reaction all lead us to believe that a mixture of sulfathiazole and sulfanilamide may offer definite advantages.

In the series of 75 cases, there were 6 deaths, a mortality of 8 per cent. There were no deaths from peritonitis. Pulmonary embolism was the cause of death in 3 cases. In 2 of these, both gastric resections, the diagnosis was confirmed by autopsy. In the third case, a right colectomy, autopsy was not done, but the embolism occurred on the eighteenth postoperative day, when the patient was ready to be discharged.

In 2 of the remaining fatal cases, both gastric resections, the cause of death was pneumonia. In 1 of these cases, two of the silkworm-gut stay sutures gave way on the fifth postoperative day and dehiscence of the wound requiring resuture occurred, following which the patient developed pneumonia. Although death was clearly due to pneumonia, at autopsy an unsuspected pelvic abscess and an abscess in the right lumbar gutter were found, although all visceral suture lines were intact and there was no evidence of leakage. This patient had had a large polypoid carcinoma of the stomach that contained an intramural abscess with acute inflammatory changes in the adjacent tissues, which may, perhaps, have led to peritoneal contamination by organisms of unusually high virulence. Autopsy was not done on the second case, but clinically, death was due to pneumonia. The sixth fatality was in a trans-thoracic gastric resection, fifteen weeks after operation. An esophagogastric fistula with empyema and inanition was the cause of death.

Additional wound complications comprised minor infection in 3 cases, major wound infections in 2, transient pancreatic drainage after duodenectomy in 1, and transient duodenal fistula in 1. The last occurred in a case in which the duodenum was

divided a few millimeters above the papilla of Vater. There was one other wound dehiscence, after a right colectomy, apparently due to mechanical factors. An incarcerated loop of small intestine distant from the anastomosis perforated and resulted in a local peritonitis. This occurred, however, after the anastomosis had begun to function. This patient still has an ileal fistula but is recovering.

SUMMARY AND CONCLUSIONS

A series of 75 cases of gastrointestinal anastomosis, or some other operative procedure in which opening and primary closure of one or more hollow abdominal viscera were done, is reported in which sulfanilamide was applied intraperitoneally along the suture lines in the viscera. There were no deaths from peritonitis. Clear evidence of intraperitoneal infection was observed post mortem in only 1 fatal case, and in this case was not the cause of death. Only 1 patient had a toxic reaction to the drug, a toxic hepatitis with recovery.

Our experience with this series has convinced us of the value of the local intraperitoneal use of sulfanilamide along the suture lines after gastrointestinal anastomosis and in all cases with peritoneal soiling. We are satisfied that the danger of serious toxic reaction to the drug is slight if the intraperitoneal dosage does not exceed an average dose of 8 gm. in adults, and if this dose is not immediately preceded or followed by the additional administration of a sulfonamide.

THE ANTI-THIAMINE FACTOR IN FISH

PHILIP S. OWEN, M.D.,† AND JOSEPH W. FERREBEE, M.D.‡

BOSTON

EPIDEMICS of a severe and unusually fatal paralytic disturbance have been observed in animals when fish has been added to their diet.¹⁻¹⁰ A review of the circumstances of these epidemics of so-called "fish disease" and a study of the factor in fish responsible for them permit certain conclusions to be drawn concerning the use of fish in diets intended for human consumption.

FISH DISEASE IN ANIMALS

In 1936 Green¹ described a syndrome in foves that was induced by adding fresh fish to their diet. The clinical and pathological features of the disturbance resemble those of Wernicke's syndrome in man.¹¹⁻¹³ The first symptom is anorexia, which is usually followed in a few days by weakness, hyperesthesia, ataxia and death.¹⁻¹⁰ Post-mortem examination of the central nervous system reveals proliferation of the endothelium and adventitia of the small blood vessels, with varicose deformities and bilaterally symmetrical hemorrhages in the paraventricular nuclei and in the gray matter of the brain stem.¹¹⁻¹³ Studies of the cord and peripheral nerves are not reported, but degenerative lesions of the myocardium and fatty infiltrations of the liver have been described. Pups nursing from mothers affected with the disorder die early, without the histologic changes seen in the older animals.¹⁴

The disease is evidently one of thiamine deficiency, since it may be produced by thiamine deficiency under experimental conditions^{15,16} and may be cured by thiamine injections.^{4-6,8} The exact distribution of the factor in fish responsible for production of the deficiency has not been surveyed. The disease, however, has been observed following the consumption of carp, Atlantic Coast whiting, Pacific Coast mackerel, Lake Superior and Lake Michigan herring, suckers, smelts, mullets and great northern pike.^{7,9} Experiments with carp have demonstrated that the factor responsible is present in large quantity in the viscera and to a less extent in the heads, skin and scales. It does not seem to be present to a significant extent in the fish muscle. Thus, diets containing 20 per

cent of fish muscle were found to be innocuous, whereas diets containing 10 per cent of whole raw fish promptly produced symptoms.^{8,9}

Of critical importance, however, is not the amount of fish present in the diet, but rather the thiamine content of the diet as a whole and the length of time during which fresh raw fish is allowed to stand in contact with the thiamine-containing foods.^{15,16} Intimate mixing of the thiamine-containing constituents of the diet with portions of raw fish rich in the anti-thiamine factor is essential to production of the disease. Raw fish fed as a separate meal is harmless.⁶

CHARACTERISTICS OF THE ANTI-THIAMINE FACTOR

The anti-thiamine factor is destroyed by cooking,¹⁵ and also by drying in air at room temperature.¹⁶ The factor is of large molecular size and

cent does not pass the membrane of living cells.^{16,17} It may be precipitated by protein precipitants and destroyed by peptic digestion.^{18,19} The reaction with thiamine appears to be enzymatic and to exhibit maxima at pH 9 and 60°C.¹⁹ Tables 1

and 2 illustrate the effect of pH and temperature on the rate at which the anti-thiamine factor of carp destroys thiamine.

CONCLUSIONS

From the foregoing review it appears that there is present in the viscera, heads, skins and scales

*From the Laboratory of Dental Medicine, Harvard School of Dental Medicine, the Second and Fourth Medical Services (Harvard) and the Thorndike Memorial Laboratory, Boston City Hospital, and the Medical Services, Peter Bent Brigham Hospital.

of certain fish a proteinlike material capable of destroying thiamine in a manner suggestive of an enzymatic reaction. When portions of fish containing this anti-thiamine factor in significant quantity are allowed to come into intimate contact with the thiamine-containing constituents of the diet, the thiamine content of these foods may be lowered to a level no longer compatible with the maintenance of normal nutrition. Epidemics of thiamine deficiency explainable on this basis have been observed in animals to whose diet fresh raw fish has been added. Similar epidemics have not been observed in man.

There are a number of reasons why thiamine deficiency of this particular mechanism of origin may not be frequent in man. The portions of fish that are rich in anti-thiamine factor are for the most part those usually discarded in the preparation of fish for human consumption, that is, viscera, heads, skins and scales. Moreover, the destructive reaction with thiamine is definitely extrinsic since the factor itself is destroyed by peptic digestion. Because the factor is also destroyed by cooking or by drying, the only opportunity for its significantly affecting thiamine nutrition lies in those occasions where the major thiamine-containing constituents of the diet are mixed with whole raw fish and the mixture is allowed to stand at room temperature for some time before being cooked, eaten or dried. Under ordinary circumstances of diet preparation such circumstances are rare.

MEDICAL PROGRESS

GENERAL ANESTHESIA

LEO P. ZENTGRAF, M.D.,* AND URBAN H. EVERSOLE, M.D.†

BOSTON

THE present-day utilization of new anesthetic agents, modern gas machines, improved techniques and certain combinations of agents has given general anesthesia a flexibility and safety indicative of important progress in recent years.

The gas machine, the principal item in the anesthetist's armamentarium, not only enables him to administer anesthetic agents economically and conveniently but also aids in the maintenance of normal physiology, reduces the explosion hazard and provides an immediately available means of resuscitation. A modern gas machine used in conjunction with an endotracheal tube is practically indispensable for the application of positive intrapulmonary pressure in intrapleural surgery.

The following is a summary of the present status of the various agents used for general anesthesia.

INHALATION ANESTHESIA

Established Agents

Diethyl ether remains the standard drug for inhalation anesthesia, because of its wide margin of safety, relatively low toxicity, economy, and ease of administration, especially by the open drop method. Since the characteristic effects of ether are well known, their discussion in this article is unnecessary.

If considerable quantities of ether are used, a marked saving in cost may be achieved by bulk purchases. The *United States Pharmacopoeia* no longer states that ether is unsatisfactory for use twenty-four hours after the seal of the container is opened, and approves the use of 3-liter containers for storage. Ether is entirely satisfactory for clinical use for long periods after the seal of the container is broken,¹ and the use of 5-pound to 50-pound drums has been recommended. With proper precautions, ether may be drawn with perfect safety from the large containers into suitable small ones for operating-room use.

Cyclopropane is thought to be the most nearly ideal anesthetic agent, because of its potency,

rapidity of induction and recovery, apparent lack of toxicity, pleasantness to the patient and the high percentage of oxygen employed in administration. Whether it merits such a position is still debatable. When mixed with oxygen, it is highly explosive, and should be used only by one familiar with its toxic characteristics, since its action is rapid and the signs of degree of anesthetic depth are not so clear cut as those when ether is used.

The most commonly noted undesirable effects of cyclopropane are the various cardiac arrhythmias. They occur most frequently under deep anesthesia but also are observed under light anesthetics. Their control remains a problem, and whether they leave any long-lasting damage has not been determined. Arrhythmias may sometimes be inhibited by the simultaneous use of procaine.² The protective action of the barbiturates has been confirmed³ and also denied.⁴ Morphine tends to exaggerate arrhythmias,^{2,3} and if large doses are used preoperatively, marked depression of respiration is likely to occur. The concomitant administration of cyclopropane and epinephrine is prone to produce ventricular fibrillation.

Since cyclopropane may have a tendency to act as a cardiac irritant, it probably should not be used in patients with cardiac impairment or with thyrotoxicosis. There have been reports of sudden deaths on the operating table of patients with thyrotoxicosis receiving this agent as an anesthetic. These deaths were probably due to ventricular fibrillation.⁵

Even in deep anesthesia troublesome laryngospasm occurs at times when high concentrations of cyclopropane are employed or when traction is exerted on the abdominal or pelvic organs.⁶

In most patients in whom a general anesthetic agent is indicated, with the exception of those undergoing abdominal surgery, cyclopropane produces satisfactory anesthesia. The degree of relaxation obtainable with safety is less than that obtained with ether; however, Guedel⁷ has offered a controlled-breathing technic to eliminate this difficulty.

As a supplemental agent for regional or spinal anesthesia, cyclopropane has proved valuable.⁸ In the presence of nausea, psychic disturbances or inadequacy of the principal agent, its use frequent-

*The articles in the medical progress series of 1941 have been published in book form (*Medical Progress Annual*, Volume III, 678 pp. Springfield, Illinois: Charles C. Thomas, 1942. \$5.00).

†Fellow Department of Anesthesia, Lahey Clinic, Director Department of Anesthesia, Lahey Clinic, anesthetist New England Hospital and New England Deaconess Hospital.

ly makes an otherwise unsatisfactory situation tolerable to both the surgeon and the patient. Cyclopropane has been used in obstetrics with good results.²

Ethylene is probably the most nontoxic of all inhalation agents with appreciable potency. Although explosive in anesthetic mixtures with oxygen, when properly used in patients with cardiac abnormalities it is safe and well tolerated. In many types of cases ethylene might well be employed with greater frequency. The concentrations required are comparable to those of nitrous oxide, but it is more potent than the latter, produces better relaxation and permits the use of somewhat higher percentages of oxygen.

Nitrous oxide is a relatively weak anesthetic gas. With an adequate percentage of oxygen, it is safe, but such a mixture frequently gives inadequate anesthesia, and consequently the flow of oxygen is reduced to a dangerous level. Sufficient morphine or a barbiturate given preoperatively often allows adequate anesthesia to be obtained with safe concentrations of nitrous oxide. Following the rectal administration of tribromethanol (Avertin) or Pentothal sodium, nitrous oxide is a most satisfactory anesthetic agent for many types of extra-abdominal operations. This combination is pleasing, especially to apprehensive patients or children, and is well tolerated by many poor-risk patients.

Ethyl chloride is a toxic drug with a narrow margin of safety.⁹ For general anesthesia it is dangerous because of its inherent tissue toxicity and because of its volatility, which may result in its vapor's rapidly displacing air in the air passages, with absorption of an overdose before the flow is controlled. A slow dropping on a gauze mask — not a spray — is the administration method of choice. Ethyl chloride should not be administered by one inexperienced in its use, but in the hands of a skilled anesthetist it is satisfactory for brief surgical procedures and as an induction agent preceding ether.

Chloroform is still considered too dangerous for frequent use. In addition to its toxicity to the liver and heart, it diminishes the plasma prothrombin,¹⁰ with consequent probable increase in bleeding hazards.

Divinyl ether (Vinethene) should not be considered a substitute for ether or cyclopropane. Because of its toxicity, it is contraindicated when hepatic or renal damage exists.¹¹ Because induction and recovery are rapid and because the drug is potent and causes little respiratory irritation, it has proved satisfactory for short surgical procedures requiring light anesthesia. Divinyl ether

is administered preferably by the open-drop method and is suitable for children, especially as an induction agent for diethyl ether. If divinyl ether is to be used for longer than thirty minutes, it should be volatilized with oxygen. This probably affords some protection against liver damage.¹²

New Agents

With the idea that new substances structurally resembling cyclopropane, ethylene and diethyl ether might be synthesized and proved to be valuable anesthetic drugs, a considerable number of chemicals have been developed. Some of them possess anesthetic qualities but because of toxicity or undesirable side effects are impractical for clinical use. However, *cyprome* and *cyclopropylmethyl ether* have been used with good results. *Cyprerthylene ether*, first used in human subjects in November, 1941, is even more promising.¹³ It presents a high potency, produces marked relaxation, and can be administered in a mixture with high oxygen concentration.

For many years *trichlorethylene* has been known to possess anesthetic qualities. During the last eight or ten years a study of its characteristics and its effects on human beings has shown certain desirable qualities.¹⁴ Trichlorethylene has only a minor degree of toxicity for the liver and kidneys, produces little irritation of the respiratory passages, has slight effect on the body chemistry and decreases capillary oozing. In spite of these admirable qualities, trichlorethylene is used but little because vaporization is difficult, which makes it unreliable for third-stage anesthesia, and because in many cases inadequate muscular relaxation results.

Although trichlorethylene is usually considered to be noninflammable,¹⁵ recent work has shown that, whereas this is true for mixtures of air and trichlorethylene under ordinary conditions of temperature and pressure, it is probably not true of mixtures of this drug with pure oxygen. Recently published figures indicate that mixtures of trichlorethylene and oxygen are inflammable within the limits of 10.3 per cent to 64.5 per cent trichlorethylene.¹⁶

It has recently been shown that this drug is capable of producing cardiac arrhythmias,¹⁷ an undesirable feature in anesthesia.

Tetrachlorethylene, a nonexplosive, noninflammable liquid with anesthetic properties, is probably nontoxic.¹⁸ In man a moderate degree of surgical anesthesia can be produced, but its disadvantages probably make it of little value clinically. Tetrachlorethylene is difficult to volatilize and is irritating to the mucous membranes and the skin.¹⁹

EXPLOSION HAZARDS

Although anesthetic mixtures in oxygen of ether, cyclopropane and ethylene are explosive, they are safe when proper precautions are taken to prevent static sparks and to exclude cautery or sparking electric apparatus from the vicinity. Modern operating rooms in which switches and wall plugs are designed to minimize the possibility of igniting inflammable mixtures, and in which good ventilation is provided, together with the use of an intercoupler and a tightly closed breathing system have done much to eliminate the explosion hazard. The likelihood that a spark or flame will ignite a mixture decreases markedly when its distance from the leaking mixture is two feet or more.

Efforts have been made to find a suitable combination of an anesthetic agent, oxygen and an inert gas—for example, helium—that is non-explosive. Several such combinations have been devised.¹⁹ Their practical value is doubtful, however, because not much variation in the relative proportions of their constituents is possible. Present day gas machines are not considered accurate enough to allow their use with any degree of safety.

RECTAL ANESTHESIA

The most widely used drug for rectal anesthesia is *tribromoethanol* (Avertin) in *amylene hydrate*. It was originally intended for use unsupplemented, but since the doses required proved too depressing, it is now employed as a basal anesthetic. In combination with nitrous oxide, it furnishes excellent anesthesia in thyroid surgery.²⁰ In apprehensive patients and children, its use does much to allay preoperative fear and facilitates rapid, smooth induction of anesthesia.

This drug might be more widely used for basal anesthesia except that it often produces a prolonged period of postoperative respiratory depression, tending to allow secretions to accumulate in the respiratory passages. This lengthy period of postoperative unconsciousness necessitates more intensive nursing care.

Pentothal Sodium, although primarily intended for intravenous anesthesia, has proved an effective and safe basal anesthetic when given rectally and followed by nitrous oxide or a small amount of cyclopropane.²¹ The action of the drug when administered rectally is essentially the same as that when given by the conventional intravenous route. Rectal installation should take place half to one hour previous to beginning the inhalation phase of the anesthesia. In healthy adults the dose is 1 cc of a 10 per cent solution for every five pounds of body weight. A smaller dose is used when indicated by the patient's age or condition.²¹ In infants, *Pentothal Sodium* has been used in this manner in

doses of 0.8 cc of a 2.5 per cent solution per pound of body weight.²²

Lyval Soluble is also a satisfactory basal anesthetic when given rectally one hour preceding the inhalation anesthetic in doses of 0.2 cc of a 10 per cent solution per pound of body weight.²³

INTRAVENOUS ANESTHESIA

Clinically intravenous anesthesia is today achieved almost solely by the use of *Pentothal Sodium* or *Lyval Soluble*, the two outstanding short acting barbiturates. The former drug is given the preference by most anesthetists in their routine work, since the rapidity of induction and the infrequency of postoperative nausea and vomiting make it most acceptable to patients.

When *Pentothal Sodium* is the sole anesthetic agent, the surgical procedure is limited generally to forty five minutes and does not require a considerable degree of muscular relaxation. A wide variety of difficult types of surgery, including intra-abdominal procedures, have been performed successfully under *Pentothal Sodium* alone, but when one considers the danger to the patient of the required deep anesthesia and the technical difficulties that the surgeon is likely to encounter in its frequent use, it seems best in such cases to rely on other agents commonly available in civilian practice.

In military surgery, however, especially under front line conditions, *Pentothal Sodium* is an extremely valuable and widely used drug. One surgeon²⁴ in describing his experience in treating battle casualties said that the wounded men were brought in frightened, heavily narcotized, tired and in more or less shock. The necessary surgical procedures usually required not over an hour, and in about 95 per cent of the cases intravenous anesthesia was employed. In the Dieppe raid, *Pentothal Sodium* was used as the sole anesthetic agent in treating 51 per cent of the casualties.²⁵ The usual rapid recovery from the anesthetic agent with few aftereffects allowed rapid evacuation of the patients to hospitals some distance from the front. Since *Pentothal Sodium* is noninflammable and easily transported, prepared and administered, it is highly acceptable under these conditions.

The scope of intravenous anesthesia has been greatly widened by its use in combination with other methods. As a supplement to spinal anesthesia, it eliminates the nausea, retching and painful traction stimuli often accompanying abdominal procedures, and does not cause the increased diaphragmatic excursions often noted when an inhalation anesthetic agent is used as a supplement.⁸ Electric apparatus and cautery may be employed freely when a spinal anesthetic and *Pentothal Sodium* are used.

Combined with local infiltration, regional or splanchnic block or nitrous oxide, Pentothal Sodium produces good anesthesia, especially for poor-risk patients.²⁶ Diabetic patients also tolerate the drug very well.²⁶ Certain hazards accompany its use, and the anesthetist should be prepared with means for combating them. Respiratory failure may result from an overdose or from laryngospasm. The latter is especially prone to occur in the presence of excessive amounts of mucus or blood or when instrumentation in the pharynx is performed. Laryngospasm may be prevented if the pharynx and glottis are sprayed with a 10 per cent solution of cocaine immediately prior to the injection of the Pentothal Sodium. Hiccups occurring under the drug usually cease if intravenous atropine (1/75 gr. in adults) or cyclopropane is administered. Atropine should be given routinely before intravenous Pentothal Sodium, and a preoperative sedative such as morphine allows the use of smaller doses.²⁷ The continuous administration of 100 per cent oxygen during the anesthesia has been recommended. On the basis of animal experiments, Beecher and Moyer²⁸ have questioned the wisdom of giving 100 per cent oxygen to patients with respiratory depression under Pentothal Sodium anesthesia; ordinarily a low concentration of oxygen in the blood stimulates the respiratory center when the sensitivity to carbon dioxide is diminished, and the use of 100 per cent oxygen removes this stimulus. The use of Pentothal Sodium anesthesia is also considered unwise when hepatic, renal or serious cardiac disease exists, or when any condition that may interfere with adequate pulmonary ventilation is present.²⁷

Although the subject is controversial, some reports indicate that the barbiturates tend to prevent or retard the onset of shock.^{26, 29}

Clinically, there is ample evidence that Pentothal Sodium is not contraindicated when the patient has been receiving sulfonamide therapy.²⁷

Pentothal Sodium may also be used as an induction agent prior to the administration of the principal agent and, if desired, can be given in the patient's room. This drug is valuable as an anti-convulsant.

Pentothal Sodium may be prepared in bulk solution. Five grams of the drug in 200 cc. of sterile distilled water gives a 2.5 per cent solution, which is satisfactory for use for several days or as long as the solution remains clear. This concentration is the one most widely used at present, since better control of the dosage is obtained, since accidental extraveneous injection is less likely to produce undesirable tissue damage and since the incidence of phlebitis is decreased.

Recently published data show that the use of

paraldehyde as an intravenous anesthetic agent has probably been responsible for a number of deaths.³⁰ Animal experiments confirmed the fact that paraldehyde was no doubt the cause of the post-mortem findings in these cases. With this in mind, paraldehyde should not be used for intravenous anesthesia, especially since Pentothal Sodium is safe and is readily available in most hospitals.

PREMEDICATION

Morphine, the *barbiturates* and the *belladonna derivatives*, atropine and scopolamine, continue to maintain their status as the standard drugs for preoperative medication. Morphine may be administered intravenously a few minutes before the induction of anesthesia, if the usual subcutaneous dose was omitted or proved insufficient to produce the desired sedation in a reasonable length of time.³¹ Morphine by the intravenous route should be given slowly, preferably in smaller doses than when given subcutaneously, and administration should be stopped if dizziness, numbness, tingling or other untoward reactions occur.³¹

A new synthetic drug, *1-methyl 4-phenyl-piperidine 4-carboxylic acid ethyl ester hydrochloride* (Demerol), has made its appearance as a substitute for morphine, especially if the supply of the latter should be threatened because of wartime conditions. It is one of a series of piperidine compounds, resembles atropine structurally, and possesses some of the properties of the latter, in addition to being a satisfactory analgesic and sedative. Demerol is said to be comparable to morphine and to be as reliable as the latter in the recommended dosage. The atropine-like properties of the drug are its ability to cause drying of the mucous membranes and its spasmolytic effect. Since it does not depress the cough reflex as does morphine and is effective for pain originating in serous membranes and smooth muscle, it may prove to be valuable in postoperative treatment. Whether its continued use will result in habituation has not been determined.^{32, 33}

CASE 29361

PRESENTATION OF CASE

First admission. A thirty-five-year-old volunteer war worker entered the hospital because of paresthasias of the fingers of nine weeks' duration.

For the previous nine weeks he had noticed tingling of the fingers; he had become noticeably weak, especially in the arms. His physician found the hemoglobin to be 65 per cent and gave him iron and cod-liver oil without any benefit. During the week before entry the tongue felt thick.

At the age of twenty-two he began to lose weight; he was told that his systolic blood pressure was 200 and that "he was threatened with tuberculosis." He went south, "took it easy" for four years and had worked hard ever since. The hypertension apparently disappeared. About a year before entry he was turned down by the draft-board physician for a cardiovascular defect, but was not told what it was.

Physical examination on admission showed a well-developed, well-nourished man. There was slight diminution to light touch and pinprick around the mouth. The tongue was slightly tremulous but not atrophic. The upper extremities were normal in color and ability to sweat. The strength of all muscle groups was definitely weakened, most conspicuously in the shoulder girdles—he could barely raise his arms above his head. There was no muscular fibrillation. He could not stand or walk on his toes or heels, or rise from a squatting position. The abdominal and back muscles were relatively strong. The Romberg sign was positive. There was no muscle tenderness, but straight leg-raising carried to 45° caused pain bilaterally. There was sensory loss for touch and pain in the distal portions of the arms and legs. Vibratory sense was diminished over the wrist, and lost over the malleoli. The triceps reflexes were barely present; the biceps, radial, ankle and knee jerks were absent; abdominal and cremasteric reflexes were present. The heart, lungs and abdomen were normal.

*On leave of absence.

The blood pressure was 134 systolic, 106 diastolic. The temperature and respirations were normal; the pulse was 84.

The white-cell count was 8700, with 66 per cent neutrophils, and the hemoglobin 14.5 gm. The urine was normal. A gastric analysis was normal. A blood Hinton test was negative. A lumbar puncture gave an initial pressure of 150 mm. (water). There were no cells in the spinal fluid; the total protein was 133 mg. per 100 cc., and the gold-sol curve 0011222200. A spinal-fluid Wassermann test was negative.

X-ray examination of the chest revealed no definite increase in the size of the heart. The apex of the heart was somewhat rounded, and the aorta was slightly tortuous; the lungs and the diaphragm were normal.

The patient was discharged, unimproved, after five days.

Final admission (two weeks later). The patient returned because of difficulty in breathing. After his discharge there was gradual progression of weakness. On one occasion he fell and had difficulty getting back to bed. For two days prior to admission there was some difficulty in breathing, and slight difficulty in swallowing and talking. There was no increase in sensory symptoms.

The weakness had increased, and it involved not only the arms and legs but also the abdomen, back and neck and intercostal muscles. Chest expansion was limited to 3 cm. at the level of the nipples. The voice was husky and frequently trailed off into a whisper. The facial, ocular and masseter muscles seemed to be normal. All the tendon reflexes, as well as the abdominal and plantar reflexes, were absent.

The blood pressure was 140 systolic, 100 diastolic. The temperature was 98.6°F., the pulse 90, and the respirations 20.

The patient was given hot packs (Kenny therapy). He developed cramps of the flexors of fingers of both hands, which recurred during his entire stay. On the third day he had so much respiratory difficulty that he had to be put into a respirator. Following this episode he was able to elevate his arms overhead and to raise his legs from the bed, but his fingers and toes remained very weak. There was preservation of the sensations of light touch and pinprick throughout. Profound disturbance of the vibration and position senses was noted in all extremities. There was minimal tenderness of the calf muscle. A lumbar puncture gave an initial pressure of 100 mm. (water), and the spinal fluid contained no cells; the total protein was 190 mg. per 100 cc.

During the next two weeks, treatment with hot packs was carried out. On the whole there was

no improvement or any definite progression. One observer stated that there was slight bilateral facial weakness. Toward the end of this period, however, the respirations became increasingly shallow, rapid and labored. Examination at that time revealed more tenderness and perhaps more weakness. Sinus arrhythmia, with a rate of 104, developed. The blood pressure was 150 systolic, 115 diastolic. Examination of the lungs was unsatisfactory, but they seemed to be clear.

On the twentieth hospital day the patient became weaker and was unable to raise secretions or to swallow, or to breathe outside the respirator. He died on the twenty-first hospital day.

DIFFERENTIAL DIAGNOSIS

DR. AUGUSTUS ROSE: I assume that discharge from the hospital at the time of the first admission was not because the attending physician believed that the patient was over his illness. There undoubtedly were other reasons, economic or something of that nature. There is no mention of mental symptoms, so I shall assume that the patient was normal mentally.

This case offers little or no difficulty in diagnosis, yet it raises the important question of polyneuritis and a discussion of the pathology of the condition. Ignoring the details of the history, this is the case of a thirty-five-year-old man who, after nine weeks of paresthesia and weakness of the extremities, developed cranial-nerve palsies and died in respiratory paralysis. The spinal fluid showed a high total protein without cells. This is the clinical picture, but fortunately is not the usual outcome of the condition known as infectious polyneuritis. It also goes under a number of other names: infective neuronitis, radiculoneuritis, polyneuritis with facial diplegia, Guillain-Barré syndrome and so forth.

Polyneuritis is a clinical picture, the essential feature of which is impairment of function of many peripheral nerves, resulting in a more or less symmetrical distribution of muscular weakness and sensory loss. This general picture is usually present in all cases regardless of the etiology of the neuritis. In many cases, however, there are characteristic clinical differences between the various types of polyneuritis. In most types of peripheral neuritis the weakness and sensory loss are chiefly confined to the distal portions of the extremities. In infectious polyneuritis, as illustrated by this case, muscular weakness also involves the proximal muscles of the extremities and the muscles of the trunk. In addition, muscles innervated by the cranial nerves arising from the pons and medulla are often partially or completely paralyzed.

The etiology of polyneuritis remains somewhat confused. In recent years we have heard more

and more about vitamin deficiency, with evidence accumulating to show that a number of different factors contribute to the clinical picture. The role of vitamin deficiency is seen to contribute to the neuritis associated with diabetes, pregnancy and certain other metabolic and toxic conditions. It has been stated to be due to a virus, transferable to monkeys, but this has not been verified. Clinical evidence, however, supports the idea of an infectious agent. Characteristically the syndrome so well described in this case comes on a few days following a mild systemic infection in which there is a mild elevation in temperature, coryza and general malaise. Frequently also, the onset of neuritic symptoms is accompanied by slight fever. The absence of these symptoms in this case, however, does not alter the probable diagnosis, for the systemic infection may be so mild that it is overlooked or forgotten by the time the more dramatic paralytic symptoms develop. The spread of symptoms is usually fairly rapid and, not infrequently, may ascend from the lower extremities, reaching the neck and bulbar-supplied muscles last. This type of spread has led some observers to infer that the disease is located in the spinal cord as well as in the peripheral nerves. In such cases the old question of Landry's ascending paralysis is considered in the differential diagnosis, although that is only a name applied to a train of symptoms and is not a disease entity. In 1927, Dr. Viets¹ published a series of cases from this hospital in which he stressed the frequency of bilateral facial weakness without evidence of involvement of other cranial nerves. In the cases of this group coming to autopsy, pathologic changes were found in the motor cells of the spinal cord and brain stem.

Great emphasis should be placed on the spinal-fluid findings in infectious polyneuritis. The high total protein, which is almost always present in varying degree, is not accompanied by an increase in the cells. This dissociation was emphasized by Guillain, Barré and Strohl² and has come to be almost pathognomonic.

Returning to this particular case, I see no reason for believing that the low hemoglobin or the signs of cardiovascular disease played any role in the patient's final illness. He certainly had a mild degree of hypertension—as shown by a persistently elevated diastolic pressure and by rounding of the cardiac apex by x-ray. There are no leads suggesting disease other than that within the nervous system, or any specific etiologic agent, such as arsenic or alcohol.

It is not safe for one to put all his eggs in one basket. Yet I am at a loss to suggest any diagnosis other than infectious polyneuritis. I shall be interested in hearing a discussion of the pathology of the case by Dr. Kubik. He has often told us

that the pathology is confined to the peripheral nerves and characterized by round-cell infiltration.

DR. JAMES B. AYER: This patient was under my observation for the greater part of his illness. The diagnosis was made on the first admission, at which time he was discharged slightly improved, apparently just from rest in bed. Later he developed respiratory difficulty and was sent back to be near a respirator.

I question whether there was a sensory disturbance of the face. Sensory disturbance in the cranial nerves in this disease are extremely rare. I was never convinced that he had facial paralysis, and only once did anyone think he had it; I repeatedly looked for it because it is so characteristic.

There was no evidence of cerebral involvement. The patient was always intelligent, and there was nothing that suggested encephalitis. Regarding the Kenny treatment, both legs and arms were more comfortable when packed; even respiration was benefited, and one could get about 1 cm. greater respiratory excursion after the Kenny pack had been applied to his chest. He thought it was better than the respirator, which was surprising to me, and I suggest this as an agent to be used in such cases.

We could never make any diagnosis other than what Dr. Rose has made.

DR. HENRY R. VIETS: I saw this man during the last week of his illness. On at least one occasion I thought he had lower facial paralysis, but it was partial and certainly not marked.

It seems to me there is no question about the diagnosis. The most difficult point in regard to polyneuritis from the clinical point of view is the prognosis. This man was a young, husky individual, and all during the course of his illness both Dr. Ayer and I were doubtful about the prognosis, even believing at times that he might recover. Certainly we have had patients as sick as he was up to the last day of his illness who have made a total recovery. One of the surprising things is that they do recover so well and recover so completely in view of the seriousness of their illness. The fact that, in this case, the shoulders were severely involved almost from the start made me a little cautious about the prognosis because the lesion was getting close to the fourth cervical segment, where the phrenic nerve comes off. We should have taken more into consideration that he was close to the danger line at all times.

CLINICAL DIAGNOSIS

Infectious polyneuritis.

DR. ROSE'S DIAGNOSIS

Infectious polyneuritis.

ANATOMICAL DIAGNOSIS

Infectious polyneuritis.

PATHOLOGICAL DISCUSSION

DR. CHARLES S. KUBIK: There have been 5 or 6 deaths from infectious polyneuritis in this hospital, with autopsies in 3 of them. In the other 2 autopsied cases, death occurred on about the tenth day of the illness. This one was unusual. The steady progression of symptoms continued for approximately fifteen weeks and eventually resulted in death. The pathological findings have been essentially the same in all three cases.

The outstanding feature is an infiltration of spinal nerve roots, spinal ganglions and peripheral nerves with lymphocytes (Fig. 1). Special stains show degenerative changes in the myelin sheaths

FIGURE 1. *Lymphocytic Infiltration of Peripheral Nerve.*

and axis cylinders, but only rarely complete destruction of fibers. Except for an axonal reaction in the anterior-horn cells, secondary to the degenerative changes in the nerve roots and nerves, nothing abnormal is found in the spinal cord, brain stem or brain.

DR. ROSE: So the disease is not entirely peripheral in an anatomic sense.

DR. KUBIK: I should consider the nerve roots as part of the peripheral system. In any case, there is no cellular infiltration in the brain or cord.

We have found pathologic changes in all cases, although it is sometimes said that there are no distinctive lesions. Since they were found in only a few out of many sections of peripheral nerve in this case, it is easy to understand why these lesions

may be missed. I should suspect that the negative findings are based on cases of deficiency neuritis that were mistaken for cases of infectious polyneuritis. Although the two conditions may resemble each other clinically, they probably have nothing in common so far as etiology is concerned. I might add that there is no cellular infiltration of the nerves in deficiency neuritis. As Dr. Rose has said, there is no good proof that infectious polyneuritis is really an infection. Bradford, Bashford and Wilson³ thought that they had transmitted the disease to monkeys, but their claims have not been confirmed. Material from 2 of our cases was inoculated into the brains of monkeys with negative results.

DR. ROSE: Has there been, to your knowledge, any case in this hospital in which there were cerebral symptoms?

DR. KUBIK: I do not know of any.

DR. ROSE: Do you remember any, Dr. Ayer?

DR. AYER: No.

DR. ROSE: Some textbooks speak of mental disturbances—not unlike those seen in Korsakoff's psychosis.

CASE 29362

PRESENTATION OF CASE

A thirty-one year old housewife was admitted because of jaundice of six days' duration.

Nine days before admission she developed soft, mushy, yellow, loose stools, which persisted for three or four days. Six days before entry she noticed jaundice of the skin, which became progressively deeper. Three days later she was seized with a sharp pain in the neck, both shoulders and both arms down to the elbows. The attacks lasted for fifteen minutes and left her completely exhausted. She had two similar attacks in the following two days.

She had had arthritis and rheumatic pneumonia at the age of twenty-one and "milk leg" at the age of twenty-seven. Two years prior to admission she developed Raynaud's disease, for which she had three hospital admissions over a period of one year. Bilateral dorsal and lumbar sympathectomies were performed with considerable relief. For the previous two years she had suffered from recurrent, slowly healing ulcers of the lower legs.

Physical examination showed a markedly jaundiced woman. The lungs were clear. There was a short systolic and a mid-diastolic murmur in the aortic area, transmitted to the neck. The extremities were warm and dry. There were many healed scars, with turgor and diminished subcutaneous tissue, on both hands.

The temperature was 99°F, the pulse 80, and the respirations 20.

Examination of the blood revealed a red-cell count of 3,690,000, with a hemoglobin of 10.5 gm, and a white cell count of 12,600, with 57 per cent neutrophils. The urine had a specific gravity of 1.009, with a + test for bile and a negative test for urobilinogen; the sediment contained 4 or 5 white cells per high power field, a culture showed many colonies of colon bacilli. The stools were guaiac negative. The blood nonprotein nitrogen was 18 mg per 100 cc, and the van den Bergh 8.2 mg direct, 12.3 mg indirect. The protein was 7.6 gm per 100 cc, the albumin being 3 gm, and the globulin 4.6 gm—an albumin globulin ratio of 0.7. A blood Hinton test was negative. The blood phosphorus was 21 mg per 100 cc, and the phosphatase 7.9 Bodinsky units. The cephalin flocculation test was ++++ in twenty-four and forty-eight hours.

The jaundice seemed to increase. On the sixth hospital day the patient had a mild chill and a slow rise of temperature to 104.5°F about one and a half hours later, after which it fell slowly to 101.5. She became incontinent, disoriented, drowsy and restless. The breath was 'mousy'. There were edema and icterus. The white cell count on the seventh hospital day was 11,400. The urine gave a ++ test for albumin and a + test for bile; it contained innumerable white cells. The patient was given daily transfusions, intravenous 25 per cent glucose and a high vitamin and high carbohydrate diet. One blood culture was reported positive for colon bacilli in both flasks. A blood culture taken on the next day was sterile. Giemsa stains of a blood smear failed to show any leptospira and guinea pigs inoculated intraperitoneally with the patient's blood remained well.

On the ninth hospital day she became stuporous. The nonprotein nitrogen was 22 mg per 100 cc, and the protein 8.6 gm. The white cell count was 22,250. On the tenth hospital day, the temperature rose to 104.5°F and the patient developed labored jerky respirations with many rales and died.

DIFFERENTIAL DIAGNOSIS

DR. AUSTIN M. BRIDGES: This case, I think, can be described as icterus gravis or malignant jaundice.

In other words the patient had fulminating hepatic failure. This state is typified by acute yellow atrophy but may be simulated by other processes causing rapid destruction of liver tissue, notably suppurative processes. Acute yellow atrophy generally runs a course of about two weeks. It begins with mild intestinal symptoms and perhaps some fever and is thought to be catarrhal jaundice. There may be vomiting. It is interesting that this patient, so far as the record goes, did not suffer from vomiting throughout her illness. I should expect it to have occurred, and I am unable to account for its absence.

After several days in the hospital the picture suddenly became critical. This phase was ushered in by nervous symptoms, and it has been recognized for at least seventy-five years that the dividing line between benign and fatal jaundice—between catarrhal jaundice and acute yellow atrophy—is drawn by nervous or mental symptoms. These symptoms indicate "cholemia," in other words, hepatic failure. One generally sees in fulminating hepatic failure something that was not present in this patient, namely, a bleeding tendency due to a fall in the prothrombin content of the blood.

The mousy odor to the patient's breath is a subjective observation indicating that hepatic failure was being considered and that the observer thought that he had evidence for it. The patient late in the course of the disease had intermittent fever, as is seen late in hepatic failure.

Concerning the laboratory findings, the maximal cephalin flocculation test gives evidence of hepatic-cell failure. There was a very slight rise in the blood nonprotein nitrogen, which in itself is of no importance. If, when broken down, it showed a rise in the amino nitrogen and a marked fall in urea, that would be evidence of "cholemia." The plasma showed only a moderate increase in globulin, and a moderate decrease in albumin. This indicates that the process was of relatively short duration—in other words, that it did not supervene after a long course of mild hepatic failure or cirrhosis. This finding, which was made on admission, is commonly seen even in cases of simple catarrhal jaundice.

We ought to consider whether the jaundice was obstructive. I find no mention of the stools except for the observation before the onset of jaundice, when they were said to be light yellow. The phosphatase in true obstructive jaundice with relatively normal hepatic-cell function should be somewhat higher than it was here; I would expect it to go up to 10 or more units. The absence of urobilinogen suggests obstruction,—that is, failure of bile to reach the intestines, where urobilinogen is formed,—but it is well known that in

acute hepatitis the urobilinogen may be absent during the acute stage and recovery heralded its reappearance. Whether this is due to functional obstruction or to loss of function of hepatic cells, I do not know, but I shall take the absence of urobilinogen to indicate only that the patient did not have hemolytic jaundice.

There is one secondary diagnosis that I should like to discuss at some length—a suppurative cholangitis presumably secondary to biliary obstruction. We recall that, particularly after the onset of the patient's illness, there was pain. This pain was suggestive of gallstone colic in its sudden exhausting character. The distribution in the shoulders and the neck is not entirely characteristic of gallstone colic but is consistent with biliary calculus. Had that pain been not quite severe it would be easy to say that it was due to an initial swelling of the liver in the early stage of acute hepatitis. The second fact favoring cholangitis is colon-bacillus bacteremia observed on one occasion. This suggests that there was infection, perhaps of the biliary tract, with this organism. However, it is well known that such bacteremia may occur in the later stages of a debilitating illness, and it has indeed been mentioned as a common finding in acute yellow atrophy. Against cholangitis is the fact that fever is a prominent feature of this picture only in its later stage; the patient does not have a septic fever during the first three quarters of the illness. The differential count also shows that the neutrophils were relatively low, implying lymphocytosis. This is characteristically seen in catarrhal jaundice, and is not characteristic of a septic process.

It is obvious that Weil's disease was considered and presumably ruled out by the inability to produce disease in guinea pigs; agglutination tests with the patient's serum were not performed. In Weil's disease, as in yellow fever, we should expect more renal damage than this patient exhibited.

Another infectious process that might be considered is endocarditis, especially since the patient was thought to have rheumatic heart disease. It is improbable that endocarditis produced so much damage in the liver with no apparent damage elsewhere. Pylephlebitis entails the same objection as suppurative cholangitis, namely, that the patient was not septic during the greater part of her illness.

If we consider acute yellow atrophy the best diagnosis, we obviously ought to consider the known etiologic factors, such as the toxic effect on the liver of specific poisons. Since she was a housewife, presumably she did not work in a triethylol factory or was not exposed to other industrial hazards. There is no evidence for any other

specific poison, such as chloroform or phosphorus, that might have caused atrophy of the liver. The incidence of acute yellow atrophy is high in pregnancy; nothing in the record suggests that the patient was pregnant, but there is no definite evidence to rule it out. It has been suggested, on purely theoretical grounds, that acute yellow atrophy may be due to the regurgitation of proteolytic pancreatic juice up the bile duct; however, unless the pathologist discovered a stone in the ampulla, I hesitate to make any such diagnosis.

Before I utter a final diagnosis I should like to ask if any competent observer noted that the liver was enlarged during the terminal two or three days.

DR. WILLIAM BECKMAN: At first, it was thought to be. Toward the end no one was able to feel it.

DR. BRUES: My final diagnosis is acute yellow atrophy of the liver, to which I shall add rheumatic heart disease and probably mild aortic stenosis and regurgitation.

DR. BECKMAN: One thing not brought out in the record is that the patient pursued a very benign course during the first five days in the hospital. We thought she had catarrhal jaundice, but we were puzzled by the fact that she had no nausea or vomiting. On the fifth day she had a violent, shaking chill, and the blood culture taken at that time was the one that was positive for colon bacilli; subsequent cultures were negative. From that day on, she went downhill and was febrile.

CLINICAL DIAGNOSES

Acute hepatitis.

Septicemia (colon bacillus).

DR. BRUES'S DIAGNOSES

Acute yellow atrophy of liver.

Rheumatic heart disease (? aortic stenosis and regurgitation).

ANATOMICAL DIAGNOSES

Subacute yellow atrophy.

Acute pyelonephritis.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: The autopsy showed a liver that weighed about 970 gm.; the normal liver in a woman of this age and size weighs about 1500 gm. The liver was mottled yellowish purple, with slightly yellowish-green areas of apparent regeneration. Microscopic examination confirmed the marked atrophy and areas of regeneration. The atrophic regions contained an occasional single liver cell and a few remaining bile ducts. There was a fair amount of regeneration, but very little fibrosis. The process had probably been going on at least three weeks and therefore might perhaps be called subacute yellow atrophy.

The heart was small and perfectly normal. Both kidneys were enlarged and swollen and contained numerous small abscesses, which accounted for the colon-bacillus septicemia and certainly must have been an added burden to a patient with severe liver insufficiency. The biliary tract was normal; there were no stones or dilation of the bile ducts.

DR. WILLIAM B. BREED: What was the sequence in this case? Did the kidney infection and the septicemia precipitate the liver disease? What was the etiology of the acute yellow atrophy?

DR. CASTLEMAN: I cannot explain the sequence in this case. It is believed that catarrhal jaundice and acute yellow atrophy may have the same etiology. Thus, if the patient with jaundice, due perhaps to some infection, gets well it is called catarrhal jaundice; if the patient dies, it is called acute yellow atrophy. Several years ago during an epidemic of catarrhal jaundice in Sweden, the incidence of acute yellow atrophy was also increased.* Most of the cases of acute yellow atrophy that we have seen have been due to drugs, such as arsenamine and cinchophen-containing products.

*Bergstrand, H. *Über die akute und chronische gelbe Leberatrophie mit besonderer Berücksichtigung ihres epidemischen Auftretens in Schweden im Jahre 1927*, 114 pp. Leipzig Georg Thieme, 1930.

In other words the patient had fulminating hepatic failure. This state is typified by acute yellow atrophy but may be simulated by other processes causing rapid destruction of liver tissue, notably suppurative processes. Acute yellow atrophy generally runs a course of about two weeks. It begins with mild intestinal symptoms and perhaps some fever and is thought to be catarrhal jaundice. There may be vomiting. It is interesting that this patient, so far as the record goes, did not suffer from vomiting throughout her illness. I should expect it to have occurred, and I am unable to account for its absence.

After several days in the hospital the picture suddenly became critical. This phase was ushered in by nervous symptoms, and it has been recognized for at least seventy-five years that the dividing line between benign and fatal jaundice—between catarrhal jaundice and acute yellow atrophy—is drawn by nervous or mental symptoms. These symptoms indicate “cholemia,” in other words, hepatic failure. One generally sees in fulminating hepatic failure something that was not present in this patient, namely, a bleeding tendency due to a fall in the prothrombin content of the blood.

The mousy odor to the patient's breath is a subjective observation indicating that hepatic failure was being considered and that the observer thought that he had evidence for it. The patient late in the course of the disease had intermittent fever, as is seen late in hepatic failure.

Concerning the laboratory findings, the maximal cephalin flocculation test gives evidence of hepatic-cell failure. There was a very slight rise in the blood nonprotein nitrogen, which in itself is of no importance. If, when broken down, it showed a rise in the amino nitrogen and a marked fall in urea, that would be evidence of “cholemia.” The plasma showed only a moderate increase in globulin, and a moderate decrease in albumin. This indicates that the process was of relatively short duration—in other words, that it did not supervene after a long course of mild hepatic failure or cirrhosis. This finding, which was made on admission, is commonly seen even in cases of simple catarrhal jaundice.

We ought to consider whether the jaundice was obstructive. I find no mention of the stools except for the observation before the onset of jaundice, when they were said to be light yellow. The phosphatase in true obstructive jaundice with relatively normal hepatic-cell function should be somewhat higher than it was here; I would expect it to go up to 10 or more units. The absence of urobilinogen suggests obstruction,—that is, failure of bile to reach the intestines, where urobilinogen is formed,—but it is well known that in

acute hepatitis the urobilinogen may be absent during the acute stage and recovery heralded by its reappearance. Whether this is due to functional obstruction or to loss of function of the hepatic cells, I do not know, but I shall take the absence of urobilinogen to indicate only that the patient did not have hemolytic jaundice.

There is one secondary diagnosis that I should like to discuss at some length—a suppurative cholangitis presumably secondary to biliary obstruction. We recall that, particularly after the onset of the patient's illness, there was pain. This pain was suggestive of gallstone colic in its sudden, exhausting character. The distribution in both shoulders and the neck is not entirely characteristic of gallstone colic but is consistent with a biliary calculus. Had that pain been not quite so severe it would be easy to say that it was due to an initial swelling of the liver in the early stages of acute hepatitis. The second fact favoring cholangitis is colon-bacillus bacteremia observed on one occasion. This suggests that there was an infection, perhaps of the biliary tract, with that organism. However, it is well known that such a bacteremia may occur in the later stages of any debilitating illness, and it has indeed been mentioned as a common finding in acute yellow atrophy. Against cholangitis is the fact that fever is a prominent feature of this picture only in its late stage; the patient does not have a septic fever during the first three quarters of the illness. The differential count also shows that the neutrophils were relatively low, implying lymphocytosis. This is characteristically seen in catarrhal jaundice, and is not characteristic of a septic process.

It is obvious that Weil's disease was considered and presumably ruled out by the inability to produce disease in guinea pigs; agglutination tests with the patient's serum were not performed. In Weil's disease, as in yellow fever, we should expect more renal damage than this patient exhibited.

Another infectious process that might be considered is endocarditis, especially since the patient was thought to have rheumatic heart disease. It is improbable that endocarditis produced so much damage in the liver with no apparent damage elsewhere. Pylephlebitis entails the same objection as suppurative cholangitis, namely, that the patient was not septic during the greater part of her illness.

If we consider acute yellow atrophy the best diagnosis, we obviously ought to consider the known etiologic factors, such as the toxic effects on the liver of specific poisons. Since she was a housewife, presumably she did not work in a trinitrotoluol factory or was not exposed to other industrial hazards. There is no evidence for any other

ceeding 650,000 for the first time since 1928. More over, the proportion of stillbirths to total births declined in the third quarter of the year to the lowest level on record, and the infant mortality approached the record low level of 50 per 1000 live births established in 1939.

These figures are not compatible with nationwide malnutrition, nor would they be found in a nation facing defeat after more than two years of war. They reflect rather, as the bulletin phrases it, the inspiring resilience of England's people under stress.

In general, despite wartime conditions and air raid casualties, the death rate in England last year was restored to its prewar level. Epidemic meningitis, always a war disease, markedly increased after the outbreak of hostilities, in 1942 its morbidity fell to about half that of 1940-1941, with, of course, under modern methods of treatment, an extremely low mortality rate. Tuberculosis, which had increased sharply in 1940 and 1941, showed a much lower incidence, the improvement being most noticeable among women and children. Deaths from diarrhea and enteritis among infants and young children increased slightly over the rate prevailing in 1941, but the deaths from diphtheria fell off sharply and epidemic respiratory diseases were conspicuous by their absence. Deaths from diabetes dropped,—overeating has not been an outstanding fault in England in the last three years,—and the mortality from peptic ulcer showed a sharp decline, furnishing as fine a bit of evidence as could be found that the emotional stress of recent years has been relieved. The suicide rate was lower, further illustrating the fact that men rarely despair of life when they have a job in hand, and the air raid deaths continued their decline from the dreadful month of September, 1940, when nearly 7000 civilians were killed. Even fatal road accidents, which have been a black mark on the escutcheon, declined 24 per cent last year from the peak of 1941.

These conditions may not continue, and the middle two of the famous horsemen may again ride with their flanking companions, but at least

for the present, it can be said that a superb job of adjustment to war conditions has been done and that thumbs are still up in Merry England.

MEDICAL EPONYM

CUSHING'S DISEASE

Dr Harvey Cushing (1869-1939), professor of surgery at Harvard Medical School, first described this disease in a paper entitled "The Bisophil Adenomas of the Pituitary Body and Their Clinical Manifestations (Pituitary Basophilism)," which appeared in the *Bulletin of the Johns Hopkins Hospital* (50: 137-195, 1932). After discussing 12 cases he concludes

A polyglandular syndrome hitherto supposed to be of corticoadrenal origin characterized in its full-blown state by acute plethoric adiposity, by genital dystrophy, by osteoporosis, by vascular hypertension, and so on, has been found at autopsy in six out of eight instances to be associated with a pituitary adenoma which in the three most carefully studied cases (Cases 6, 7, 10) has been definitely shown to be composed of basophilic elements, the lesion in one instance (Case 7) having been clinically predicted before its postmortem verification.

While there is every reason to concede, therefore, that a disorder of somewhat similar aspect may occur in association with pituitary, with gonadal or with adrenal tumors, the fact that the peculiar polyglandular syndrome, which pains have been taken herein conservatively to describe, may accompany a basophil adenoma in the absence of any apparent alteration in the adrenal cortex other than a possible secondary hyperplasia will give pathologists reason in the future more carefully to scrutinize the anterior pituitary for lesions of similar composition.

R W B

MASSACHUSETTS MEDICAL SOCIETY

STATED MEETING OF THE COUNCIL

A stated meeting of the Council of the Massachusetts Medical Society will be held in John Ware Hall, Boston Medical Library, 8 Fenway, Boston, on Wednesday, October 6, 1943, at 10:00 a.m.

Business

1. Call to order at 10:00 a.m.*
2. Presentation of record of meeting held May 24, 1943 (Published in the *New England Journal of Medicine*, issue of July 8, 1943.)
3. Reports of standing and special committees
4. Appointment of an auditing committee
5. Fill any vacancies in the offices of the Society
6. Such other business as may lawfully come before this meeting

MICHAEL A. TIGHE, MD, Secretary

*It should be noted that the meeting will be called to order at 10:00 a.m. rather than 10:00 a.m.

ADVANCE INFORMATION FOR THE COUNCIL

REPORT OF PROGRESS BY THE POSTWAR LOAN FUND COMMITTEE

The Postwar Loan Fund Committee was organized on June 16, 1943, with fifteen members appointed by the president, Dr. Roger I. Lee.

The second meeting of the committee of the whole was held on Wednesday, August 11, 1943, at 8 Fenway, Boston, at which time the reports of the five subcommittees appointed by the chairman to study certain phases of this problem were read by the chairman of each subcommittee and discussed by all members of the committee of the whole. This is a report of progress of the committee of the whole.

The first subcommittee (Dr. Peirce H. Leavitt, chairman) studied the following questions:

- (1) Amount of loan to be granted.
- (2) Whether or not interest is to be charged.
- (3) Whether or not endorsers will be necessary.
- (4) Length of time the loan may run.

The committee reported that it believes that the amount must, of course, be uncertain, but would depend on two factors: the amount of money raised by the Society and the need of the applicant. The committee expressed the opinion that just enough interest to remind the applicant that he had a loan and to cover the carrying charge should be collected — this interest not to exceed 2 per cent. The committee stated that in its opinion no endorsers should be asked from members of the Society, and further stated that the length of time the loan may run should be within a two-year period. The committee of the whole, after discussing this subcommittee's report, accepted these conclusions.

The second subcommittee (Dr. Walter G. Phippen, chairman) then reported on the questions studied by them:

- (1) Eligibility of persons to borrow money from the fund.
- (2) Whether or not physicians other than members of the Massachusetts Medical Society at the time of entering the armed services should be permitted to borrow from the fund.

The committee reported that it believed that only men who were members of the Massachusetts Medical Society when they entered the armed forces should be permitted to borrow from the fund. None of the members believed that the fund should be open to all physicians in Massachusetts. The committee of the whole discussed this report, and it was approved in principle.

The third subcommittee (Dr. Charles Wilinsky, chairman) considered the question whether the fund should be raised by:

- (1) Increasing dues.
- (2) Assessing members \$10 or more for one year.
- (3) Assessing members \$10 or more over a period of three to five years.

The committee reported as follows:

It is our considered opinion that these funds should be raised not by increasing the dues, but rather by an

annual assessment of \$10 for the duration of the war unless otherwise modified by future action of the Council.

The committee reported that the present by-laws of the Society make provision for such assessments and authorize the Treasurer to collect them. The report of this subcommittee was considered at great length by the committee of the whole, and the report was accepted in principle.

The fourth subcommittee (Dr. Herbert L. Lombard, chairman) reported on how best to inform the members of the Society in the armed forces of the availability of this fund. The committee reported as follows:

We unanimously agree on three points:

Information should be printed in the *New England Journal of Medicine*. There should also appear in a box on the cover of the *Journal* an announcement calling the article on the inside page to the attention of members.

Form letters should be sent to men in the armed services notifying them of this action by the Society.

Form letters should be sent to other members of the Society with the annual bills for dues, stating the availability of these loans.

This report was also accepted in principle by the committee of the whole after considerable discussion.

The fifth subcommittee (Dr. George Leonard Schadt, chairman) made a report on the question concerning the relation of the individual county district societies to the Society in developing and making the Postwar Loan Fund workable. The subcommittee believed that the fund should be administered from the headquarters of the Massachusetts Medical Society, rather than from the district societies, so that no member would be embarrassed in going to his district society and asking for a loan. It was also thought that a member desiring a loan would be more apt to ask for it if it were done through the headquarters of the Society. This question was also discussed at length and agreed to in principle by the committee of the whole.

GEORGE LEONARD SCHAT, *Chairman*

REPORT OF THE COMMITTEE ON PUBLIC RELATIONS

Congress has appropriated funds to provide medical, nursing and hospital maternity and infant care for wives and infants of enlisted men up to the seventh pay grade under plans developed and administered by state health agencies and approved by the chief of the Children's Bureau.

The Committee on Public Relations met in conference with Dr. Vlado A. Getting, state commissioner of public health, who discussed the administration of this plan in Massachusetts. In this state all deliveries will be in a hospital. All deliveries will be by graduates of Grade A schools or by those approved by a technical committee; the latter committee for the most part is identical with the Committee on Maternal Welfare of the Massachusetts Medical Society. Dr. Getting in this connection pointed out that a ruling by the Attorney General of the Commonwealth made it possible for the Department of Public Health to set standards for the care of the patients coming under this provision that are

different from those set by the Board of Registration in Medicine. In other words, the right to practice medicine in Massachusetts does not necessarily give the individual doctor the right to participate in this plan.

The service in Massachusetts will be limited to the wives and offspring of privates and the next three higher grades of enlisted personnel of the Army, Navy and Marines. The application for help, under this plan, must be signed by both the physician and patient.

The plan provides for the payment for consultations with other obstetricians, pediatricians and surgeons. These services are to be paid for without deduction from the sum agreed on in the original plan for obstetric care. The maternity benefit is limited to those who are willing to accept ward care in a hospital. The doctor is to be paid the sum of \$50 for the prenatal, the delivery and ordinary post-partum care. Home visits are to be paid for at the rate of \$5 to \$10 for the first visit and lower fees for subsequent visits.

Hospitals within Metropolitan Boston are to be paid at the rate of \$450 a day, and those outside of this area at the rate of \$350 a day.

Dr Getting asked for the endorsement of this plan in principle only. The Committee on Public Relations endorses the plan in principle.*

Further information on this subject is contained on page 945 of the July 31, 1943, issue of the *Journal of the American Medical Association*.

ALBERT A. HORNER, Secretary

DEATHS

BRENNAN—JOHN J. BRENNAN, M.D., of Worcester died August 26. He was in his eightieth year.

Dr Brennan received his degree from Harvard Medical School in 1886, and later studied in Vienna and London. He was a member of the Massachusetts Medical Society and the American Medical Association and a former member of the State Board of Optometry.

His widow, two sons and a daughter survive.

DAUDELIN—S. ALPHONSE DAUDELIN, M.D., of Worcester, died August 28. He was in his seventy-fourth year.

Born in Sutton, P. Q., Dr Daudelin received his degree from Laval University, Montreal, in 1895. He was one of the original founders of the old Franco-American Dispensary, which was the parent of the former Louis Pasteur Hospital. In 1907, Dr Daudelin was appointed by President Theodore Roosevelt as high commissioner and plenipotentiary from the United States to France for a period of six months covering the Maritime Exposition. The French government awarded him the Cross of Knight of the Legion of Honor, and on the completion of his mission, Dr Daudelin remained in France for advanced study, specializing in eye, ear, nose and throat. He was elected to membership in several important French medical societies, and was named and served as head of the eye and ear clinic at Amiens, France. While in Paris, Dr Daudelin helped found the Comité France-Amérique, an organization that now has branches in all leading cities in this country. He was a member of the Massachusetts Medical Society and the American Medical Association.

His widow survives.

*The Executive Committee at its meeting on August 25, 1943, likewise endorsed the report in principle.

MISCELLANY

NOTE

Dr Harry C. Solomon has recently been appointed professor of psychiatry at Harvard Medical School and medical director of the Boston Psychopathic Hospital. He succeeds the late Dr C. Macfie Campbell.

AWARD TO GENERAL ELECTRIC X-RAY CORPORATION

Robert P. Patterson, Under Secretary of War, has recently announced a second award for excellence of war production to the General Electric X-Ray Corporation, of Chicago. This permits the company to add a white star to its Army-Navy "E" flag, which has flown over the plant since January 26 of this year.

BOOK REVIEWS

A Short History of Cardiology. By James B. Herrick, M.D. 8°, cloth, 258 pp., with 48 plates and frontispiece. Springfield, Illinois: Charles C. Thomas, 1942. \$3.50.

In this interesting resume of the history of cardiology, Herrick first reviews the period from Hippocrates to Harvey, and rightly calls attention to the fact that in the Hippocratic writings, although there is an interesting fragment on the anatomy of the heart, the only consideration of its function is the employment of the pulse in the estimation of fever, whereas the matter of the pathology is scarcely treated, in fact was practically unknown. Aristotle's mistake in attributing to the heart the functions of the brain is well known. Celsus was responsible for the confusion of disease of the heart with that of the cardiac opening of the stomach, the *morbus cardiacus*, which produced so much confusion for so many years.

The great Galen knew the anatomy of the heart, except for his fatal mistake about the pores in the septum, which kept him so far from the true explanation of circulation. Nonetheless, eminent authorities have said that he contributed more to our knowledge of the heart than anyone before Harvey. He proved by experiment that the arteries contained blood and not air, and the acuteness of his observations is shown by his discovery in the embryo of the ductus arterialis and ductus botalli, of which, however, he had no conception of the function. He gave tremendous and even bewildering attention to the pulse, writing sixteen essays on that subject.

The author gives an interesting résumé of progress of knowledge of cardiology during the two hundred years preceding Harvey and rightly calls attention to the influence of important world events, such as the invention of printing and gunpowder, the fall of Constantinople and the discovery of America, on medicine in general and on cardiology in particular.

Leonardo da Vinci's influence on cardiology is adequately treated, and a drawing of his is reproduced that shows even the moderator band of the right heart. The contributions of Vesalius and the martyr Michael Servetus are well described. The next period includes Harvey to Laennec. The author truly says that no abstract of Harvey's work can do it justice. The story of the contributions and controversies of Columbus and Fabricius are well told. Facts about Lower, Mayow and Hales bring out the fascinating story of the gradual growth of knowledge by the scattered contributions of individuals.

Space allows details regarding the progress of

the story of cardiology down to present times; the parts played by all the great contributors are taken up in order and adequately discussed in a masterly fashion. The book throughout is characterized by a broad point of view. It is extremely well illustrated, with portraits of the principal participants in the march of science. The book is fascinating reading, and to him who seeks—and who does not—the history of an important part of medical knowledge, it can be most highly recommended.

Manual of Oxygen Therapy Techniques, including Carbon Dioxide, Helium and Water Vapor. By Albert H. Andrews, Jr., M.D. 12°, cloth, 191 pp., with 33 figures and 16 tables. Chicago: The Year Book Publishers, Incorporated, 1943. \$1.75.

This is a technical handbook rather than a medical textbook on gas therapy. Accordingly, only a little over four pages are given to the medical aspect of this subject. In the chapter entitled "Physiology of Respiration and Rationale of Inhalation Therapy," the author manages to clarify the mechanism of respiration in terms of ventilation, the transportation and absorption of oxygen, and the elimination of carbon dioxide. From an adequate oxygen supply, which is derived from normal breathing, the author passes over to the abnormal condition in which anoxia or "oxygen want" occurs. To relieve this oxygen deficiency, he suggests the use of gas therapy, employing oxygen, carbon dioxide, helium and water vapor.

The rest of the book is strictly technical and is therefore crowded with details, tables and figures. These relate to the purchase and maintenance of equipment from the standpoint of economy and efficiency, as well as the indications for use, the technic of application and the necessary precautions. In addition to the usual procedures, the author pays attention to certain exceptional cases. Thus, he gives specific instructions for this form of treatment when it is administered to infants in incubators or when it is to be carried out in the home, where hospital facilities are lacking.

The reviewer is not aware of the existence of an oversupply of texts on this subject. He is therefore of the opinion that this manual will prove to be a useful guide to those of the medical profession who are called on to administer gas therapy.

The Principles and Practice of Medicine: Originally written by Sir William Osler. By Henry A. Christian, M.D., LL.D., Sc.D. (hon.), F.R.C.P. (Can.). Fourteenth semi-centennial edition. 4°, cloth, 1475 pp. New York: D. Appleton-Century Company, Incorporated, 1942. \$9.50.

There is something appealing about meeting a book that is fifty years old and still young, that has gone through fourteen editions, each one successful, and that has kept alive a tradition of good medical writing through the hands of three different authors.

The fourteenth edition of Osler looks not unlike the first: the reviewer's copy of the first edition happens to be bound in green whereas the fourteenth is in red. But the two books can stand side by side companionably, as should all medical fathers and sons, the older book perhaps still able to show the younger something in the way of literary style. Youth in return now adds to the parent volume a full half century of new ideas, customs and medical knowledge.

When Dr. Christian took over the task of editing the

thirteenth edition of Osler he did this with a sympathetic understanding of what Osler had in mind. This edition appeared in 1938 and was at once well received by the medical reading public. That it was successful is proved by the fact that a new edition has been forthcoming so quickly.

The fourteenth edition begins with a chapter on functional diseases of the nervous system, an arrangement that might have made Dr. Osler smile. The book continues to be a complete handbook of internal medicine, up to date in every particular and continuing to have what, to the reviewer at least, is a particular charm—the even character of writing that can be found only in a one-man book. Each chapter has now appended a select group of references to important literature. Tropical diseases are discussed in a way that will appeal to all medical officers. On the whole, any student or practicing physician brought up with an admiration for Osler will feel that this textbook is still the proper one to use.

Clinical Anesthesia: A manual of clinical anesthesiology. By John S. Lundy, M.D. 8°, cloth, 771 pp., with 266 illustrations. Philadelphia and London: W. B. Saunders Company, 1942. \$9.00.

Dr. Lundy has contributed his wide experiences of over twenty-five years in the practice of anesthesia. They are mostly personal expressions gained at the Mayo Clinic. There is much controversial material in the book; however, the author is frank and honest in his statements, which are fortified by an experience probably unequalled by any anesthetist in the country.

Dr. Lundy deserves much credit for pioneering in the field of anesthesia, having established the use of many of the newer drugs and technics, and many of the procedures described in his book were originated by him. In the opinion of the reviewer, reference to the works and technics of contemporaries and mention of the variety of apparatus and equipment in universal use, together with more illustrations, would have given the reader a broader knowledge of modern anesthesia.

The book opens rather abruptly with the choice of anesthetic agents and methods. If the reader were introduced to the basic fundamentals of anesthesia and if the development of the subject matter followed in chronological sequence, it seems that a clear picture of anesthesia as a whole would be presented. The tabulation of anesthetic agents and methods according to the various surgical procedures is unique; comments in the text are referred to by interrogation points on the charts.

The following chapter, covering the use of local anesthetic agents, is well written and extremely valuable. It is the high light of the book for reference by anesthesiologists and surgeons.

The chapter on spinal anesthesia relates the author's personal experiences but does not enlighten the reader concerning the many advances made with agents other than procaine. More emphasis on this subject would have aided the reader. The author's opinions on complications and dosages are stressed.

The chapter on equipment and drugs is extremely well written with many suggestions of value.

The next seven chapters consider general anesthesia, the stages and signs of general anesthesia, preoperative and postoperative care, the agents employed for general anesthesia and the gaseous agents used for the support of respiratory function. It seems as though more refer-

ence could have been given to the technic of carbon dioxide absorption, which has revolutionized the administration of inhalation agents

Endotracheal or intratracheal anesthesia is well described as well as its many complications

The chapter on general anesthesia in dentistry and obstetrics barely covers two important fields of surgery that have been sadly neglected

The chapter on intravenous anesthesia is excellent, as might be expected, since the author has been responsible for pioneer work in this field. The methods of rectal and oral intubation rate the few pages consistent with their position in anesthesia. Balanced anesthesia, a term coined by the author, is mentioned in a two paragraph chapter

The chapter on anesthesia for nonsurgical conditions demonstrates the mastery of the author in diagnostic, prognostic and therapeutic nerve blocks, procedures concerning which most physicians are relatively ignorant

The remaining chapters and the appendix cover venipuncture, intravenous therapy, resuscitation, records, the anesthetic statistics of the Mayo Clinic from 1924 to 1940 and the chemistry of analgesics and anesthetics, as well as a chronological table of anesthesiology and allied subjects and conversion tables of weights and measures

This book is well worth reading for reference to the experiences, impressions, and recollections of a pioneer physician and master in modern anesthesia

Diseases of the Liver, Gallbladder and Bile Ducts. By S S Lichtman, MD. 8°, cloth, 906 pp, with 122 illustrations and 1 colored plate. Philadelphia: Lea and Febiger, 1942. \$11.00

This book is a great storehouse of facts and opinions about the liver and its diseases. Its value is increased by a long list of well-chosen references at the end of each chapter. The material is so varied and extensive that it is hard to single out special chapters for review.

The book is well arranged starting with 100 pages on the structure and physiology of the liver, followed by about 50 pages on liver poisons, nutrition, diet in protection and damage to the liver, the role of vitamins and the mechanism of jaundice. In discussing jaundice only Rich's classification into retention and regurgitation types is described. From the reviewer's point of view, McNee's classification of external obstructive, hepatocellular and hemolytic jaundice seems more useful.

About 50 pages are given to the symptomatology of diseases of the liver. The section is well arranged although the description of the various symptoms and signs is somewhat uneven in quality. Regarding the spleen the practicing physician is probably more interested in the percentage that are palpable than that of those weighing more than 300 or 600 gm at necropsy.

About 95 pages are devoted to a description of laboratory and liver function tests, all of which is valuable for reference. Many of the fifty tests described are little used now and have only a historical interest. The inclusion of so many tests is possibly confusing to the practitioner.

Then follow about 400 pages covering specific diseases of the liver. The author's classification of seven types of catarrhal jaundice seems rather elaborate in a disease in which necropsy is rare and their separation into two groups—with and without initial gastrointestinal symp-

tons—appears to be somewhat artificial. Cirrhosis of the liver is given an especially complete description. To list ten types of cirrhosis on one page is rather confusing but this disease is described under the familiar headings—portal bilirubin and pigment cirrhoses and Bant's disease. In the jaundice of hepatocellular disease (catarrhal jaundice, toxic hepatitis, cirrhoses and so forth), the author seems to overemphasize the mechanical factor of obstruction within the liver and to minimize the poor excretion of bilirubin by the damaged lobular cells. The chapter on the hepatorenal syndrome does not help much in clarifying this difficult subject. The figures for the incidence of syphilis of the liver date back to a generation or two ago, when the diagnosis and treatment of syphilis were very different from what they are at present, it is now a relatively rare disease in the ward or at necropsy. The incidences of the common types of jaundice, differential diagnosis and diagnostic errors are given careful consideration.

In addition to the paragraphs on treatment under the various diseases, a 25 page chapter is given to the treatment of liver disease in general. This is sound and up to date but might well be enlarged at the expense of the many pages on laboratory procedures.

The last 110 pages are devoted to diseases of the gall bladder and biliary passages.

The author has drawn liberally on the best literature for facts, opinions, tables and illustrations. The paper, type and illustrations are excellent, as are many of the photomicrographs.

Nasal Medication. A practical guide. By Noah D Fabrikant, MD. 8°, cloth, 122 pp with 20 illustrations. Baltimore: The Williams & Wilkins Company, 1942. \$7.50

This book is a practical guide not only for the specialist in rhinology but also for the general practitioner and pediatrician. The author is associate in rhinology, rhinology and otology at the University of Illinois College of Medicine. He has devoted considerable time to research in the physiology of the nasal mucous membranes and in the pharmacologic action of the common drugs used in nasal medication. The book includes a brief section covering the anatomy of the nasal cavity and the paranasal sinuses, including both gross anatomy and histology. He also discusses histopathology and nasal physiology. In the latter subject the biochemistry of the nasal secretions is discussed and the hydrogen ion concentration of these secretions is described in considerable detail. The significance of the latter has only recently been recognized and the author is one of the most enthusiastic contributors to this newer conception of nasal physiology. A great deal of emphasis is laid on the effect of drugs on ciliary action, it being considered particularly harmful to destroy or inhibit this action which is of tremendous importance in keeping the nasal mucous membrane free of foreign particles.

Contrary to common belief menthol, eucalyptol and eucalyptol seem to have no beneficial effect in opening the nasal passages. In fact menthol in some experiments has seemed to produce a narrowing of the nasal passages and an increase in the resistance to the stream of air passing through the nose. The cooling action of menthol has probably caused patients to believe that there was a clearing of the airway. The author adds: Definite destructive changes throughout all layers of mucous membrane are produced by a 5 per cent solution of menthol.

Ephedrine hydrochloride seemed to produce little if any change in the tissue, whereas epinephrine hydrochloride in dilutions of 1:1000 used over a long period of time caused considerable damage to the tissues.

It is recommended that, if aqueous solutions are used, they should be isotonic. There is a discussion of the use of oils as sprays or drops, including the possible complication of lipid pneumonia. A great deal has been written by many authors on the latter subject. This author summarizes the pros and cons. He quotes Wishart, who points out that there are really very few cases of lipid pneumonia when one considers the large amount of oil inhaled by an enormous number of people.

There are short discussions on the use of silver nitrate, zinc ionization, sodium sulfathiazole and Mercurochrome.

Finally, there is a complete description of methods of applying nasal medication. These include the displacement method of Proetz, the lateral-head low-posture method, Beck posture, nasal tampons, sprays, cotton applicators, inhalers, jellies and emulsions, irrigations and even snuffs. Irrigation of the sinuses is also discussed, and at the end there is a chapter on nasal medication in disease.

The book is clearly written. It is not too technical and is well documented. It gives a fair discussion of many controversial subjects. Its greatest value is a real attempt to place nasal medication on a scientific basis.

The Electron Microscope. By E. F. Burton, Ph.D., head of the Department of Physics and director of the McLennan Laboratory, University of Toronto; and W. H. Kohl, development engineer, Rogers Radio Tubes, Limited, Toronto. 8°, cloth, 233 pp., with 144 illustrations. New York: Reinhold Publishing Corporation, 1942. \$3.85.

No library should be without this extremely valuable book. The electron microscope is destined to play an increasingly important part in the newer experimental techniques that are to be applied in the field of biology, of which medicine is integral. The authors are to be congratulated on the readable style of their book. There are many instructive diagrams and plates, and a useful general bibliography is appended.

Contribucion al estudio anatomico clinico de las afecciones del endocardio. A doctorate thesis (Universidad Nacional de Buenos Aires, Facultad de Ciencias Medicas, No. 5636) by Manuel Perea Muñoz. 4°, paper, 363 pp., with 92 illustrations. Buenos Aires: "Esmeralda," 1942.

This thesis is simultaneously a brief review of the literature on endocarditis and an analysis of 206 cases of abnormalities of the endocardium in a series of 1000 autopsied cases studied since 1936 in the Laboratory of Pathological Anatomy, Ramos Mejia Hospital, Buenos Aires. Among these cases, there were 64 with valvular disease.

The twenty-five chapters in the book take up the classification of endocarditis and discuss acute and subacute bacterial endocarditis, syphilitic involvement of the endocardium, rheumatic endocarditis, "benign" endocarditis, endocardial atheroma and calcification, neoplastic disease and malformations, along with valvular defects.

The author's 206 cases are summarized under the headings of the various chapters. Of 44 cases of bacterial endocarditis, 15 are said to have been the result of sepsis, 4 are labeled terminal, 5 acute bacterial, and 20 subacute

bacterial. Fifty-four cases on a rheumatic basis are also summarized, 36 in men and 18 in women. Thirteen cases of syphilitic involvement of the endocardium are included, as well as 41 cases of atheroma of the endocardium and 27 of valvular sclerosis. A few congenital defects are also added, but they can hardly be classed as true endocardial disease.

The volume presents detailed studies of this rather small group of cases, but the lesions are so varied and the cases in the different categories are so few that statistically the volume is of little importance and it seems larger than necessary for presentation of these data. The chief value of the book lies in the individual case reports, which are worthy of perusal. The volume is well printed and the illustrations are good. There is a short bibliography.

Effects of Alcohol on the Individual: A critical exposition of present knowledge. Volume 1. *Alcohol Addiction and Chronic Alcoholism.* Edited on behalf of the Scientific Committee of the Research Council on Problems of Alcohol by E. M. Jellinek, Sc.D. 8°, cloth, 336 pp., with 43 tables and 5 figures. New Haven: Yale University Press, 1942. \$4.00.

The Research Council on Problems of Alcohol, a recent organization, has been extremely active. Under the chairmanship of Dr. Karl M. Bowman, and with a board of men, most interested in this problem, it has fostered research and issued an excellent journal, *The Quarterly Journal of Studies on Alcohol*, from the Laboratory of Applied Physiology, Yale University.

This book is a survey of the general problems with extensive bibliographies. The book is divided into sections on alcoholic addiction, mental disorders associated with alcoholism, studies on vitamin deficiencies, the encephalopathies, cirrhosis of the liver and Marchiafava's disease. In these finely written chapters, one has at hand an up-to-date account of each subject, thoroughly documented, with the literature carefully analyzed. Much of this literature, incidentally, was collected by Dr. Merrill Moore, under the direction of the Works Progress Administration.

The book can be highly recommended as a comprehensive review of the subject, as a reference work and as a basis for studies on an acute problem, particularly important in wartime.

Surgical Physiology. By Joseph Nash, M.D. 4°, cloth, 496 pp., with 16 illustrations. Springfield, Illinois: Charles C Thomas, 1942. \$4.00.

This book is based on lectures given by the author at New York University College of Medicine as part of a graduate course in surgery. As indicated by the title, aspects of physiology that are of especial importance in surgery have been emphasized. The text is written in a clear, concise manner. The book is divided into seven sections dealing with the following subjects: the circulatory system, the respiratory system, the alimentary system, the body fluids, the endocrine glands, the cerebrospinal nervous system and the autonomic nervous system. There is an excellent list of references dealing essentially with the more recent contributions of physiology to surgery.

This book should make a strong appeal to the practicing surgeon and to the postgraduate student.

ENDEMIC ROCKY MOUNTAIN SPOTTED FEVER IN MASSACHUSETTS

A DANIEL RUBENSTEIN, MD,* AND HAROLD F. ROWLEY, MD†

BOSTON AND HYANNIS, MASSACHUSETTS

ALTHOUGH Rocky Mountain spotted fever has been reported from all geographical regions in the United States,¹ it was not recognized in New England prior to 1937, when 2 cases were discovered in Rhode Island² and 1 in Massachusetts.³ From that time until 1942 at the end of the so-called "tick season" 8 cases were reported from four of the six New England states: Massachusetts, 4; Rhode Island, 2; Connecticut, 1; and New Hampshire, 1. The source of infection of 3 of these cases was found to be in regions outside of New England. The 5 remaining cases originated in Massachusetts, which is apparently the sole New England state where the disease is endemic.

All 5 Massachusetts infections were acquired on Cape Cod. Four cases were attributed to three contiguous communities comprising an area of fifty-nine square miles. It must be borne in mind that all endemic Massachusetts cases occurred during the three-year interval from 1937 to 1939, and that this disease has not reappeared on Cape Cod since 1939.

The distribution according to the month of onset of the Massachusetts cases was as follows: May, 1; June, 1; July, 3. The dog tick, *Dermacentor variabilis*, which is the vector of this disease in the East, becomes most plentiful during the latter part of May or early in June, and declines sharply after mid-July.⁴ There is usually a lag of several weeks between the time of maximum abundance of ticks and the peak in case incidence.

Of the 5 cases endemic in Massachusetts, 3 have been reported previously.^{2,3} This paper will include a discussion of the two remaining cases. From one of these the causative virus was recovered⁵ and has been maintained by serial passage in guinea pigs. The isolation of this virus has

presented the only opportunity to study the endemic agent responsible for Rocky Mountain spotted fever in Massachusetts.

CASE REPORTS

CASE 1: R. E., a 4-year-old boy, was admitted to the Children's Hospital on June 5, 1939, with complaints of difficulty in walking and fever of 1 week's duration. He came from Cape Cod, where he had been bitten by several ticks during the 3 weeks before admission. He had been well until 1 month before admission, when he developed a limp for which a local physician could find no explanation. Nine days before entry, he became irritable and the temperature was found to be elevated. He complained of severe headache and joint pains so severe that he was unable to stand. Two days later a rash appeared, beginning on the wrists and ankles and spreading to the trunk, neck and face. The temperature remained elevated throughout the week before admission.

On admission the temperature was 101.2°F, the pulse 100, and the respirations 20. There was moderate generalized adenopathy. Although limitation of motion was noted in the shoulders, wrists, fingers and ankles, no outward changes could be detected. There was a generalized maculopapular eruption (Figs. 1 and 2). The lesions were discrete and measured from 2 to 3 mm. in diameter; they were present on the head, neck, trunk and extremities, including the palms and soles. The remainder of the physical examination revealed no other abnormality.

Urinalysis was essentially negative. The red-cell count was 3,600,000, and the hemoglobin 90 per cent (Sahli). The white-cell counts ranged from 20,000 on admission to 8600 on June 14. Blood smears were normal. Lumbar puncture on June 6 showed no abnormal findings. Tuberculin tests on June 6 and June 8 were negative. A blood culture taken on June 5 was negative. A blood Hinton test on June 5 was negative. A Weil-Felix reaction on June 5 was positive in a dilution of 1:5120. Electrocardiograms on June 7 and 14 were not remarkable. Chest plates on June 5 and 7 showed slight peribronchial congestion.

The patient was drowsy and apathetic during the first 2 days. The temperature remained elevated during this time and became normal on the 3rd hospital day.

*We are indebted to Drs. R. Hart M. Smith and John A. V. Nave of the Children's Hospital for permission to publish this case report.

*State Director of Health, Office of Communicable Diseases, Massachusetts Department of Public Health.

†Member, Medical Service, Cape Cod Hospital, Hyannis, Massachusetts.

though it rose to just above 100°F . on one or two occasions thereafter. The pulse averaged 120 for several days. The rash gradually disappeared and had faded completely

vere frontal headache, which persisted for several days. There was gradually increasing restlessness, irritability and a whimpering cry at night. On the 4th day of the

FIGURE 1. Case 1.

at the end of a week. Recovery was uneventful, and the joint complaints had disappeared completely at the time of discharge.

CASE 2. M. E. S., an 8-year-old girl residing in Dennis, Massachusetts, was admitted to the Cape Cod Hospital in Hyannis on June 12, 1938, with complaints of headache, fever and malaise. She had been well until 5 days previous to admission, when she began to complain of se-

illness, a macular eruption appeared on the buttocks and spread to the arms, legs and face. The temperature during the first 5 days of the illness varied between 99 and 105°F . At times the patient was irrational. The past history was not contributory; there had been the usual childhood diseases. Seven siblings and the parents were living and well.

On admission the temperature was 100.8°F ., and the pulse 120. Physical examination revealed a well nourished

child lying apathetically in bed. The face was dusky. Except for an eruption on the skin, the examination was negative. Maculopapular lesions were generally distributed over the face, forearms, both buttocks and the labia majora. These lesions were discrete in some areas and confluent in others, and faded on pressure.

FIGURE 2 Case 1

This photograph shows the eruption on the soles of the feet

Urinalysis showed varying degrees of albuminuria from June 12 to July 12. The red-cell count, which was 4,500,000 on admission, gradually dropped to 2,600,000 on July 6. Hemoglobin determinations ranged from normal levels at admission to 45 per cent (Sahli) early in July. The white-cell count rose from 7200 on June 12 to 23,000 on June 16. During the subsequent months it fell slowly to about 12,800. Differential counts were not unusual except for a moderate increase in polymorphonuclear leukocytes to about 85 per cent during the first 10 days of the illness. A blood culture taken on June 21 was negative. A lumbar puncture on August 1 revealed a clear fluid, no increase in pressure and a total cell count of 34 lymphocytes. The blood chemical findings were normal. A lumbar puncture on September 2 showed no abnormalities. Electrocardiograms were reported as follows: June 26, PR interval of 0.16 second, July 26, sinoauricular tachycardia and a PR interval of 0.20 second, October 12, PR interval of 0.16 second and a high take off of the ST interval in Leads 1 and 2. The serologic studies* were as follows: The Weil-Felix reaction was positive in dilutions of 1:320 on June 15, of 1:640 on June 22 and of 1:320 on July 4. On June 22, the agglutination reaction with a rickettsial antigen was positive in a dilution of 1:640, and on February 15, 1943, a complement fixation test for Rocky Mountain spotted

fever was positive in a dilution of 1:128 and one for endemic typhus was negative. On June 15, 1938, 3 cc of blood was inoculated at the bedside into two guinea pigs. The infectious agent was isolated from each animal.

The rash noted on admission gradually faded and was replaced on the 8th day of the illness by a generalized petechial eruption somewhat accentuated on the wrists, ankles and upper back. There were few lesions on the face and the anterior aspect of the trunk. On June 17, a nonpitting edema was noted on the face, eyelids and feet. The rash, which had been bright pink, assumed a darker hue. In some areas where the eruption appeared to be most hemorrhagic the lesions coalesced to form large purplish blotches. These were most prominent over the wrists and feet. Three days later the rash became more extensive as a fresh crop of petechiae appeared.

The irritability noted on admission persisted. Although stuporous at times, the patient could be aroused to respond to questions. She gradually lapsed into coma. There was evidence of increasing involvement of the central nervous system. The pupils became dilated and did not react to light. There was slight weakness of the left side of the face. Control of the vesical and anal sphincters was lost. From day to day there was considerable variation in the neurological signs. Having lost the ability to take food by mouth, the patient was fed by gavage, and this had to be continued until October 16. She remained comatose for about 3 months. During this period no voluntary muscular movements could be detected. On August 6, the patient began having numerous attacks of opisthotonos lasting from a few minutes to several hours. These attacks recurred for 3 weeks. During the latter part of September movements of the fingers and arms were first noted. Feeding by stomach tube was discontinued as the swallowing reflexes were restored. Mental recovery was slow. On October 27, the patient spoke for the first time in 4 months. At discharge on December 7, she was alert mentally, although she still spoke in a whisper.

Beginning June 22, extensive sloughing of the skin was noted. This continued until a considerable proportion of the body integument was involved, including the skin of the left leg, left mid thigh, both knees and the extensor surface of the upper and lower thirds of the right thigh. These areas healed quite slowly and were eventually the sites of extensive scar tissue formation.

On July 29, the course was further complicated by intermittent attacks of acute pulmonary edema. During these episodes the pulse became rapid, and auscultation revealed coarse rales throughout both lung fields.

During the early part of the illness the temperature and pulse were markedly elevated, the temperature on June 24 having been recorded as 106°F (axillary). Fever of considerable degree persisted until late in September, a period of 3 months. From October to November it varied from 99° to 101°F and it gradually became normal late in November. The pulse level corresponded in general with that of the temperature. The total duration of elevated temperature was 5½ months.

Shortly after discharge, the patient was able to stand alone for the first time in several months. As mental improvement continued, she was soon able to read and write. She was readmitted in August, 1939, because of difficulty in walking owing to contracting scar tissue in the region of the sacrum and both thighs. There was marked

*The agglutination tests were performed by Florence K. Fitzpatrick, Ph.D., of Sharp and Dohme Incorporated, Clendinning, Pennsylvania, and the complement fixations on tests by Dr. I. A. Bengtson of the United States Public Health Service.

relief following plastic surgery of the skin. In 1942, the patient's mentality had been completely restored.

Bacteriologic data. The infectious agent was recovered by intraperitoneal inoculation of guinea pigs with blood from the patient taken on the 8th day of the illness. In subsequent studies, the incubation period of the disease in the guinea pig was about 5 days.⁶ The agent was apparently not exceedingly virulent for guinea pigs, since there were no fatalities among any of the inoculated animals. Although all the guinea pigs reacted to the injection of the agent by showing elevation of temperature, only 30 per cent of them showed noticeable scrotal swelling. All the animals that recovered were found to be solidly immune when reinoculated with a virulent strain of Rocky Mountain spotted fever. The isolated agent was effectively neutralized by convalescent serum obtained from the patient. Animals already immune to Rocky Mountain spotted fever did not react to inoculation with the agent.

Convalescent serum obtained 4½ years after onset of the disease in 0.5-cc. and 0.25-cc. amounts neutralized completely a Bitter Root Valley strain of Rocky Mountain spotted fever virus.⁷ Control animals receiving the same virus together with normal human serum died of the disease.

DISCUSSION

Since 1931, when the identification of Rocky Mountain spotted fever in the eastern part of the United States⁸ led to the discovery of numerous cases in that region, it had been held that this disease was more fatal in the West than in the East. Laboratory data supported this idea for several years. Strains isolated in the West were more virulent for guinea pigs than were those recovered in the East. During 1940, however, Topping and Dyer⁹ were successful in isolating from a patient in Washington, D. C., a highly virulent strain of Rocky Mountain spotted fever virus that had many characteristics of the most virulent strains obtained from Bitter Root Valley, Montana. According to the reactions of this virus in guinea pigs,—that is, the duration of the incubation period, the ability to produce fatal disease, and the scrotal lesions,—the Washington strain was highly virulent. Furthermore, in 1941 a strain of low virulence was recovered from a case in Wyoming.¹⁰ Statistical studies had already shown that when fatality rates of Eastern and Western cases were arranged according to comparable age groups, apparent differences between them vanished.¹¹ Hence, the terms "Eastern" and "Western" when applied to Rocky Mountain spotted fever had lost their former significance.

The strain isolated in Massachusetts, when judged by the usual criteria, was of low virulence. However, the clinical course of the patient from whom the virus was isolated was by no means mild. Actually this case presented clinical findings ordinarily associated with the severest type of infection. Marked involvement of the central

nervous system with coma, opisthotonos, muscle tremors and severe cutaneous manifestations, such as a confluent hemorrhagic eruption followed by necrosis and sloughing, is found in most fulminating cases.¹² The patient in Case 2 showed all these findings. Moreover, the prolonged hyperpyrexia and severe mental disturbance offer additional evidence of an exceedingly severe infection.

Rumreich, Dyer, and Badger¹³ in 1931 observed that disturbances of the central nervous system in Rocky Mountain spotted fever are often severe. Wolbach,¹⁴ discussing the pathology of this disease, described focal brain lesions often associated with thrombosis of small blood vessels and necrosis. Hassin¹⁵ described a fatal case in an eleven-year-old girl who, in addition to coma and a confluent hemorrhagic rash, presented signs of meningeal irritation including rigidity of the neck, a positive Kernig sign and a count of 10 cells in the spinal fluid. The histopathology at post-mortem examination was described as a nonsuppurative meningoencephalitis. Although spinal-fluid findings in cases of Rocky Mountain spotted fever are usually within normal limits, pleocytosis is occasionally noted. Carey¹⁶ in 1939 reported 2 cases with spinal-fluid counts of 24 and 224 cells, respectively; the smear in the second case revealed 12 per cent polymorphonuclear leukocytes and 88 per cent lymphocytes. A third case presented xanthochromic fluid. Apparently central-nervous-system manifestations of Rocky Mountain spotted fever are at times an integral part of the clinical picture.

Patients may exhibit varying degrees of edema. As in Case 2, this occurs during the acute stage of the illness. Parker¹⁷ observed that albuminuria is frequently encountered and that complete urinary retention may occur. Ong and Raffetto¹⁸ analyzed 18 cases in children and noted edema in 4 of them. In 2 cases the edema was generally distributed, and in the other 2 it was local, affecting the hands and feet in one patient and the face and feet in the other. The exact cause of this edema, which is usually nonpitting, has not been established. One might postulate a marked reduction in serum protein as a possible explanation. No studies concerning this aspect of the disease could be discovered in the literature.

The early diagnosis of Rocky Mountain spotted fever depends primarily on the evaluation of the available clinical data. Unfortunately, all serologic tests are negative during the first week of the disease. It was recently stated that the Russians have developed a method by which typhus fever can be diagnosed on the second or third day.¹⁹ No details concerning this test have as yet been revealed. Isolation of the Rocky Mountain spotted fever virus must be performed early in the disease before lysis has occurred. This proce-

dures, however, is lengthy, and there is considerable delay before the etiologic agent is definitely identified. The Weil-Felix reaction, using various strains of the genus *Proteus*, has been useful in the diagnosis of rickettsial disease after the first week of illness. This test, however, does not distinguish between typhus fever and Rocky Mountain spotted fever. Epstein²⁰ in 1922 and Zinsser and Castañeda²¹ in 1932 showed that convalescent serums agglutinate rickettsial antigens. Fitzpatrick and Hampil²² observed that in infected rabbits the development of rickettsial agglutinins precedes that of *Proteus* agglutinins. Recently Bengtson and Topping²³ demonstrated the value of the complement-fixation test in the diagnosis of rickettsial infections. They suggested that this test can be used in the differential diagnosis of Rocky Mountain spotted fever and typhus fever. In cases of typhus fever significant titers are obtained by this test on the ninth and tenth days after onset. The reaction remains positive for many years after recovery. Thus, in Case 2 a positive complement-fixation test for Rocky Mountain spotted fever in a dilution of 1:128 was obtained four and a half years after onset. The complement-fixation test for typhus fever was negative.

The only laboratory confirmation of the diagnosis of Rocky Mountain spotted fever in Case 1 was the Weil-Felix reaction. However, the history of several tick bites, the clinical picture and the positive agglutination reaction leave little doubt concerning the diagnosis.

Recently Topping²⁴ found that monkeys and guinea pigs survived experimental inoculation with the virus of Rocky Mountain spotted fever following the administration of a hyperimmune rabbit serum. Tissues of infected ticks were used as the antigen in the preparation of this serum. Kurotchkin, von der Scheer and Wyckoff²⁵ then showed that an effective serum results from injecting rabbits with rickettsiae cultivated in the yolk sac according to the method of Cox.²⁶ Newer methods used in the cultivation of rickettsiae have facilitated considerably the development of rickettsial vaccines and therapeutic serums.^{6, 26, 27} The successful use of serum in the treatment of experimentally infected animals has suggested its application to human cases of Rocky Mountain spotted fever. Such a therapeutic serum is now available commercially.* It is to be expected that this form of treatment should be most effective early in the course of the disease, before the serologic tests become positive. Hence, familiarity with the clinical signs and symptoms of Rocky Mountain spotted fever is important.

A prophylactic vaccine made from the tissues

of infected adult wood ticks (*D. andersoni*) has been available for many years.²⁸ Field studies performed in the West with this killed vaccine have demonstrated that it has definite immunizing value. In 1937, Bengtson²⁹ reported protection against infectious doses of the Rocky Mountain spotted fever virus in guinea pigs previously immunized by a formalized rickettsial antigen prepared from infected guinea-pig tissues grown in tissue culture. Cox,³⁰ in 1939, demonstrated the protective value for guinea pigs of vaccine prepared from rickettsiae cultivated in embryonic chick tissue. In Massachusetts the risk of acquiring Rocky Mountain spotted fever, even in the endemic area, is so small that routine prophylactic inoculation is scarcely justifiable.

The possibility of the future occurrence of Rocky Mountain spotted fever in Massachusetts merits careful consideration. At first glance some reassurance may be derived from the failure of any new cases of Massachusetts origin to appear since 1939. In 1935, Parker,³¹ however, called attention to the tendency of this disease to occur in cycles. Hence, in some local endemic areas in the West, intervals between cases were sometimes quite prolonged. In one county the disease disappeared for nine consecutive years only to reappear. This phenomenon is particularly likely to occur in regions similar to the endemic area in Massachusetts, where Rocky Mountain spotted fever exists in a localized region.

It is odd that Massachusetts remained free of this disease until 1937. Although the clinical manifestations of Rocky Mountain spotted fever are striking, experience in other states has demonstrated that the disease frequently goes unrecognized.¹³ It is now well known that prior to 1931 these cases were often labeled "endemic typhus." Investigation of the records of the Massachusetts Department of Public Health did not, however, bring to light any similar confusion. Observations in the West have shown that the virus of Rocky Mountain spotted fever can exist for many years in the ticks of a given area without the occurrence of the disease in man.³² Later, owing to some factor as yet unknown, the disease suddenly makes its appearance.

Although thousands of persons are exposed to ticks each spring and summer throughout Cape Cod and its adjoining islands, the paucity of cases of Rocky Mountain spotted fever indicates that the proportion of infected ticks is small. Of the three species of ticks concerned in the natural transmission of the disease, two varieties are present on the Cape; namely, the dog tick (*D. variabilis*) and the rabbit tick (*Haemaphysalis leporis-palustris*). Surveys conducted in 1938 showed that

*Manufactured by the Lederle Laboratories, Incorporated, Pearl River, New York.

although the dog tick is found throughout the New England states, it is most plentiful on Cape Cod and the islands of Martha's Vineyard, Nantucket and Naushon.⁴ In the East, only the dog tick causes the transmission of the disease to human beings. The rabbit tick, which does not bite man, is important in the maintenance of the virus in nature and is only indirectly involved in the occurrence of the disease in man.⁵

There are several factors that help to maintain and propagate the virus in nature. Experimental work with *D. andersoni* has demonstrated that the infectious agent, once acquired by the immature forms of the tick, is passed on to the adult stage.³³ The agent is also transmissible through the ova of infected females. Furthermore, when infected immature or adult forms of the tick feed on a susceptible host, this host becomes infected, and other ticks that feed on this host during the infectious stage may acquire the virus.¹⁷ Studies with *D. variabilis* have suggested a similar method of transmission.³⁴

It might be argued that the endemicity of Rocky Mountain spotted fever in Massachusetts is a temporary and perhaps accidental occurrence rather than a natural phenomenon, and that the virus was brought into this area by infected ticks on dogs, these ticks in turn transmitting the virus to native Massachusetts ticks. Another possible avenue of introduction is by means of the rabbit tick. For many years rabbits have been imported into the Cape for hunting purposes. Parker³⁵ has postulated that in the West the virus of Rocky Mountain spotted fever passes from infected rabbit ticks to previously uninfected wood ticks through the rabbit, a host common to both species. Although the adult dog tick is rarely found on the rabbit, the accession catalogue of the United States Bureau of Entomology and Plant Quarantine, reveals that the immature forms are more frequent on the rabbit.⁴ A similar mechanism may be assumed in the East. On the other hand, the simultaneous appearance of Rocky Mountain spotted fever throughout widespread areas in the East suggests long-standing endemicity rather than a gradual spread from one region to another. Nevertheless, the situation in Massachusetts, where relatively few cases have been discovered, may not be entirely analogous to that in other Eastern areas where the disease is more prevalent. No matter how the virus was introduced into Massachusetts, the occurrence of future cases is not a remote possibility. A marked increase in prevalence is, however, extremely unlikely. An awareness of this disease on the part of physicians may disclose additional cases.

SUMMARY

Eight cases of Rocky Mountain spotted fever have been reported from four New England states from 1937 to 1942. Five of these cases had their origin in Massachusetts during the three-year period of 1937 to 1939. The total endemic area in Massachusetts comprises only fifty-nine square miles.

Two cases of Rocky Mountain spotted fever are presented. From one of these the infectious agent was recovered, this being the only case of Massachusetts origin thus far reported from which the virus has been isolated. Neutralizing antibodies were demonstrated in the blood of this patient four and a half years after recovery.

Absence of cases in Massachusetts since 1939 does not necessarily imply a disappearance of the virus, since epidemiologic data acquired in the West demonstrate that the disease may vanish from a localized endemic area for several consecutive years, only to recur.

Although the occurrence of Rocky Mountain spotted fever in Massachusetts may have been the result of an accidental and perhaps transitory introduction of the infectious agent from outside sources, there is a possibility that the virus may have existed here for many years. The relatively few cases suggest that only a small proportion of the ticks on Cape Cod harbor the infectious agent.

THE ASCORBIC ACID CONTENT OF LATE-WINTER TOMATOES*

ARTHUR D. HOLMES, PH.D.,† CARLETON P. JONES, M.S.,‡ and WALTER S. RITCHIE, PH.D.§

AMHERST, MASSACHUSETTS

THE tomato is generally considered one of the most important of the protective foods, owing largely to its vitamin C content. It is commonly classed as a vitamin C food and is frequently listed as one of the richest natural sources of ascorbic acid (vitamin C). Since it can be raised easily even by amateur gardeners, it is almost universally recommended for the home garden. It is also grown in enormous quantities for commercial canning, and for the manufacture of tomato juice. As a result of this extensive use and great popularity of the tomato, many studies have been made of its ascorbic acid content.

Apparently a number of factors affect the amount of ascorbic acid developed in tomatoes. For instance, Tripp, Satterfield, and Holmes¹ found varietal differences ranging from 14.8 mg. per 100 gm. for John Baer tomatoes to 21.8 mg. for Pritchard, and MacLinn and Fellers² report values varying from 9.0 mg. for Pritchard Stokes to 59 mg. for Princess of Wales (Sutton). The reports by Booher, Hartzler and Hewston,³ Curran,⁴ MacLinn, Fellers and Buck,⁵ Hamner and Maynard⁶ and others who have carefully reviewed the literature indicate that field-grown, fully ripened, vine-matured, summer tomatoes contain about 25 mg. of ascorbic acid per 100 gm. Thus a good-sized tomato of this type could supply nearly half the 75 mg. of ascorbic acid recommended by the Committee on Food and Nutrition of the National

Research Council⁷ for the daily needs of the human adult.

One frequently finds on the market, however, tomatoes that in neither color, taste nor physical appearance compare with the high quality of the field-grown, vine-matured summer tomatoes. Such tomatoes are commonly found in the stores of the northeastern United States during the late winter and early spring months. Inasmuch as these tomatoes are grown, shipped and sold under conditions quite different from those of the normal, local growing season, it appeared desirable to determine the ascorbic acid content of typical late-winter tomatoes. Such data are of particular interest to the physician, nutritionist and homemaker who wish to ascertain accurately the amount of ascorbic acid supplied by late-winter tomatoes, and the present study was conducted to accumulate these data.

The tomatoes analyzed were obtained from six local stores. Three of these were of the small private or independent type and three were representative of the large chain grocery stores. The tomatoes were purchased in small retail packages or by the pound, just as a homemaker would purchase them for home use.

Samples for analysis were obtained by cutting slices, weighing 10 to 15 gm., through the medial section in the same manner as the tomato is prepared for serving. The assay procedure described by Tripp, Satterfield and Holmes¹ was followed. The skin was quickly removed and the slices immediately submerged in acetic acid and thoroughly macerated by grinding in a mortar with acid-washed sand. Thus, destruction of vitamin C by enzymes was reduced to a minimum. The mix-

ture of finely ground tomato, acetic acid and sand was transferred to a centrifuge tube and spun at 2000 r.p.m. for ten minutes, which produced a clear supernatant liquid. The ascorbic acid content of this liquid was obtained by titration with sodium-2, 6-dichlorophenolindophenol dye to a faint-pink end point.

The results obtained from the assay of 58 tomatoes are reported in Table 1, which also includes data concerning the source, weight and cost, the amount of tomato required to yield 75 mg. of ascorbic acid and the cost of this amount from the tomatoes in question. The average weights of the tomatoes obtained at the thirteen purchases were 93.7, 88.2 and 92.8 gm. for chain store A, 93.6 and 83.0 gm. for chain store B, 80.7 and 83.2 gm. for chain store C, 102.8 and 74.9 gm. for independent store A, 93.0 and 91.4 gm. for independent store B and 89.7 and 97.3 gm. for independent store C. The average weight of all the tomatoes was 88.8 gm. The cost per pound varied from 18 cents for the first purchase from independent store B to 42 cents for the second purchase from independent store A.

The ascorbic acid content of the tomatoes is reported on a 100-gm. basis. It varied widely within each of the thirteen lots as well as between the lots. The average values were 6.0, 6.8 and 8.2 mg. for chain store A, 9.3 and 10.8 mg. for chain store B, 4.0 and 11.3 mg. for chain store C, 5.7 and 13.4 mg. for independent store A, 10.4 and 8.5 mg. for independent store B and 9.2 and 7.5 mg. for independent store C. The average ascorbic acid content of all the tomatoes was 8.8 mg. per 100 gm. The lowest value obtained was 2.5 mg., and the highest was 22.0 mg. for tomatoes purchased from chain store C. This latter value, and a few of those obtained for other tomatoes, are similar to those obtained by a number of investigators for field-grown tomatoes, but the average ascorbic acid content of the late-winter tomatoes, 8.8 mg. per 100 gm., is only about one third that of summer tomatoes. In fact, it is definitely less than the ascorbic acid content of canned tomatoes, which are available at the time late-winter tomatoes are consumed. Daniel and Rutherford⁸ found that the ascorbic acid content of tomatoes canned six months previously was 14 mg. for glass containers and 15 mg. for tin containers. Rogers and Mathevs⁹ compared commercial and home-canned tomatoes and found 13.8 mg. of ascorbic acid for the former and 13.9 mg. for the latter. Hence, it is obvious that whereas the late-winter tomato possesses attractive decorative features for the table, particularly in salad combinations, it does not have the ascorbic acid

value of fresh summer tomatoes or of tomatoes canned six months previously.

Obviously, tomatoes cannot be relied on as the sole source of ascorbic acid in the dietary. Nevertheless, for the sake of comparison, an estimation has been made of the amount of these tomatoes that would be required to supply the 75 mg. of ascorbic acid recommended by the Committee on Food and Nutrition of the National Research Council⁷ for daily consumption by adult man. The lowest amount of tomato required was 341 gm., or about three quarters of a pound, and the maximum amount required was 3000 gm., or approximately 6½ pounds. It is clear from these values that late-winter tomatoes as ordinarily eaten in the average home can contribute only a small portion of the daily human requirements for ascorbic acid.

The cost of the quantity of tomatoes required to contribute 75 mg. of ascorbic acid to the diet varied from 17 cents for a purchase at independent store B, to \$2.18 for tomatoes purchased from chain store C. The average costs for 75 mg. of ascorbic acid in the thirteen purchases of tomatoes were 90, 72 and 59 cents for chain store A, 71 and 50 cents for chain store B, \$1.58 and 56 cents for chain store C, \$1.08 and 53 cents for independent store A, 33 and 64 cents for independent store B and 61 and 70 cents for independent store C. The average cost of 75 mg. of ascorbic acid from the late-winter tomatoes was 72 cents. It is interesting to compare this cost with 4.8 cents reported by Holmes, Patch and Tripp¹⁰ for 75 mg. of ascorbic acid obtained from oranges available at the same season of the year. Obviously neither the tomatoes nor the oranges would be consumed solely for their ascorbic acid content, but on this basis it is significant that the ascorbic acid content of the late-winter tomatoes cost fifteen times as much as ascorbic acid supplied by oranges purchased at the same season of the year.

CONCLUSIONS

It is quite evident from the results of this study that the homemaker, nutritionist and physician must not consider late-winter tomatoes as equivalent to vine-matured, sun-ripened summer tomatoes as a source of ascorbic acid for the human dietary. In computing the vitamin C value of a diet containing late-winter tomatoes, one should not assign to them more than one third the ascorbic acid value ordinarily used for fully ripe, summer tomatoes.

THE INCIDENCE OF GALLSTONES IN THE HIGHER AGE GROUPS*

FREDERICK I. DESSAU, M.D.†

BOSTON

THE post-mortem records of the Long Island Hospital have been examined for the purpose of determining the incidence of gallstones in the higher age groups. The Long Island Hospital is designed for the medical care of the destitute of the City of Boston. The majority of its patients belong to the higher age groups and most of them are of Irish extraction; a minority are of Italian origin and a few are Negroes.

The post-mortem records, 3242 in all, for the years 1900 to 1942, inclusive, were studied with reference to the frequency of gallstones in relation to age, sex and lesions of the gall bladder, and to the question of an increase of cholelithiasis in recent decades.

The results yield only minimum figures because all post-mortem protocols without definite statements regarding the presence of gallstones were listed as negative. Cases of choledocholithiasis were listed as positive because the gall bladder is generally regarded as the sole source of concretions in the extrahepatic bile ducts.

Table 1 shows the incidence of gallstones found in 2791 post-mortem examinations of patients above the age of forty. The incidence increases with age. Below the age of forty, in 451 post-

stones. This steady rise in incidence of gallstones with age (by decades) has been reported by many authors (Crump,¹ Hansen,² Hamilton,³ Gross,⁴ Jaffé,⁵ Ludlow,⁶ Mosher,⁷ Naunyn,⁸ Ophüls⁹ and Scheel¹⁰) but has been denied by a few (Hesse and Hesse¹¹ and Ryerson¹²). Belief that cholelithiasis originates at a much earlier period, to become manifest in later life only, finds no support in the Long Island Hospital figures.

Table 2 presents figures regarding the association of gallstones and grossly manifest disease of the gall bladder. These are minimum figures because allowance has to be made for the incompleteness of many of the post-mortem protocols

TABLE 2. Incidence of Gall-Bladder Disease in Cases with Gallstones.

and for the varying degree of competency of the persons who made the examinations. Most of the lesions recorded were acute or chronic cholecystitis, fibrosis or hydrops of the gall bladder. There were a few cases of carcinoma (2 in males and 2 in females). Little attention was found to have been paid to cholesterosis of the gall bladder. However, the fact that only 38 per cent of all diseased gall-bladders containing calculi showed easily recognizable gross lesions corresponds with other reports—Scheel¹⁰ reporting 33 per cent of gall bladders with lesions and Ophüls⁹ (post-mortem material) 38 per cent. These low figures cast some doubt on the surgical dictum that there are no innocent gallstones. Cholecystitis without gallstones was found in about 2.5 per cent of the post-mortem examinations.

TABLE 1. Incidence of Gallstones, 1900-1942.

mortem examinations, the incidence was 1.5 per cent. Above the age of eighty, more than a third of the post-mortem examinations revealed gall-

*From the Department of Pathology, Harvard Medical School, and the Department of Pathology, Long Island Hospital.
†Instructor in pathology, Harvard Medical School; formerly, pathologist, Long Island Hospital.

A definite sex difference in the incidence of gallstones, with ratio of almost 2:1 in favor of women, is evident from Table 3. This is lower than the ratios reported by many authors for Europe and the United States: Jaffé⁵ gives about 3:1, Mitchell¹³ 3.5:1, Courvoisier¹⁴ 3:1, Brockbank¹⁵ above 2.5:1 and Hurst¹⁶ 5:1. However, Schretzenmayr,¹⁷ of Vienna, Gross,⁴ of Leeds, England, and Hamilton,³ of Adelaide, Australia, give a 2:1 ratio, and Ludlow's⁶ Lakeside Hospital (Cleveland) ratio of less than 2:1 corresponds most closely to that reported here. The higher incidence in women has often been attributed to the influence of pregnancy. The marked rise in incidence above the age of fifty (Fig. 1) does not support such a view

FIGURE 1. Incidence of Gallstones at Autopsy in Patients over Forty Years of Age.

and this is also the case with the reports of Scheel,¹⁰ Gross,⁴ Hamilton³ and Lichtwitz.¹⁸

Comparison of the presence of gallstones in the post-mortem material of the Long Island Hospital from 1900 to 1922 and 1923 to 1942 (Tables 3 and 4) shows a definite increase for the latter period.

TABLE 3. Incidence of Gallstones, 1900-1922.

Age	NUMBER OF CASES			PERCENTAGE WITH GALLSTONES		
	MALE	FEMALE	TOTAL	MALE	FEMALE	TOTAL
yr.						
41-60	204	233	437	4.4	17.6	11.4
61-80	260	355	615	13.0	29.8	22.8
81 and over	39	61	100	23.0	31.1	28.0
Totals	503	649	1152			18.9
General averages				10.3	24.5	

This increase involved all age groups above forty years and both sexes. The tendency of the sex difference to decrease in recent years is indicated

not only by these findings but also by a comparison of the older literature with publications of recent date. Because of the great variation in incidence of cholelithiasis recorded from different countries,

TABLE 4. Incidence of Gallstones, 1923-1942.

Age	NUMBER OF CASES			PERCENTAGE WITH GALLSTONES		
	MALE	FEMALE	TOTAL	MALE	FEMALE	TOTAL
yr.						
41-60	271	107	378	11.4	22.4	14.6
61-80	715	353	1068	17.6	32.5	22.6
81 and over	115	78	193	27.2	46.8	35.2
Totals	1101	538	1639			22.2
General averages				17.0	32.7	

only figures collected in the same general region are truly comparable. From Chicago, Mitchell¹³ in 1918 gave a 3.5:1 ratio, and Jaffé⁵ in 1933 a 3:1 ratio. From Cleveland, Ludlow⁶ in 1930, gave a ratio of less than 2:1. The reports of Gross⁴ and Hurst¹⁶ indicate a similar shift for England.

A high incidence of gallstones is supposed by some authors, including Mosher,⁷ to occur in poorly nourished populations. Others, including English,¹⁹ maintain the contrary. The material reported here seems to favor the first view, but from lack of comparable material from higher income groups this question is left undecided.

SUMMARY

The data obtained from post-mortem records at the Long Island Hospital show that the incidence of gallstones increases with age.

Cholecystitis was present in 42 per cent of the males and 34 per cent of the females who had gallstones.

Cholecystitis without gallstones was found in 2.5 per cent of the cases.

A higher incidence of gallstones was found in the 1923-1942 period than in the 1900-1922 period.

The sex difference in incidence of gallstones has decreased in recent years.

CLINICAL NOTE

KINEPLASTIC AMPUTATION OF THE FOREARM

JOHN D. ADAMS, M.D.*

BOSTON

KINEPLASTIC amputation for the utilization of muscle power to activate a prosthesis is

the indifference and disfavor with which this method was received some thirty years ago. This procedure has a special value at the present time because it may play a leading part in the rehabilitation of those injured in the war.

The purpose of reporting the present case is to emphasize some of the points brought out by Kessler in his various articles. The report also carries a plea to surgeons who do original am-

FIGURE 1.

This photograph shows the pins in place, with the prosthesis removed.

not a new procedure. Credit for it is due to Kessler,¹ whose work has done much to counteract

*Orthopedic surgeon-in-chief, New England Medical Center.

putations to bear in mind the possibility that some type of prosthesis will be worn on the stump. In many cases one sees an attempt to save too

much of the arm, thus leaving a stump that will not adapt itself to any type of prosthesis. As a result, reamputation becomes necessary.

The technic of kineplastic amputation as described by Kessler, although comparatively simple,

The only way in which the value of this operation can be shown to a patient is to demonstrate a successful case. The study of photographs and reading matter will not convince him. He must be taught the precise limitation of function that

FIGURE 2

In this photograph the prosthesis has been attached. Note the wishbone and the mechanics of the prosthesis.

requires care and precision in several points, as follows:

- 1 The skin flap should not be over 35 cm square, otherwise there is likely to be some irritation from the pins. Also, one should not pass the skin tube through too much of the muscle belly, and the tendons should of course be avoided.

- 2 The edges of the skin tube should be carefully closed before it is canalized through the muscle.

- 3 Excess tension in closing the skin flap should be avoided.

- 4 The prosthesis should not be applied until all symptoms of discomfort and redness have disappeared from the skin tube.

will result from the amputation, and the decision whether it is to be performed should be left to him. The patient must be made to understand that the success of this procedure lies in complete co-operation. To become proficient in adapting oneself to the mechanical principles of a prosthesis takes time and patience. A course of education in the use of the involved muscles should be carried out in the interval between amputation and attachment of the prosthesis.

There are many handicapped people with amputations of the forearm who through years of effort have adapted themselves to devices of every kind, such as hooks and appliances, and who would be unwilling to forsake them for such a procedure as this. Such persons should not be allowed to demonstrate their appliances to the patient until

he has had an opportunity to see all types of prostheses and devices and to make his own selection among them. Kineplastic amputation has a definite place in such a selection.

CASE REPORT

A. G., a 21-year-old mill hand, was referred by Dr. Harold Kurth, of Lawrence. On October 9, 1941, he caught his left hand in a carding machine. It was practically stripped of soft tissue, and all the bones of the hand sustained multiple comminuted compound fractures. It was impossible to identify the tendons, so that amputation was decided on. This consisted in an ordinary flap amputation, which left a stump measuring 20 cm. from its distal end to the tip of the acromion. The flexor and extensor muscles were fastened to the ends of the amputated radius and ulna and the fascia to give anchorage for flexion and extension. Convalescence was uneventful and the patient returned to work in 3 weeks.

Having heard of Kessler's kineplastic amputation, he asked me to perform one. He was instructed to exercise the stump, going through the motions of closing and opening the fingers so as to develop and train the muscles of the forearm. He was most co-operative and did this religiously.

On March 26, 1942, the kineplastic amputation was done. Two flaps were marked out according to the Kessler technic. The dressing was not changed for 10 days. The skin grafts, which were small, took well. On

May 7, measurements were taken and a cast was made, pins having been left in the skin tube for the previous 2 weeks. On July 13, the prosthesis was attached.

At the present time, the patient is working full time. He has become proficient in manipulating his fingers, and is able to pick up his dinner pail, a suitcase, and a cigarette and to hold playing cards in his hand. In other words, following the application of the prosthesis he has learned to activate the artificial fingers with the muscle motors of his forearm as though he had his own fingers. The only complication was a slight irritation of the skin at the edge of the skin tube, which was probably due to the flap's having been made a little too large.

SUMMARY

Kineplastic amputation of the forearm by Kessler's technic is advocated as a valuable and successful procedure.

Complete co-operation of the patient is essential, and there should be preliminary training and exercise of the muscles of the forearm to facilitate function after the attachment of the prosthesis.

A successful case of kineplastic amputation is reported.

MEDICAL PROGRESS

CANCER: RESULTS OF TREATMENT*

IRA T. NATHANSON, M.D.†

BOSTON

THERE is still a conviction among the laity and some of the medical profession that cancer cannot be cured or controlled. This pessimism exists in spite of extensive and convincing evidence to the contrary. It is a well-accepted fact that present-day treatment is effective in the early stages of the disease, before it has spread to distant organs or tissues that are essential to life. Moreover, the prognosis is far from hopeless even in more advanced cases. Unfortunately, however, a large proportion of the patients reporting for treatment are still in far-advanced stages. As was stated in a previous report,¹ powerful weapons are available that, if used judiciously and intelligently, will do much to control the disease. Naturally, all look forward to the discovery of an agent that will have a specific action or will enable the body to over-

whelm the cancer cell, but even if such an agent is found, it is apparent that it cannot be expected to cure all the cases. In the absence of specific treatment, one should not assume a defeatist attitude regarding present-day therapy, especially since reports in the last several decades reveal an increasing number of cures.

The present report deals with the probability of cure of the commonest forms of neoplastic disease. Although no attempt has been made to review the entire literature of the last ten years, it is hoped that the material cited represents the major contributions. It is a herculean task to evaluate critically each end-result study, but fallacies and discrepancies will be discussed so far as possible. The main purpose is to point out that cancer is a controllable disease; the figures that represent a cross section of the results in the large clinics throughout the world (Table 1) attest to this fact.

Certain fundamental concepts must be defined in order to understand and evaluate the reported statistics. First, what is a cancer cure? It is com-

*The articles in the medical-progress series of 1941 have been published in book form (*Medical Progress Annual*, Volume III, 678 pp. Springfield, Illinois: Charles C Thomas, 1942. \$5.00).

monly said that cancer is never completely cured, even though it may remain quiescent. In the case of certain lesions this may be true. However, autopsy findings on patients who die of other diseases and who have no clinical sign of cancer seldom reveal any active disease. Thus, clinical freedom from demonstrable disease must be accepted as the criterion. Perhaps the terms "clinical cure," "free of disease" and "survival without disease" are more applicable. Secondly, what period of time should elapse before one is justified in reporting a

life expectancy of the patients thereafter is essentially the same as that of the normal population. On the other hand, late recurrences of such lesions as cancer of the breast, ovary and so forth are notorious, thus making a ten-year period more desirable.

In the evaluation of end results many other factors must be considered. Foremost is the natural history of the untreated lesion, for without knowledge of this, the efficacy of treatment cannot be judged.²⁻⁴ The period in which the cases were

*Three-year rate.

clinical cure? Authorities throughout the world have agreed on an arbitrary elapsed time of freedom from disease for five years after the last treatment as a reasonable period to warrant the publication of statements regarding control of the disease. It should be realized that cancer is usually a disease of old age and that a number of patients who remain free of cancer die of intercurrent disease before the prescribed time for reporting the results of treatment. It must be pointed out, also, that in certain cancers a shorter interval is reliable, whereas in others longer periods are necessary. For example, a three-year survival without evidence of cancer is sufficient for lesions involving the oral cavity, since few cases recur after that time and the

treated is important, since methods of therapy, especially radiation, have improved markedly in the past twenty years. The stage of disease at the time the patient first comes for treatment alters end results considerably, since some clinics receive a much higher proportion of early cases than do others. Other points of major significance are the histologic criteria of cancer defined by the examining pathologist, the criteria of operability in the various clinics and the judgment and skill of the therapist in choosing and performing the most efficacious form of treatment in the given case. Finally, the method of calculation of end results is probably the greatest single factor in accounting for the differences in the reported figures. Many

clinics report the absolute cure rate—that is, the percentage of the total number of patients examined who are alive and free from recurrence after a stipulated number of years. All patients who are lost to follow-up examination, whether or not they had disease when last seen, and those who die of intercurrent disease before the specified period are counted as dead of cancer. Untreated and hopelessly advanced cases that receive only palliative therapy are also included in the totals. Since this does not give a true index of the efficacy of treatment, but merely denotes the prognosis for the particular lesion, other methods of reporting have been used. The commonest is the so-called “relative cure” or “determinate cure,” but the definition is variable from clinic to clinic. Some clinics include every patient except those who are not treated or who are lost immediately after treatment; others exclude patients in whom no attempt at cure was made, or who were lost to follow-up (even though free of disease), or who died of intercurrent disease. To report that patients were free of disease “from one to ten years” is of little value unless the actual number per year is stated. Even then, recurrence is frequent in the few years after treatment, and inclusion of cases recently treated to increase the number in a reported series is merely confusing. In many instances, a selected group of cases treated by specific methods is published, and this information is of value only in judging the efficacy of such therapy. Thus, it can be seen that reports cannot be directly compared unless the series are of similar composition and the methods of calculation the same. It is obvious that all the above factors must be considered before one can pass final judgment on any single report.

SKIN

Cancer of the skin is curable in a high percentage of cases, since the lesions are easily detectable and accessible to therapy by any of the accepted methods. The reports in the literature give credence to this thesis. Magnusson⁵ reports three-year cures in 76 per cent of cases of verified skin cancer, as against 75 per cent of those diagnosed clinically. The results in all cases were 75 per cent three-year and 55 per cent five-year survivals without disease. Warren, Simmons and Rea⁶ report freedom from disease in clinically diagnosed cancer of the skin without biopsy as 57 per cent for three years and 48 per cent for five years. However, they state that only 16 per cent of the patients were known to be living with cancer or had died from it. Of the remainder, 19 per cent died of intercurrent disease and 16 per cent were lost to follow-up. These are included as failures. As they point out, if the latter two groups, who were free of disease, are included as

cured, the survival rate becomes 84 per cent. It is also of interest that in this age group the expected mortality from natural causes is about 25 per cent within the five-year period. Thus, it is impossible to compute the actual curability rate of all patients who enter the clinic.

Histologic Type and Grade of Malignancy

The histologic type and grade of malignancy definitely alter the prognosis of the disease. Basal-cell cancer seldom if ever metastasizes, whereas metastases in epidermoid or squamous-cell cancer are not infrequent. Schuermann⁷ reports 74 per cent five-year cures in basal-cell cancers and 45 per cent in epidermoid cancers of the skin. The absolute cure in 401 cases of both types was 68 per cent and the relative cure 85 per cent. Poppe⁸ had three-year cures of 73 per cent and 55 per cent in basal-cell and epidermoid cancer, respectively, and 87 per cent in mixed types. McDowall⁹ states that in his series 234 (60 per cent) of 390 cases of epidermoid cancer and 310 (70 per cent) of 440 cases of basal-cell cancer were free of disease, but this refers only to primary healing and does not give the true end results. Warren and Hoerr¹⁰ reported 39 per cent five-year cures for epidermoid cancer, of which 44 per cent were in low-grade and 24 per cent in high-grade lesions. The mortality rate from cancer only was 27 per cent in low-grade and 51 per cent in high-grade lesions. The combined mortality rate from cancer only was 32 per cent, whereas the remainder, who were not included as cured, either died of intercurrent disease, were observed for less than five years or were lost before the specified period. Warren, Gates and Butterfield¹¹ studied the various types of basal-cell cancers and found 38 per cent five-year cures. The method of reporting was similar to that used in a previous study.⁶

Clinical Type and Site of Cancer

Halberstaedter and Simons¹² pointed out that if the lesion was superficial the curability was 83 per cent, but if it was infiltrating the rate dropped to 37 per cent. The survival rate in lesions of the exposed portions of the skin, such as the face and hands, is generally higher than in those elsewhere.^{10, 13}

BREAST

Most end-result studies deal only with operable lesions, so that the actual prognosis for all cases is considerably lower than that usually reported. The criteria of operability as well as the methods of therapy vary in the different clinics. Other factors are important, such as the stage and histologic type of the disease and the tendency for the lesion not only to invade the lymph nodes but to metastasize to distant organs. However, the re-

sults in any operable series are sufficiently good to warrant optimism regarding the treatment. In treatment, some clinics use surgery or radiation alone, whereas others combine the methods in various ways. The value of supplemental radiation is still debatable, but there should be no question concerning the type of surgical procedure to be performed. Some writers^{14, 16} have suggested that simple mastectomy alone or perhaps combined with radiation gives results comparable to those in lesions treated by more radical operations. The reasoning is based on observations of a highly selective group of patients, poor follow-up studies and fallacious suppositions. These writers maintain that the prognosis is so poor in the presence of lymph-node metastases that there is little to be gained by rigorous therapy. The results of therapy in the leading clinics completely refute these arguments. In the first place, the operative mortality of radical mastectomy is seldom more than 2 to 3 per cent, so that on this score alone one cannot justifiably withhold the radical operation. Secondly, the curability rate by radical surgery in cases with axillary metastases is sufficiently high to prove conclusively that it will save many lives. Thirdly, the clinical appraisal of axillary metastases is notoriously fallible and the curability by any method of radiation is exceedingly low. Consequently, one cannot be sure that simple mastectomy will completely eradicate the disease even in the absence of clinically demonstrable metastases. Fourthly, it is essential to remove the pectoral muscles even in the absence of axillary disease, since they are sometimes invaded by the tumor. Fifthly, the proportion of patients entering any clinic with axillary metastases and even more advanced disease is much higher than that of patients in whom the lesion is confined to the breast alone.

It has been found that in untreated cases approximately 15 per cent of the patients were still living six years after the discovery of the disease.^{2, 4} The delay in therapy in a study of cases treated before the last decade averaged about a year; it is less at the present time. The life expectancy from onset of over 1500 cases in all stages and treated from either a curative or a palliative standpoint reveals that 28 per cent were still alive six years after onset.⁴ Hence, taking all cases into consideration, therapy of any kind seems to improve the prognosis. However, the figures improve still more when only the operable lesions, treated by appropriate radical measures, are considered. In contrast to many types of cancer, those of the breast have a tendency to produce late metastases. Consequently, for ideal end-result studies at least a ten-year period should elapse after treatment. The five-year

however, give an accurate index of the prognosis of the treated lesion.

Five-year end results for operated cases range from 30 to 51 per cent¹⁰⁻³²; the absolute curability for all patients who have treatment of any kind (palliative or curative) is 22 to 28 per cent.^{4, 21} When the disease is confined to the breast, the five-year survivals range from 55 to 80 per cent and the ten-year survivals from 36 to 70 per cent. Involvement of the axillary nodes lowers the curability, but the rate is still far from poor. Representative results range from 18 to 45 per cent for five years and from 9 to 18 per cent for ten years. The extreme rates are unusual, for in most cases the results are about midway between them. The radical operation is fairly well standardized, so that except in those clinics where less radical procedures are carried out, the differences in results are due in large part to the criteria of operability. Thus, it can be easily seen that the radical operation is to be preferred and that it should be carried out whenever possible in spite of the fact that a few highly selected cases do almost as well by less radical measures. The merits of radiation alone or in combination with surgery have been reviewed by Brunschwig.³³ He concluded that the possible beneficial effects of preoperative radiation are vitiated by the morbidity resulting from the subsequent operation in a field so irradiated. He further stated that there was no evidence that postoperative radiation increases the survival rate if the disease is confined to the breast, but that it may possibly increase the rate in cases with axillary lymph-node involvement.

ORAL CAVITY AND RESPIRATORY TRACT

The degree of curability in cancers of the oral cavity and respiratory tract varies considerably with the site of origin of the primary lesion. In general, those lesions that arise in the anterior portion have a much higher rate of cure than those situated more posteriorly. Many factors account for these differences, most important of which are the histologic grade of malignancy, —the more anterior lesions are usually of lower grade, —the size of the lesion, the mobility of the part, accessibility for treatment and the extent of lymphatic drainage. Recurrence of the primary lesion or the appearance of metastases is rare after three years of freedom from disease,⁴ although the tendency to the formation of multiple new cancers is relatively high.³⁴ Much of the advance in the therapy of lesions of the oral cavity and respiratory tract is due to the splendid work of Coutard,³⁵ who advocated the protracted type of radiation. This principle used elsewhere in the body has also resulted in the eradication of cancers that would

otherwise have been considered hopeless. It has its greatest value in the treatment of inoperable disease, particularly that involving the tonsils, pharynx and larynx.

Lip

The end results in cancer of the lip include only those lesions that arise on the mucous membrane. Those that appear first on the skin of the lips and invade the mucous membrane secondarily may behave like true lip cancers, but in actuality are skin cancers. Reports of five-year cures range from 59 to 70 per cent, but include both absolute and relative figures.³⁰⁻⁴⁵ Subdivision of results into cases with and without lymph-node metastases gives a better idea of the prognosis in the single case. If the nodes are not involved the curability rate is approximately 85 per cent, whereas with nodal metastases it declines to between 30 and 40 per cent. The uniformity of excellent results from the different clinics is striking and encouraging, in spite of the fact that variations exist in the methods of calculation and therapy. In each instance the series is large, so that the type of case coming to the clinic is not of prime importance. It can likewise be pointed out that most cancers of the lip are of a low grade of malignancy and of relatively small size and that metastases occur in from only 15 to 25 per cent of cases⁴⁷ so that most lesions are favorable for cure.

Buccal Mucosa

The lesions of the buccal mucosa comprise those in which the primary site of origin is the inside of the cheek. Extension of disease to adjacent structures greatly influences the prognosis. Lesions that arise in the anterior portion are most favorable for cure. There are relatively few papers on this subject alone, but taken together they represent a sufficient number of cases to be significant. The five-year curability rate ranges from 26 to 31 per cent, and again the uniformity of results is striking.⁴⁵⁻⁴⁸ The curability rates in cases without metastases approaches 50 per cent, whereas in those with nodal involvement it is approximately 25 per cent, provided cure of the primary lesion is accomplished.⁴⁵

Gingivae

Reports on cancers of the gums should include only those lesions that arise from the mucous membrane overlying the upper and lower alveoli. There is relatively early invasion of the adjacent structures, since the ridges are narrow. This characteristic in itself markedly alters the prognosis. In contrast to lesions of the lip and buccal mucosa, there is a considerable disparity in the end results. Much of this is probably due to the definition of the actual site of origin. In some series

only those lesions that are entirely confined to the gingivae are included, whereas in others, regardless of the extent of disease or the site of origin, all lesions involving the gingivae are taken into consideration. When the disease has extended beyond the gums, the site of origin is sometimes difficult to determine.

Curability rates for lesions of the lower gingiva vary from 15 to as high as 60 per cent,^{45,47-52} and for the upper gingiva they range from 33 to 74 per cent.^{45, 51-54} The figures at the lower extreme usually represent absolute cures, whereas the others are relative rates. This does not entirely explain the discrepancies, and it is not likely that the great differences are due to variations in the technic of therapy alone. The discrepancies would be partially rectified by a definitive method of reporting the actual extent and type of disease.

Palate

In the evaluation of results in this type of cancer, lesions of the hard palate should be separated from those of the soft palate. Lesions of the former are usually less malignant and arise in an immobile part where there is a sparsity of lymphatic drainage. As elsewhere, invasion of adjacent structures alters the outlook. In many cases it is difficult to determine the site of origin, but this is of no practical significance, for if the soft palate is invaded, the lesion behaves as though it had arisen there. Few reports concerning the curability of the lesions are available. In studies restricted to epidermoid carcinoma, three-year cures for lesions of the hard palate were 45 per cent and for those of the soft palate were 20 per cent.⁴⁷ The combined figures for epidermoid cancer of the hard and soft palates range from 30 to 38 per cent.^{45, 55} When considered from the standpoint of histologic type, the five-year rate has been reported as 88 per cent for adenocarcinoma and 38 per cent for epidermoid carcinoma by one group,⁷³ and 23 per cent for all types of malignancy by another.⁵⁶

Tongue

Only those cancers that are confined to or arise primarily in the tongue are included. Some authors do not distinguish lesions of the tongue and floor of the mouth, but this is usually satisfactory since there is little difference in their behavior. The position of the primary lesion is important, since lesions of the anterior portions are usually less malignant. The lesions metastasize early, owing in large measure to the relatively high grade of malignancy, the muscular action of the tongue and the abundance of lymphatics. End-result studies from a large number of clinics reveal variations in five-

year cures from 14 to 37 per cent.^{45, 48, 50, 52, 57-60} Most figures, however, are approximately midway between the extremes—that is, 25 per cent. Cures as high as 50 per cent have been obtained for cancers of the anterior third of the tongue, whereas those for the base are as low as 5 per cent.

Floor of Mouth

There are few studies restricted to lesions arising solely in the floor of the mouth. In this group, five-year cures from 18 to 32 per cent have been published,^{45, 48, 50, 67, 68} but as in cancer of the tongue, most figures are an average of the extremes (25 per cent). The same factors that operate in the prognosis of cancer of the tongue should be considered in lesions involving the floor of the mouth.

Tonsils

Lesions of the tonsils are highly malignant and, as is to be expected, the curability rate is low. Frequently the first sign noted by the patient is a swelling in the neck caused by lymph-node involvement. Most observers^{33, 48, 69-72} report the five-year rate to be about 18 per cent, although two clinics^{48, 69} had rates as high as 30 and 32 per cent. The latter figures are well substantiated, and in this instance it is likely that the methods used represent a definite advance in therapy.

Pharynx

The pharynx is anatomically divided into the nasopharynx, the mesopharynx (the oropharynx, which in reality includes the soft palate and the fauces) and the hypopharynx. As in the case of the tonsils, the first sign may be a swelling in the neck.

The curability rates of cancer of the nasopharynx for five years of 30, 25 and 18 per cent have been recorded.^{35, 73, 74} The average five-year survival rate of lesions of the mesopharynx has been reported as 15 per cent.⁷⁵ The results of treatment in cancer of the hypopharynx are extremely poor and range from 6 to 12 per cent^{25, 48, 76, 77}; these figures were confined to lesions that arose primarily in the hypopharynx.

Larynx

Confusion in the evaluation of end results in cancer of the larynx exists because of differences in the definition of the terms "intrinsic" and "extrinsic." True laryngeal lesions are those that arise in the cavity itself and are intrinsic. Subsequent extension to include the aryepiglottic fold, the pyriform fossa or the postcricoid region—which are in reality parts of the hypopharynx—makes it difficult in many cases to determine the primary site of origin. When tumors arise outside of the cavity but in juxtaposition, they are really hypopharyngeal cancers, but have been called

extrinsic lesions of the larynx by many observers. Once the lesion extends beyond the laryngeal cavity, it behaves like lesions that arise in the hypopharynx, so that this differentiation is not significant. Intrinsic lesions, which arise in and remain confined to the larynx, are usually operable, whereas those that extend beyond or arise in the hypopharynx are seldom amenable to surgical removal.

In the previous section, cancers arising in the hypopharynx were considered, but the figures presented below refer not only to those lesions that are truly laryngeal but to those that extend outward to involve adjacent structures as well. The curability rate of intrinsic cancer of the larynx is relatively high. In the operable group treated by laryngofissure—obviously very early lesions—the five-year rate averages about 80 per cent.^{32, 78, 79} One group⁶⁰ reports 96 per cent survivals without disease from two to thirteen years. The results of total laryngectomy average about 55 per cent. The results of therapy in the inoperable group are much lower, but considering the extent of disease in many cases the results are encouraging. For example, Coutard⁸¹ reports 27 per cent five-year cures. It must be remembered that the lymphatic drainage of the true larynx is relatively sparse, whereas that of adjacent structures, including the hypopharynx, is exceedingly rich. Thus, regional lymph-node metastases are much less frequent in the former (18 to 35 per cent) than in the latter (56 to 74 per cent).⁴⁵ It is not surprising that differences in prognosis have been observed between intrinsic and extrinsic lesions of the larynx. The smaller size of the former, the barrier exerted by the laryngeal cage to extension of disease and the lower incidence of lymph-node metastasis are the main factors accounting for this.

THYROID GLAND

Cancer of the thyroid gland is frequently discovered after routine thyroidectomy for other reasons. The prognosis in the cases without clinically demonstrable cancer is excellent, whereas those lesions that are suspected or are detected before operation have a much lower curability. The prognosis is also altered by the frequency of blood-vessel invasion, nodal metastases and dispersion to distant organs. As in the case of cancer of the breast, end results for periods longer than five years are desirable. Portmann⁸² reports 27 per cent five-year survivals in 200 consecutive cases, whereas DeQuervain⁸³ found 31 per cent in a group of lesions diagnosed clinically and subjected to radical operation. Pemberton⁸⁴ had 70 per cent five-year cures in a series of cases in which the lesion was found incidentally or was suspected at operation. As emphasized by Lahey et al.⁸⁵ and by Pemberton,⁸⁴ the prognosis also varies considerably with the histologic type and mode of spread.

The curability is most favorable in papillary adenocarcinoma, in which the rate is as high as 80 per cent, as contrasted with diffuse carcinoma, small-cell or giant-cell carcinoma or sarcoma, where the rate is 20 per cent or less. Fortunately, many of the cases belong to the more favorable group, so that the general prognosis is good.

GASTROINTESTINAL TRACT

It is the opinion of most people that cancer of the gastrointestinal tract is a hopeless disease. Early diagnosis is sometimes difficult and seldom made, especially since patients minimize their symptoms and usually do not report for examination until the disease is relatively advanced. This is truer for cancer of the stomach than for lesions of the colon and rectum. In spite of these shortcomings and considering the magnitude of the procedures in operable cases, the end results are excellent. In recent years, the operability rates for all lesions have risen, which augurs well for the future. At the same time, the mortality rate for radical procedures is declining, because of a better acquaintance with technics and preoperative and postoperative management. Variations in the reported results depend to a large extent on the criteria of operability of the various clinics, the operative mortality and the stages of disease comprising the series reported. Some clinics attack only relatively early lesions, whereas others attempt heroic procedures in an effort to cure the disease. At any rate, it is clear that cancer of the gastrointestinal tract in the operable stage is a curable disease.

Stomach

Approximately 50 per cent of all patients with cancer of the stomach are operable, but actually only about a half of these are suitable for radical curative procedures.⁸⁶⁻⁹⁰ In reality many of these are borderline lesions. The five-year curability rate of all cases that enter the hospital is about 5 per cent.^{87, 88} However, the prognosis in resectable lesions is much brighter in spite of operative mortalities ranging from about 15 to 30 per cent.⁸⁶⁻⁹¹ The rates of survival in this group as reported in large series vary from 15 to 30 per cent, although most of the results are between 20 and 25 per cent.⁸⁶⁻⁹⁸ Some of the figures include operative mortality, whereas others pertain only to those patients who survive the operation. If the lymph nodes are not involved, five-year survival rates range from 45 to 62 per cent, but decline to 18 per cent when the nodes are involved and to about 10 per cent when the neighboring organs are invaded.⁸⁶⁻⁸⁹

Colon

The operability rates in cancer of the colon are fairly high, but the criteria vary in the different

clinics. In recent years, it has been reported as being from 55 to 85 per cent, although the higher figures in this range are unusual.⁹⁹⁻¹⁰⁵ The operative mortality ranges from about 12 to slightly over 20 per cent.⁹⁹⁻¹⁰⁵ The higher rates may have been partially due to attempts to cure patients who were not in the best of physical condition or in whom the disease was fairly extensive. Staging of the operation also alters the mortality rate.⁹⁹⁻¹⁰¹ In general the two-stage procedures have a lower mortality. Ochsner and DeBakey¹⁰⁵ collected the statistics from the literature and found that the operability in different clinics varied from 38 to 81 per cent but averaged 59 per cent. In 2991 collected cases the operative mortality was 22 per cent and the curability rate in nearly four thousand reported resections ranged from 41 to 53 per cent. An absolute cure of 29 per cent has been reported by Cattell and Sugarbaker.¹⁰⁴ There is a definite uniformity of five-year survivals in patients whose lesions were subjected to resection. In clinics caring for large numbers of cases, most figures range from 47 to 56 per cent.⁹⁹⁻¹⁰⁹ The site of the lesion is important. Five-year survivals for cancers of the right colon range from 51 to 71 per cent,^{99, 102, 107, 110} for the transverse colon average about 40 per cent,⁹⁹ and for the left colon average about 38 per cent.^{99, 102, 107} The degree of mural penetration and the grade of the tumor must be considered, especially in relation to lymph-node metastases.¹¹¹ In the absence of positive nodes, the five-year rate for all cases is as high as 63 per cent and only declines to approximately 45 per cent when the nodes are involved. Lesions of low-grade malignancy have the highest curability. For example, it has been reported that Grade I lesions without metastases are curable in 69 per cent of operated cases, as contrasted with 37 per cent in Grade IV lesions. If the lymph nodes were invaded, the survival rates were 55 and 15 per cent, respectively.¹⁰³

Rectum

The operability rate of cancer of the rectum has increased and the operative mortality has declined because of the great advance made in operative treatment, largely through the efforts of Miles, Jones, Lahey and others. The operability rate in cancer of the rectum at the present time ranges from 50 to 75 per cent^{100, 101, 104, 112} and the operative mortality varies from 7 to 13 per cent (average 10 per cent).^{100, 101, 104, 112-115} Cattell and Sugarbaker¹⁰⁴ report an absolute curability of 25 per cent, but the five-year rates on resectable cases range from 38 to as high as 73 per cent.^{100-104, 108, 112-117} The latter figure is unique and is based on a selected group of patients. Most figures approximate 45 per cent.

URINARY TRACT

The two commonest sites of cancer in the urinary tract are the bladder and the kidney. Lesions of the urethra and ureter are relatively rare. Therefore, only the former lesions will be considered.

Bladder

There are a variety of forms of cancer of the bladder, and although many are slowly growing, in general the disease is very lethal. Here as elsewhere, the curability depends on the type and extent of the disease, the grade of malignancy and the degree of radiosensitivity and operability. The method of therapy varies from electrocoagulation or radium implantation for the smaller lesions to partial or complete cystectomy for operable cancer, and to x-ray therapy only for the more advanced cases. The American Urological Association has established a registry for bladder cancer as an aid to better diagnosis and treatment. Ferguson et al.¹¹⁸ analyzed the reports on 658 cases sent into the registry and found that five years following operation 23 per cent were living, but that only 16 per cent were free of disease. Since these were operable lesions, the group must be considered as those favorable for cure. Reports from single clinics usually deal with the results of treatment by different methods or according to the type of lesion. Obviously this represents selection of cases, so that it is difficult to evaluate the actual prognosis of bladder cancer as a whole.

In lesions amenable to local radium implantation, the recent five-year cure rates vary from 38 to 44 per cent.¹¹⁹⁻¹²¹ Only 10 per cent of the more advanced cases, treated by x-ray alone, survive without disease five years after treatment.¹²² Five-year cures of infiltrating cancers of the bladder are as high as 55 per cent if treated by total cystectomy, but are only 18 per cent when partial cystectomy is done.¹²³ Barringer,¹²⁴ in a comprehensive study of 257 patients undergoing all types of therapy, found a 40 per cent five-year relative rate (based on 211 cases) and an absolute rate of 33 per cent. If the lesion was of papillary character, the relative cure was 56 and the absolute cure 45 per cent; if infiltrating, it was 29 and 25 per cent, respectively.

Kidney

There are few recent reports on cancer of the kidney, and these have to do with favorable lesions. Smith¹²⁵ combined various reports and quotes a five-year survival rate of 19 per cent. The figures of Hyman¹²⁶ and of Beer¹²⁷ are almost identical. They found an operative mortality of about 10 per cent and a curability rate of 33 per cent of the survivors. Priestley¹²⁸ reported that 38 per cent of patients with hypernephroma, 35 per cent of

those with epidermoid cancer of the renal pelvis and 20 per cent of those with Wilm's tumor (adenofibrosarcoma) survived for five years following operation.

MALE GENITAL TRACT

Cancers of the male genital tract, except those involving the penis, have a low curability rate, especially since few patients present themselves for treatment in the early stages. Furthermore, cancers of the testicle and scrotum are usually highly malignant, whereas cancer of the prostate, although usually quite slowly growing, seldom causes symptoms until the disease is fairly well advanced. Since cancer of the scrotum is fairly rare, it will not be discussed.

Penis

Cancer of the penis behaves like that of the lip regarding its mode of growth, grade of malignancy and propensity to metastasize. Many patients, however, report for treatment when the disease is advanced, so that the chances for cure are less favorable. The usual five-year curability rates range between 33 and 50 per cent¹²⁹⁻¹³²; in highly selected and favorable cases they are as high as 75 per cent.¹³³ The rate is about 60 per cent in the cases without lymph-node involvement and declines to 25 per cent when lymph nodes are invaded. If cure of the local lesion is obtained in the latter group, the curability rises to 42 per cent.¹⁴

Testicle

Cancers of the testicle except for the teratomas are usually highly malignant and metastasize early to the regional, periaortic and thoracic nodes as well as to distant organs. Chorioepitheliomas are the most malignant, and cures are seldom recorded. Dean¹³⁴ found 29 per cent of five-year cures in 170 cases of all types of testicular tumor. In 23 without demonstrable metastases, however, the rate was 79 per cent. Smith et al.¹³⁵ reported 15 per cent of their patients as alive and well two years or more after treatment. Higgins and Buchert¹³⁶ state that five years is not a long enough follow-up period to establish the final result and report 14 per cent ten-year cures. Luddy and Desjardins¹³⁷ report 53 per cent five-year survivals in obviously selected cases, and state that in cases without metastases at the time of treatment there is a 60 per cent chance of surviving five years or longer, whereas other cases have a 30 per cent probability. Payne¹³⁸ found 40 per cent of 38 cases free of disease for five years.

Prostate

Until the advent of castration and the use of estrogenic hormones in the treatment of cancer of the prostate, the curability rate was exceedingly

low.¹³⁹ A considerable time must elapse to evaluate the efficacy of this new treatment, but there is no question that as a palliative, even if not a curative, measure it greatly increases the life expectancy of men suffering from this disease. It is unusual to detect the lesion in its early stages, and many are found only after prostatectomy for clinically benign hypertrophy. Barringer's¹⁴⁰ figures from an unselected group of cases demonstrate strikingly the stage of disease when his patients were first seen. Less than 5 per cent of the tumors were small, 7 per cent were medium, and 88 per cent were classed as large. The series included 351 patients, of whom only 8 per cent of 322 followed were living and well for three to seventeen years. Smith¹⁴¹ reported 28 per cent living from one to five years or more in early and moderately advanced cases treated by total perineal prostatectomy. In early cases selected and treated by the same operation, the following percentages of five-year cures have been recorded: Belt,¹⁴² 58 per cent; Young,¹⁴³ 53 per cent; and Colston,¹⁴⁴ 50 per cent.

FEMALE GENITAL TRACT

Comprehensive reports of the results of many clinics in cancer of the female genital tract have been published by Meigs¹⁴⁵ and by Morton.¹⁴⁶ Consequently, the reader is referred to these publications for details. The lesions differ considerably in histologic type, in radiosensitivity and in accessibility for treatment by radiation or surgery. Hence, treatment for each lesion is governed by these considerations. Only the commoner lesions are discussed below.

Vulva

Cancer of the vulva usually occurs in the older age groups and is usually of squamous-cell origin. These lesions as a rule do badly with radiation, so that they are essentially a surgical problem. The lesions frequently grow rapidly, metastasize freely and early to the regional lymph nodes, and have a great tendency to develop local recurrence. The development of new primary cancers in the same region after previous vulvectomy is not unusual. Representative five-year cure rates vary from 26 to 32 per cent.¹⁴⁷⁻¹⁵⁰ All authors agree that the early lesions yield a high percentage of cures, but there is a considerable decline when the nodes are involved.

Vagina

Reports on the cure of cancer of the vagina are scarce. In general the curability rate is quoted as 30 per cent.¹⁵¹

Cervix

Cancer of the cervix is the commonest form of cancer of the female genital tract and is usually

of squamous-cell origin. It spreads early to adjacent structures, such as the vagina, broad ligaments and uterine cavity; in addition, it metastasizes freely to the regional lymph nodes. A number of classifications have been proposed to facilitate evaluation of the end results. This is essential because of the marked differences in the stage of the disease when the patient is first seen. Except for minor variations all are in essential agreement. The stages are roughly classified as:

Stage I. Confinement of disease to the cervix.

Stage II. Involvement of the vagina or extension into the uterine cavity.

Stage III. Extension to one or both broad ligaments.

Stage IV. Fixation of the uterus, or wide extension into both broad ligaments or into the bladder or rectum, or distant metastases.

The literature on cancer of the cervix is voluminous. Since the lesions are usually radiosensitive, there are a large number of papers dealing with the relative merits of operative versus radiation procedures in the treatment of the more favorable cases (Stages I and II). The reports from most clinics, however, reveal that the greatest number of cases are first seen in the more advanced stages. The majority of reports of five-year end results for all stages combined vary from 20 to 40 per cent.¹⁵²⁻¹⁷⁵ These differences are partially accounted for by the method of reporting and by the percentage of each stage in any one clinic. The average report reveals figures midway between the extremes. Five-year cures by stages are as follows, the lowest figures usually representing absolute cures: Stage I, 40 to 80 per cent; Stage II, 34 to 65 per cent; Stage III, 13 to 35 per cent; and Stage IV, 0 to 8 per cent.

Although radiation is used almost entirely in some clinics, there are many advocates of radical hysterectomy (Wertheim, abdominal route, or Schauta, vaginal route) for the earlier cases. One of the major indications is the removal of lymph-node metastases, which ordinarily are not only resistant but also inaccessible for adequate irradiation. So far as the local lesion is concerned, either radiation or surgery is an efficient method of therapy. Occasionally an early lesion is radioresistant, and in these cases surgical removal can usually be done subsequently. Bonney,¹⁵⁴ who advocates Wertheim hysterectomy, found an operability rate of 63 per cent and reports five-year cures of 40 per cent; in cases without nodal involvement the curability rate was 53 per cent, and in those with nodal metastases, 22 per cent. This is to be compared with the results of radiation, especially since the mortality is higher from operation (average 15 per cent) than from radiation (usually less than 3 per cent), even in the most skilled hands. There-

fore, this must be balanced in judging the efficacy of any therapy. Nevertheless, it is apparent that no one form of therapy suffices for all cases, and as in cancer elsewhere, the decision concerning the merit of any treatment should be made in the given case.

Fundus of Uterus

Cancers of the endometrium are usually adenocarcinoma and differ considerably in their radiosensitivity. The lesions may remain confined to the uterine cavity for a long period of time before they penetrate the myometrium or spread to the cervix. Metastases to lymph nodes occur relatively late in the disease. The usual treatment of the operable lesions at the present time is total hysterectomy. The inaccessibility of the lesion for local radiation therapy, the difficulty in determining the exact site of origin and the frequent radioresistance of the lesions favor the employment of surgical procedures wherever possible. However, cures in operable cases may be obtained by judicious radiation therapy. Many clinics now combine the methods by inserting radium into the uterine cavity and subsequently performing a hysterectomy.

The curability for operable cancer of the endometrium treated by hysterectomy alone or combined with radiation is high; that of the inoperable group is quite low. Statistics do not as yet prove the value of complementary radiation in surgically treated cases. Five-year survival rates, including therapy of all types in all cases, average about 40 per cent (range 35 to 45 per cent).^{157, 161, 167, 176-183} Hysterectomy alone or in combination with radiation yields cures of 48 to 70 per cent in the operable group, whereas radiation alone—including both operable and inoperable cases—produces relative cures of 35 to 45 per cent. The published figures comparing the relative merit of surgery and radiation in operable cases favor the former, but this is to be expected, since the operative mortality is low (2 to 4 per cent) and eradication of the disease is more certain. Nevertheless, in poor-risk patients and in the inoperable group, radiation can be expected to give good results.

Ovary

There are a number of histologic types of cancer of the ovary. Difficulties in the classification of these tumors exist because of variations among the forms. The rate and mode of growth are of particular importance in the curability of the lesions. Encapsulated tumors offer the greatest chance for cure. When the cancer has spread beyond the ovary and cure cannot be attained, the survival rate with disease present may still be considerable, since many of the lesions are slowly growing. Fur-

thermore, some of the tumors are radiosensitive, so that the life expectancy without cure may be further increased by radiation. Unfortunately, the tumors seldom produce symptoms until the process is fairly well advanced, so that the over-all curability rate is not so high as one would hope.

Meigs¹⁸⁶ reports a 16 per cent 5-year survival rate. This figure is absolute regarding the prognosis of all types of ovarian cancer after treatment. Early cases have a higher curability rate. Lynch¹⁸⁷ points out that because of the individual characteristics of growth, the five-year period is inadequate for evaluation of cure. Recurrence of slowly growing tumors may not be detected before this interval, thus making estimation of clinical cure difficult. His figures reveal a 35 per cent five-year survival rate following treatment. Walter et al.¹⁸⁸ discuss the merits of radiation in conjunction with surgery. Their five-year results for treatment with surgery alone were 6 per cent, with surgery and inadequate radiation 10 per cent, and with adequate radiation 29 per cent. These figures are difficult to assess, since the terms "inadequate" and "adequate" are matters of definition.

SARCOMAS

In general, the curability of sarcomas is low, except when the disease is treated in the early stages. Even then control of these lesions is difficult because of the great tendency to metastasize through the blood stream.

Malignant Melanoma

Malignant melanoma metastasizes freely by way of either the lymphatics or the blood stream. It is radiosensitive in about 10 per cent of cases. The criteria of malignancy used by the pathologist are of major importance in the end-result reports. Five-year curability rates vary from 22 to 42 per cent.^{45, 189-192} As in other reported series, most of the figures are midway between these extremes.

Fibrosarcoma

Fibrosarcoma rarely metastasizes through the lymphatics, but it is difficult to eradicate locally and spreads freely through the blood stream. Three-year cures average about 21 per cent, whereas the five-year rate is approximately 18 per cent.¹⁰¹⁻¹⁹⁰

Osteogenic Sarcoma

The American College of Surgeons has established a registry for bone tumors for the purpose of verifying the diagnosis, for evaluating the various forms of treatment, and for a better understanding of the course of the disease. There is a wide variation in the histologic type and in the site of origin. The accessibility for treatment and the frequent blood-stream metastases influence the

prognosis. Reports reveal five-year survival rates in favorable cases of 19 to 39 per cent (average 30 per cent).¹⁹⁷⁻²⁰² The higher results refer to those most suitable for operative treatment. The results in all cases are obviously lower, but the figures are of importance as indicating that treatment of the disease is not hopeless.

Malignant Lymphoma and Hodgkin's Disease

The lesions of malignant lymphoma and Hodgkin's disease are usually highly malignant and very radiosensitive. As a result, even though the eventual curability rate is exceedingly low, the prolongation of life by radiation is considerable. Variability in histologic type and the mode of spread of the individual forms frequently alter the prognosis.^{203, 204} Several reports reveal that in certain types of the diseases a number of patients survive for five years and that in some cases the disease has been completely controlled.²⁰³⁻²⁰⁶

OTHER ORGANS

It is too early to appraise the results of the newer concepts of treatment of such cancers as those of the esophagus, lungs, duodenum, bile ducts and pancreas. Formerly these lesions were considered as hopeless, but as previously pointed out,¹ the recent rapid strides in surgical treatment offer hope of a cure of a reasonable number of patients.

* * *

The present-day treatment of cancer is effective in controlling the disease in its various manifestations. In several forms the rate of cure is even higher than that of some other diseases. It cannot be emphasized too strongly, nor be repeated too often, that the prevention, early diagnosis and treatment of cancer are the means to a better curability rate. Palliative therapy for the more advanced lesions is of great value in the prolongation of life and in the alleviation of suffering in the final stages of the disease.

Variations in the methods of reporting end results make it difficult to gauge accurately the curability rates in the different types of cancer. Nevertheless, even at present, it is clear from a careful analysis of the statistics of clinics throughout the world that there is a fairly good agreement in the survival rates. It is hoped that more uniform and complete methods of reporting results will be adopted, so that series of cases from each clinic can be compared directly, which may lead to more efficient therapy.

CASE 29371

PRESENTATION OF CASE

A thirty-two-year-old housewife was admitted to the hospital because of stupor and convulsions of eighteen hours' duration.

For the past ten years the patient had had bronchial asthma, for which she had been repeatedly admitted to this hospital. No definite causative agent could be identified, but she was known to be sensitive to morphine, codein, aspirin and barbiturates, and she had been taught to give herself adrenalin subcutaneously and aminophyllin intravenously. During her fifth admission, five and a half years prior to the present one, she had had an attack of violent abdominal pain associated with diarrhea. At that time the spleen was found to be "easily palpable." The abdominal pain cleared up without residual, and during the next eight months, when she had been examined repeatedly in the Out Patient Department, the spleen had not been felt. The sixth hospital admission had been occasioned by a miscarriage at three months, from which she recovered uneventfully. The seventh admission was about four and a half years before the final one, because of marked increase in the severity of her asthma associated with the production of blood-tinged sputum. There were signs of consolidation at the left base and culture of the sputum grew Type 1 pneumococcus. She recovered uneventfully without the aid of serum or chemotherapy. At that time the spleen was again palpated and the liver edge was felt 2 cm. below the costal margin. After discharge she continued to have asthma but was able to control her symptoms by means of adrenalin and aminophyllin. Four months before her final entry to this hospital she was admitted to another hospital, where an acutely inflamed appendix was removed. At the same operation a uterine dilatation and curettage, a bilateral salpingectomy and a left oophorectomy were performed. Following the operation the patient was well, except for profuse vaginal discharge, until three days before entry, when she felt as if she had the "grippe." She became so cold and chilly that she had to use hot water bottles and extra blankets. There was a feeling

of "feverishness in the inside." She lost her appetite and developed headache, pain in the back of the neck and pain across the lumbar region of the back. One day before admission she became confused and irrational. Although her asthma had decreased markedly during the day or two preceding entry, seven empty aminophyllin ampules were found near the bed the night before admission. About 2:00 a.m. of the day of admission she became rigid and opisthotonic, and then "shook all over" and frothed slightly at the mouth. The attack lasted about five minutes, during which time she was completely unconscious. Her physician, who arrived forty-five minutes later, gave her 1 cat unit of digitalis intramuscularly to "slow the heart, which was beating 130 to 140 per minute." Later that day she became more stuporous and irrational. A second physician was called, who sent her to the hospital.

Physical examination showed a well-developed and well-nourished woman breathing in a rapid and labored fashion. She was somewhat lethargic and would not answer questions except with "yes" and "no." The tongue was moderately dry. There was moderate resistance to flexion of the neck, and she was unable to place her chin on the chest. The lungs were resonant, and the breath sounds coarse and rough throughout, with a few wheezes. There was generalized tenderness to deep palpation of the abdomen, and bilateral costovertebral angle tenderness. An irregular ecchymotic area was present on the radial aspect of the right index finger. The biceps, triceps, radial, knee and ankle jerks were equal and active. The Babinski, Chaddock, Gordon and Oppenheim tests were positive on the left, with unsustained ankle clonus and a doubtful Kernig sign; all were equivocal on the right.

The red-cell count was 3,580,000, with a hemoglobin of 11 gm. The white-cell count was 13,200, with 80 per cent neutrophils; on smear, there was marked shift to the left, and toxic granulation of the neutrophils. The urine was acid with a + test for albumin and for acetone; the sediment contained 5 to 6 white cells per high-power field and innumerable red cells and granular and cellular casts. Lumbar puncture gave an initial pressure of 165 mm. and a final pressure of 120 mm. after 10 cc. of fluid had been withdrawn. The spinal fluid was faintly cloudy and contained 20 polymorphonuclears, 50 lymphocytes and 830 fresh red cells per cubic millimeter; many intracellular and extracellular gram-negative biscuit-shaped diplococci were seen in the smear, but culture on various mediums gave no growth. Spinal-fluid Wassermann and Hinton tests were negative; the protein was 33 mg., and the sugar 53 mg. per 100 cc. A blood culture taken on the

*On leave of absence.

day of admission was reported positive for *Staphylococcus aureus* (coagulase positive) in both flasks. A blood Hinton test was negative.

Half an hour after admission the patient was given 5 gm. of sodium sulfadiazine in 500 cc. of saline intravenously. The following day the neck was less stiff, the headache was less and she was more responsive although still quite restless. Respirations were labored, and the lungs were full of rhonchi and wheezes. She was given intravenous fluids and 2 ampules of aminophyllin without much apparent improvement. The sulfadiazine level on that day was 13 mg. per 100 cc.; the non-protein nitrogen, 37 mg. per 100 cc.; the chloride, 88.3 milliequiv. per liter; the carbon dioxide combining power, 20.1 millimols per liter; the protein, 6.5 gm. per 100 cc.

On the second hospital day, three successive white-cell counts were 4700, 3800 and 3700 respectively, with 93 per cent toxic-appearing neutrophils. The sulfadiazine was stopped. The following day the temperature was 100.4°F, and the white-cell count 3500. An x-ray film of the chest, taken with a portable machine on the fourth day, showed mottled increased density at the right base that seemed to be less than it was at the time of examination a year previously. The lung markings were prominent throughout the chest, which was quite emphysematous. The right costophrenic angle was obliterated. No evidence of abscess or bronchiectasis could be demonstrated.

The temperature on the following day rose to 104.4°F. The patient complained of severe headache and pain in the left shoulder and right hip. The ecchymotic area on the right forefinger had broken down, with discharge of reddish-brown purulent material. Similar bluish-black ecchymotic areas were found on the tip of the fifth finger, the sole of the left foot and the right heel. A large area of swelling, exquisite tenderness and redness appeared on the right buttock, near the site of an intramuscular injection of paraldehyde, from which colon bacilli, hemolytic *Staph. aureus* (coagulase positive) and alpha-hemolytic streptococci were cultured subsequently. There was a profuse, greenish, creamy, vaginal discharge, in which many gram-positive cocci in small clumps were seen on the smear. A lumbar puncture gave a clear fluid containing 29 red cells, 2 polymorphonuclear cells and 5 lymphocytes per cubic millimeter. The initial pressure was 275 mm.; the final pressure, 100 mm. The spinal-fluid protein was 31 mg. per 100 cc., and the sugar 64 mg.; culture again yielded no growth. The temperature remained between 102 and 104.5°F. Two other blood cultures were reported positive for hemolytic *Staph. aureus* (coagulase positive). The

white-cell count rose to 10,600 on the sixth hospital day.

The patient received 4 gm. of sulfadiazine on the seventh and eighth hospital days and then continued on daily doses of 6 gm. of sulfathiazole. She complained of severe pain in the left anterior chest, where a loud grating pleuritic friction rub could be heard. There was no cough or hemoptysis. The white-cell count was 11,500; the urine showed a ++ test for albumin and contained numerous white and red cells.

On the ninth day many petechiae were noted on the flexor surfaces of the hands and feet, on the conjunctivas and in the buccal mucosa. On the eleventh hospital day the patient's condition was essentially the same. The sulfathiazole level was 13.4 mg. per 100 cc., and the nonprotein nitrogen 52 mg. The blood culture was still positive for hemolytic *Staph. aureus* (coagulase positive). The white-cell count was 12,300. The temperature ranged between 101 and 104°F. The urine showed a ++ test for albumin and a ++++ test for diazine crystals.

On the twelfth day the patient had a convulsion. The sulfathiazole level was 15.2 mg., and the nonprotein nitrogen 120 mg. per 100 cc. The carbon dioxide combining power was 23.2 millimols, and the chloride 74.5 milliequiv. per liter. The white-cell count was 13,500, and the hemoglobin 9 gm. per 100 cc. The spleen was felt for the first time since admission. The sulfathiazole was stopped, and the patient was given 20,000 units of penicillin intravenously, followed by two similar doses in the next four hours and then 10,000 units every two hours for the next two days. Her condition remained about the same. On the fifteenth day she had repeated convulsions and became comatose. The sputum was bloody. There was considerable breakdown of the tissue over the back, the buttocks and the right heel.

An x-ray film of the chest showed a few small linear areas of increased density just behind and above the left diaphragm. No frank areas of consolidation or evidence of pleural effusion or empyema could be seen. A lumbar puncture revealed an initial pressure of 85 mm. The fluid contained 600 red cells, 130 polymorphonuclear cells and 6 lymphocytes per cubic millimeter; no microorganisms were seen in the smear. The blood culture was still positive. The patient received three transfusions of 500 cc. of blood in the following three days and considerable intravenous fluid. The urinary output, however, became very low, and she developed diarrhea. The temperature ranged between 103 and 105°F., the pulse above 100, and the respirations about 40; the blood pressure was 70 systolic, 10 diastolic. The white-

cell count was 17,000, with 84 per cent neutrophils. Injections of 25 per cent glucose in saline were given intravenously, with no apparent effect on the output of urine.

On the nineteenth hospital day the patient's condition appeared worse. She developed anasarca. The left arm was slightly stiff; the left biceps and triceps reflexes were present, but no other reflexes could be elicited. The temperature was 104°F. She was given 40,000 units of penicillin every two hours for five doses without any apparent benefit, and died on the twentieth hospital day.

DIFFERENTIAL DIAGNOSIS

DR JOHN NORCROSS*. I think it is fair to say that it is not easily possible to connect all the conditions in this case under one diagnosis. I am going to say that the first part of the story is not connected with the second; that is, the long history of asthma and the violent abdominal pain and palpable spleen recorded at one admission are not related to the events that occurred in the first admission. What caused the abdominal episode, I do not know. We are not given much detail about it and I do not believe, from the point of view of the final episode, that it is important. Four and a half years previously she had had pneumonia, and at that time the spleen was again palpable. I assume from the history that it was then no longer palpable until the final admission.

I think we might date the present illness from four months before the final entry. She continued to have asthma, but at that time she was taken to another hospital where an acutely inflamed appendix was removed. At the same time a uterine dilatation and curettage was done and some of the pelvic organs removed. I think we can safely say that she had a profuse vaginal discharge shortly after this operation, and probably before it also, and since her tubes and one ovary were removed, she may well have had chronic pelvic inflammatory disease, for which this operation really was done. Regarding the appendix, it may or may not have been acutely inflamed.

Two days before entry the patient became acutely ill with fever, chills and rapidly developing signs of meningismus and meningitis. We are told that seven empty ampules of aminophyllin were found near the bed. I have never seen a patient who received the contents of seven aminophyllin ampules in a short course of time; that might cause a convulsion, but I doubt it. In any case I do not believe that it is important from the point of view of the final diagnosis.

At the time of entry to the hospital she was found to be stuporous and had signs that were

consistent with meningeal irritation. She also had an ecchymotic area on the right index finger, and positive Babinski and related signs on one side, which are perhaps unusual at this time in the course of meningitis but not at all impossible. She had some degree of anemia, a slight leukocytosis and, what is more important, a marked shift to the left, with toxic granulations in the polymorphonuclear leukocytes.

The urine was abnormal but we do not know whether it was a catheterized specimen. Since she had a profuse vaginal discharge, some of the white cells may have come from the vagina, but the changes were primarily due to disease of the urinary tract. The cellular findings and the granular and cellular casts all signify serious irritation of the kidneys.

The lumbar puncture gave an initial spinal fluid pressure of 165 mm, and a final pressure of 120 mm. I wonder if the initial pressure could have been higher. The fluid was faintly cloudy, and the cell count showed only a few polymorphonuclear cells, 50 lymphocytes and 820 fresh red cells. Regarding the red cells, I should like to know whether they were present in the early part or at the end of the tap; they may have been the result of difficulty in tapping. "Many intracellular and extracellular gram negative biscuit-shaped diplococci were seen in the smear." That is the most important finding. They could have been one of two organisms, — gonococci or meningococci, — and I think at this point we should decide which was the more likely. Apparently the service never knew because they were unable to grow them out on a culture medium. The sugar was 53 mg per 100 cc, which is certainly high for an acute meningitis. A blood culture taken at the same time was reported positive for *Staph. aureus* (coagulase positive). This was repeated several times throughout the rest of the course in the hospital, and we know, therefore, that the patient had a true bacteremia due to a pathogenic staphylococcus. We also know that four months previously the patient had had a radical pelvic operation, presumably associated with an infection in the pelvis, which was likely caused by the gonococcus. Therefore, I am going to venture the guess that this was a gonococcal meningitis.

The patient was given sulfadiazine and responded quite satisfactorily, but they apparently dared not give more because the white cell count rapidly dropped either because of the toxicity of the condition or because of sensitivity to the drug. We learn later that the clinical symptoms improved and that a second tap done shortly thereafter was negative. No organisms were seen in the smear, and the culture yielded no growth.

*Physician, Lahey Clinic.

The patient then began to take a definite turn for the worse and there were other manifestations, first in the joints, then in the skin and then subcutaneous abscesses. We can therefore say that she had a definite bacteremia, and we have adequate proof from the blood cultures that a pathogenic staphylococcus was the etiologic organism. She then developed pleuritis, further skin manifestations, with petechiae, and additional evidence pointing to trouble with the kidneys. We are told that she had many sulfadiazine crystals in the urine. We also know that at that time the sulfadiazine was changed to sulfathiazole. We wonder, of course, what role these drugs played in the kidney picture. I think we can assume that they played some part, but a minor one. There was evidence of nephritis as the story started, and I think that the later picture was largely a progression of that condition. On the twelfth day she had a convulsion. At that time the nonprotein nitrogen was 120 mg. A lumbar puncture was done shortly thereafter, at which time the spinal fluid contained red cells, polymorphonuclear cells and lymphocytes, but no microorganisms. The blood cultures were still positive. The convulsion might have been caused by the uremia, but I think that it was mostly due to infiltration of the central nervous system by the infection. The urinary output became low, she developed diarrhea and further evidence of uremia, and in spite of the fact that penicillin was given, she rapidly grew weaker and died.

In summary, we have a patient with a picture suggesting gonococcal meningitis, from which she apparently recovered. She then developed evidence of a severe bacteremia, with multiple embolic phenomena of a septic type. There are several possible sources for the bacteremia. The pelvis was the obvious source, and at one point the vaginal smear showed a pathogenic organism that was morphologically identical to that found in the blood culture. I assume that this was the primary source of the organism. The patient also had subcutaneous abscesses, which might have been the source of the bacteremia, but I think that they were secondary rather than primary. The causative organism—a staphylococcus—should have responded better than it did to the sulfonamide drugs, and most certainly to penicillin, unless it was in a place that was difficult to reach, such as the heart valves. The heart is not mentioned in the entire history, and I assume that the physical findings were negative. Nevertheless, that is often true in acute bacterial endocarditis, and it seems to me that the most likely diagnosis is, in addition

to the gonococcal meningitis, an acute bacterial endocarditis, due to *Staph. aureus*, the original source having been in the pelvis. We know that the patient had bronchial asthma and that she had bacteremia and, terminally, septicemia. I think she also had embolic glomerulonephritis, with sulfadiazine contributing to the kidney failure and uremia. She may have had multiple brain abscesses or one abscess as part of the general process.

DR. WILLIAM BECKMAN: On the ward we were as bewildered as Dr. Norcross was by the presence of gram-negative intracellular organisms in the spinal fluid obtained at first lumbar puncture, but in view of the prevalence of meningitis at that time we assumed that they were meningococci. When the patient did not respond to chemotherapy we abandoned that idea. We were considerably less astute on the ward than Dr. Norcross because we did not combine the previous abdominal operation with the present illness.

DR. FRANCIS M. RACKEMANN: This woman had been a patient in the Allergy Clinic for some years. The interesting thing was the method by which she relieved her attacks. She took aminophyllin intravenously two or more times every day for months at a time, and had been giving it to herself. Her husband also learned how to administer it. When I was asked to see her, my first thought was that she was responsible for the septicemia, because she often told me that she carried her syringe loose and "naked" in her handbag along with her handkerchief and other things and that if she was caught with an attack when she was downtown on a shopping tour she did not bother to wash or clean it in any way, but used it as it was to give herself an intravenous injection. I should like to add that, as is so often the case, the asthma, which was so severe and so persistent, having occurred daily for some years, cleared entirely during the infectious period.

CLINICAL DIAGNOSES

Septicemia (*Staph. aureus*).
Acute bacterial endocarditis (*Staph. aureus*).

DR. NORCROSS'S DIAGNOSES

Acute bacterial endocarditis (*Staph. aureus*).
Bacteremia and septicemia (*Staph. aureus*).
Embolic glomerulonephritis.
Uremia.
Brain abscesses?
Gonococcal meningitis, healed.
Bronchial asthma.

ANATOMICAL DIAGNOSES

Pelvic abscess, with extension to right buttock.

Septicemia (*Staph. aureus*).

Acute bacterial endocarditis, mitral valve (*Staph. aureus*).

Septic infarcts of brain, meninges, lung, kidney and spleen.

Subcutaneous abscesses.

(Bronchial asthma.)

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: Of course, the most interesting feature of this case was to discover the source of the obvious staphylococcal septicemia. We found a bacterial endocarditis on the mitral valve—a large, friable, shaggy vegetation, 2 by 2 by 1 cm., attached to one of the leaflets, without any underlying old disease of the valve. This indicates that the lesion was acute rather than subacute, the latter usually developing on a previously damaged valve. On microscopic examination the vegetation was filled with staphylococci.

There was a very large abscess in the right pelvis; it was intraperitoneal and extended down to the obturator foramen, connecting with a large sloughing ulcerating infection on the right buttock. Both tubes had been partially removed. The ovaries were still present and did not appear to be infected. The fundus of the uterus contained a great deal of friable material, and this proved to be inflammatory. Since there was no extension through the wall of the uterus, I do not believe that the uterus was the primary source. I am still not sure whether the abscess was the residuum of an acute appendicitis or of acute pelvic inflammatory disease, and I do not know how one can tell. The abscess was tremendous. The fact that it was on the right rather than bilateral is a bit in favor of its having been due to appendicitis. The organism was the staphylococcus rather than the colon bacillus, which is the usual finding in abscesses following appendicitis, but during the long period following operation the staphylococcus might have overgrown the colon bacillus. There were subcutaneous abscesses throughout the body. The spleen weighed 1030 gm. and contained numerous septic infarcts, which had broken down and formed abscesses. A few small infarcts were present in the kidneys, and numerous abscesses of all ages were found in the lung. There was no embolic glomerulonephritis, and no evidence of sulfonamide changes in the kidneys.

Dr. Kubik will tell us about the brain.

DR. CHARLES S. KUBIK: The brain showed numerous septic infarcts and several small abscesses, one of which was about 1.5 cm. in diameter. I should like to ask about the biscuit-shaped organisms found in the spinal fluid.

DR. BECKMAN: The fluid was examined by several extremely reliable people; but, of course, it is possible that they were overdecolorized staphylococci.

DR. KUBIK: I should say that the meningeal symptoms were almost surely related to the bacterial endocarditis. There were patches of subarachnoid exudate, such as are frequently observed in subacute or acute bacterial endocarditis; these usually result from septic emboli to meningeal vessels rather than from septic infarcts within the brain substance.

CASE 29372

PRESENTATION OF CASE

First admission. A fifty-one-year-old housewife was admitted to the hospital because of swelling of the abdomen and jaundice of several weeks' duration.

Twenty-eight months before admission, she developed "grippe," with fever of 104°F., weakness, anorexia and malaise. The abdomen was enlarged. There were jaundice and right epigastric pain. She was admitted to a community hospital where, following x-ray examinations, she was told that she had three tumors but that she was too weak to be operated on. She was discharged home under the care of a practical nurse. During the next seven months she was bedridden, and although she lost 15 pounds of weight, she gradually gained strength and resumed her household activity for the next eighteen months. The jaundice had apparently disappeared. At that time, that is, three months before admission, she fell, striking the chest and right side of the abdomen. Five days later she had a swelling of the right knee, which persisted for several days. The vague pain in the right upper quadrant returned. One month before entry she developed a "cold" and coincidentally became jaundiced. The urine became dark, but no change in the character or color of the stools was noted. Three weeks before admission her abdomen and feet began to swell and steadily became larger. During one week she had nocturia (three or four times). Her appetite had been poor for the three weeks preceding entry, but there had been no nausea or vomiting.

Five years before admission, following her husband's death, the patient began drinking hard liquor—mostly gin—rather heavily and "stopped eating."

Physical examination showed deep jaundice of the skin and scleras. Numerous telangiectases were present on the face and neck, and there were many dilated superficial veins over the abdomen. A few dry râles were heard at the right base. The abdomen was large and tense, and the umbilicus

was everted. There was a definite fluid wave, with bulging flanks. The liver was easily ballotable 11 cm. below the costal margin in the midclavicular line; the edge was vaguely irregular and could also be felt on the left side of the abdomen. The spleen was palpable 4 cm. below the left costal margin. There was moderate pitting edema of the feet and lower legs. The ankle and knee jerks were absent.

The blood pressure was 140 systolic, 80 diastolic. The temperature was 99.3°F., the pulse 104, and the respirations 19.

The urine was brown, had a specific gravity of 1.018 and gave a +++ test for bile. Examination of the blood showed a red-cell count of 3,250,000, with a hemoglobin of 70 per cent. The white-cell count was 14,900, with 62 per cent neutrophils. The stools were brown, mushy and guaiac negative. The blood protein was 8.9 gm. per 100 cc., the albumin being 3.4 gm. and the globulin 5.5 gm., making an albumin-globulin ratio of 0.6; the van den Bergh test was 13.1 mg. direct and 19.6 mg. indirect. The prothrombin time was 38 seconds (normal, 18 seconds). The hematocrit was 40. A blood Hinton test was negative.

On the second hospital day a paracentesis yielded 5000 cc. of clear bile-colored fluid with a total protein of 1.7 gm. per 100 cc. No sediment could be obtained. Culture gave no growth. Palpation of the abdomen then revealed a firm, nodular, irregular, tender liver extending across the upper abdomen down to 3 cm. above the umbilicus. The spleen was palpable four fingerbreadths below the costal margin. The patient was placed on a high-vitamin, high-carbohydrate diet. X-ray examination on the sixth hospital day showed a high diaphragm on both sides, a small amount of fluid in both pleural cavities and a transverse position of the heart.

The patient was now given 1 ampule of Hykinone daily. During the first ten days she was weak, drowsy and nauseated. The pulse was elevated. Later, however, her general condition improved appreciably. On the fifteenth hospital day the temperature and respirations were about normal, and the pulse 90 to 100. The blood protein was 5.6 gm. per 100 cc., the albumin being 3.4 gm. and the globulin 2.2 gm., making an albumin-globulin ratio of 1.6. The van den Bergh test and the prothrombin time were unchanged. A cephalin-flocculation test on the blood was +++ in twenty-four and forty-eight hours. The urine gave a ++ test for albumin and a +++ test for bile. The white-cell count was 12,700.

One month after admission the pulse ranged between 90 and 70, and the temperature between 98 and 100°F. The blood protein was 7.5 gm.

per 100 cc., the albumin being 2.8 gm. and the globulin 4.7 gm., making an albumin-globulin ratio of 0.6. The blood bilirubin, according to the van den Bergh test, was slightly lower. The patient was transfused. A second paracentesis during the fifth hospital week gave 5000 cc. of similar fluid. The liver was then palpable 7 cm. below the costal border at the midclavicular line. Temperature and respirations were normal, and the pulse ranged between 60 and 100. She was discharged to a nursing home.

Final admission (nine days later). Following discharge the patient did fairly well until four days prior to re-admission, when she developed chilly sensations, irritating cough productive of small quantities of greenish sputum and a temperature of 102°F. The following day, during a bout of coughing, she suddenly felt weak, dizzy and slightly nauseated. There was some desire to move the bowels. Two days prior to re-admission she vomited black, foul-tasting "blood" on two occasions; no bright blood was seen. The day before entry she had frequent, loose, tan stools.

Physical examination was essentially the same as before. There was no peripheral or sacral edema.

The blood pressure was 130 systolic, 55 diastolic. The temperature was 100°F., the pulse 20, and the respirations 30.

The red-cell count was 2,700,000, with a hemoglobin of 7 gm. The stools gave a +++ guaiac test.

During the next two days, she had several "currant jelly" stools. She became disoriented and delirious, and died on the third hospital day.

DIFFERENTIAL DIAGNOSIS

DR. WYMAN RICHARDSON: The moral of this case perhaps is, If you let demon rum get after you too much, be sure to eat enough. The interpretation of drinking "rather heavily" differs with each patient but when associated with the remark that she "stopped eating," it probably means a good deal more drinking, rather than less.

To go back to the history a moment, the question is, Did the illness begin with the febrile episode twenty-eight months before admission? It is stated that the abdomen was enlarged. If this means enlargement due to ascites, this suggests that her illness began before the febrile illness if it was just fat, maybe not. I suspect, however, that her illness began before the febrile episode. I shall disregard the three tumors.

The patient then entered this hospital with evidence of something wrong in the liver. Physical examination revealed a big liver, which, by some observers, was thought to be nodular. It is difficult

cult to be sure about a nodular liver. Certainly one cannot feel a hobnail on a liver, but sometimes when there is tumor or the hepar-lobatum type of syphilis of the liver one can feel what might be called nodules or an irregular liver. It is significant that the spleen was palpable. Whether it is important that the knee jerks were absent, I am not certain.

The laboratory data are consistent with hepatic failure. As we have seen several times, the total protein was elevated, but the elevation was due to increase in globulin, often with a decrease in albumin. Just why it changed so quickly between the second and third determinations, I do not know.

The blood picture, so far as we are given it, is not suggestive of the ordinary type of pyogenic infection. We are told that the stools were brown; in other words, she was putting out some bile. The anemia appears to have been of the macrocytic type, since, according to the hematocrit of 40, the volume of the cells must have measured over 100 cubic microns. I should like to point out that each time the patient had a febrile episode, she seemed to get worse, until the final admission when she had sudden weakness, dizziness and nausea, obviously associated with hemorrhage. The bleeding in this case appears to have been massive and rather more than one would expect simply from the lack of prothrombin. In other words it suggests that there were varicose veins and that she ruptured such a vessel.

So we have a patient with hepatic failure, a big liver and a history of alcoholism. The diagnosis that I think most nearly fits the situation is a toxic cirrhosis and hepatitis, probably alcoholic. There is abundant experimental evidence in animals that substances that are toxic for the liver can be controlled to a considerable extent by dietary measures or the use of substances derived from food. It is also suggested that the people who get into liver trouble from drinking are deficient in their diets in some respect.

There are other conditions that have to be seriously considered. First, I shall mention the question of tumor. The bugbear of hepatoma always comes in, and usually one is wrong, because it is a relatively rare tumor. The cases of hepatoma that I have seen or discussed here have had a more clear-cut story of an antecedent portal type of cirrhosis of rather long standing. Furthermore, the presence of an enlarged spleen may be taken as evidence against other types of neoplasm, although one cannot be sure of that. There is nothing to suggest tumor except the original observation that there were three tumors. Just how they were discovered, whether by x-ray or physical examination, is not clear. In general the story

to me is perfectly easily explained on the basis of hepatic failure. The increase in the amount of failure associated with the febrile episodes is probably that commonly seen with ordinary respiratory or other epidemic infection. I am going to rule out tumor.

Another consideration that we always have to think of is syphilis. We regularly get caught on syphilis of the liver, in some cases by laying too much stress on a negative Hinton test that was not done in dilutions and in others by not paying enough attention to a positive Hinton test. This patient had a negative test. The absence of knee jerks does not necessarily mean that she had syphilis. I cannot be sure that she did not have syphilis of the liver, but I do not see anything in favor of it.

Finally, can this be subacute yellow atrophy in which regeneration had been going on for a long time? In such cases the liver may be enlarged, but I doubt that it would be as big as this one was.

To summarize, I should call this a toxic hepatitis and cirrhosis of the liver—probably alcoholic. I think the patient had varices, and probably died of hemorrhage from varices, although there can be a considerable amount of hemorrhage without one's being able to discover the source. I might add one thing. It is not too uncommon to find a peptic ulcer in association with cirrhosis of the liver. Possibly I ought to throw that in so as not to get caught, but I shall say that the hemorrhage was from varices, even though they were not demonstrated by x-ray study. So much for the liver.

The patient had a chill, fever and greenish sputum, and she may have had some pulmonary infection terminally.

DR. BENJAMIN CASTLEMAN: There was an x-ray film of the esophagus.

DR. MILFORD SCHULZ: I cannot be sure that there are any esophageal varices in this film.

DR. WILLIAM BREED: Is there no way, except by guessing, to determine the presence or absence of hepatoma on superimposed cirrhosis?

DR. SCHULZ: Sometimes a hepatoma projects through the diaphragm, forming a bulge in the upper part.

DR. CASTLEMAN: Is it not true that these patients have fever and signs of malignant disease?

DR. RICHARDSON: Not necessarily, but I think one might get a hint in the blood picture if there were widespread bone-marrow involvement.

DR. ROBERT KINNEY: Is it not worth while to examine the ascitic fluid for tumor cells?

DR. CASTLEMAN: Unless there is widespread seeding, which is extremely unusual in hepatoma, it is difficult to find tumor cells in the ascitic fluid.

DR. JACOB LERNAN: We thought that the diagnosis was alcoholic cirrhosis and that she had, in

addition, a superimposed toxic hepatitis. We also believed that hepatoma was not likely because of the relatively short duration and the rapid onset of jaundice.

CLINICAL DIAGNOSES

Alcoholic cirrhosis of liver.
Toxic hepatitis.
Bleeding from esophageal varices.

DR. RICHARDSON'S DIAGNOSES

Toxic hepatitis.
Cirrhosis of liver, probably alcoholic.
Hemorrhage from varices.
Pulmonary infection (terminal)?

ANATOMICAL DIAGNOSES

Cirrhosis of liver, alcoholic type.
Acute hepatitis, severe.
Gastrointestinal hemorrhage from gastric varix.
Jaundice.
Ascites.
Splenomegaly.
Bronchopneumonia.
Leiomyoma of uterus.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: At autopsy this patient had a large liver, which weighed 2500 gm. It was hard and green. Ordinarily, a hard, green liver immediately makes one think of biliary obstructive cirrhosis. Examination of the biliary tract, however, showed that it was perfectly normal; there was no obstruction. The granularity of the liver

was that ordinarily seen in alcoholic cirrhosis. The nodules were uniformly minute, in contrast to the toxic or healed acute-yellow-atrophy type of cirrhosis, in which the nodules vary in size. The liver of alcoholic cirrhosis is usually yellowish brown, not green; however, microscopic sections showed why it was green—a marked acute hepatitis was superimposed on the alcoholic cirrhosis. The liver cells were granular and necrotic, and in many places had disappeared. The spleen was also enlarged, weighing 420 gm. The uterus contained a huge fibroid; hence, the patient did have three tumors—an enlarged liver, an enlarged spleen and an enlarged fibroid uterus.

The cause of exitus was hemorrhage into the gastrointestinal tract, but not from esophageal varices. The submucosal esophageal veins were not prominent. However, in the stomach, 4 cm. proximal to the pylorus, we found a small papilla 4 mm. long and 2 mm. in diameter, which on microscopic examination proved to be a thrombosed varix. This had ruptured and was the source of the gastrointestinal hemorrhage, rather than rupture of a vessel at the base of a peptic ulcer. Close by was a small erosion without the fibrinoid change characteristic of peptic ulceration. There were two small varices beneath this erosion, and I believe that pressure of the larger varix, plus perhaps the impaired vascularity due to the two smaller varices, accounted for the erosion. There was no gastritis such as one might expect to go along with peptic ulceration.

The patient also had terminal bronchopneumonia.

BLOOD PLASMA

With the accelerating tempo of the war, the need for blood plasma is constantly increasing. In fact, the demands on the various blood-donor centers of the American Red Cross have become so great that some difficulty in obtaining the required number of donors is being experienced. Just why this is so is difficult to understand, since the total amount of plasma for which any one center is responsible can be obtained from a relatively small percentage of the surrounding population, and certainly the slight sacrifice of time and minor discomfort to the donor are greatly outweighed by the saving of the lives of literally

thousands of soldiers and sailors on extended battlefronts.

It has been said that the medical profession has failed to support the program wholeheartedly, and this statement is based chiefly on the fact that many members of a prospective donor group often refuse to give blood, with the excuse that their physicians have advised them against it. Although it is true that a few ultraconservative physicians question the advisability of repeated bleedings on the ground that no one knows the eventual effect, it is difficult to understand how the removal of moderate amounts of blood at adequately spaced intervals in a healthy and active person can do the slightest harm. The healthy professional donor who has given blood for a hundred or more transfusions is no rarity. Furthermore, in those with moderate or severe hypertension or with an excessive amount of blood, as in erythremia, blood-letting at regular periods is an accepted therapeutic procedure. In other words, there seems to be little sound evidence for believing that many of these excuses are founded on fact, but rather are "white lies" prompted by fear and conceived at the moment as the "easiest way out."

In any event, it behooves physicians to support this worthy program to the utmost. Properly couched statements concerning the value and need of plasma, the care taken at the donor centers to weed out persons who should not give blood and the relative safety and minimal annoyance of the blood-taking procedure will do much to reassure those who are hesitant to do their bit toward the saving of a life.

ROCKY MOUNTAIN SPOTTED FEVER

An article published elsewhere in this issue of the *Journal* calls attention to the need for Massachusetts physicians to appreciate that Rocky Mountain spotted fever is endemic in the Cape Cod region. Although no cases have been reported since the summer of 1939, this is no guarantee that the infective agent has been eliminated. In fact, in areas in the West, where the disease is

relatively prevalent, cases in any one endemic area may not be reported for several years, only to recur subsequently.

It is pointed out that although the infective agent may have been introduced within the past decade by a dog carrying infected ticks or by tick-infested rabbits imported from regions where the disease is endemic, it seems more likely that a small number of local dog ticks—the insect vector of the disease to human beings—have harbored the virus for many years. However, the incidence of infection among ticks must be exceedingly low to account for the rarity of the disease.

The paucity of cases certainly does not warrant the widespread use of the specific rickettsial vaccine, but all physicians should bear in mind that any patient with an unexplained maculopapular rash and fever who has visited Cape Cod is likely to be suffering from Rocky Mountain spotted fever. This is particularly true in the case of children who are more likely than adults to have been bitten by ticks. The diagnosis can be established early in the disease by recovering the infective agent from the patient's blood, but the procedure is time consuming. After the first week of the disease, several reliable serologic diagnostic methods—agglutination tests with strains of *Proteus* (Weil-Felix reaction) or with rickettsial agents or complement-fixation tests—are available, and the latter have been shown to remain positive for several years after an attack of the disease. With these laboratory aids, together with quite characteristic clinical symptoms, diagnosis should not be difficult.

MEDICAL EPONYM

FELTY'S SYNDROME

Augustus Roi Felty (b. 1895), when a junior member of the staff of the Johns Hopkins Hospital, was the author of a paper "Chronic Arthritis in the Adult Associated with Splenomegaly and Leucopenia" in the *Bulletin of the Johns Hopkins Hospital* (35: 16-20, 1924):

The syndrome occurred in individuals of middle age (45-65), the average being 50 years. All the patients gave a history of marked loss of weight since the on-

set of symptoms. . . . The arthritic process is distinctly chronic. . . . The objective findings both by physical examination and roentgenographic study are neither widespread nor indicative of a very damaging or destructive process. . . .

In every case the spleen was palpably enlarged . . . firm but not tender. . . . In every instance there was noted a yellowish-brown pigmentation of the skin. . . .

In all cases save one there was a slight secondary anemia. . . . Most striking was the leucopenia, which was a distinctive feature in every case. The leucocyte counts varied from 1000 to 4200. . . .

The etiology is entirely obscure, though the various findings seem best accounted for as manifestations of a single disease process:

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

O'BRIEN—JOHN F. O'BRIEN, M.D., of Fall River, died June 11. He was in his fifty-eighth year.

Dr. O'Brien received his degree from McGill University Faculty of Medicine, Montreal, Quebec, Canada, in 1910. He was a member of the Massachusetts Medical Society and the American Medical Association.

SENECAL—RAYMOND E. SENECA, M.D., of New Bedford, died August 24. He was in his fifty-second year.

Born in St. Cesaire, Canada, Dr. Senecal received his degree from Boston University School of Medicine in 1917. He was on the staffs of St. Luke's Hospital and Union Hospital, New Bedford, and Acushnet Hospital and St. Anne's Hospital, Fall River. Last month he was appointed a member of the Public Health Council by Governor Saltonstall. Dr. Senecal was president of the New Bedford Medical Society at the time of his death. He was a member of the Massachusetts Medical Society, the American Medical Association, the Franco-American Civic League and the Franco-American Historical Society.

His widow, a son and two daughters survive.

STICKNEY—ROBERT C. STICKNEY, M.D., of Beverly, died September 7. He was in his forty-ninth year.

Dr. Stickney graduated from Dartmouth College and received his degree from Columbia University College of Physicians and Surgeons, New York, in 1919. He specialized in pediatrics and was a member of the staff of the Beverly Hospital and the North Shore Babies Hospital in Salem. Dr. Stickney had been chairman of the Beverly Board of Health for many years. He was a member of the Massachusetts Medical Society and the American Medical Association.

His widow, a son and a daughter survive.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

THE EMERGENCY PROGRAM FOR THE CARE OF WIVES AND INFANTS OF MEN IN THE ARMED FORCES

The Children's Bureau has approved the Massachusetts plan for the emergency care of the wives

and infants of men in certain groups in the armed forces. The funds for the program are provided by the federal government and administered by the Massachusetts Department of Public Health through the Division of Child Hygiene. Payment is made for complete maternity service including prenatal care, delivery in a hospital, postnatal care and pediatric care of the infant until its first birthday. In each case the physician and the hospital agree to accept no additional fees from any other source for the patient during the period when care is authorized for payment by the Massachusetts Department of Public Health.

ELIGIBILITY

The wives of men in Grades 4, 5, 6 and 7 of the Army, Navy, Marine Corps and Coast Guard are eligible under this plan. Also included in the group are the wives of Army and Navy aviation cadets. Wives of men who are in Grades 1, 2 and 3 may receive care only if they sign a certificate of need.

APPLICATIONS

Applications for maternal or infant care must be made by the service man's wife and her physician on a special form provided by the Department of Public Health. This application should be sent immediately to Dr. Florence L. McKay, director, Division of Child Hygiene, 73 Tremont Street, Boston. Application forms are available through the Division of Child Hygiene, state district health officers, local boards of health, prenatal clinics, chapters of the American Red Cross, Army cantonnments, Navy stations, visiting nurse associations, bureaus of the Travelers Aid Society and similar social service organizations.

TYPES OF CARE PROVIDED

Maternal care. The Massachusetts plan provides payment for hospital delivery only. The attending physician may be paid for one of the following:

Prenatal, delivery and post partum service (the latter includes examination of mother and infant six weeks). Prenatal visits should include pelvic measurements and, routinely, weight, blood pressure, urinalysis and hemoglobin determinations.

Delivery and post partum service only.

Prenatal service only.

The physician who gives maternal care sends a report of service rendered on a special form to the Division of Child Hygiene with his bill for services. Payment will be made only on receipt of the bill and the report. If there is a question concerning the care given, the Technical Committee on Obstetrics will act on the case. A minimum of ten days and a maximum of fourteen are allowed in the hospital for ordinary cases. If more time is needed, special authorization must

be asked by the physician. Prenatal clinics are to be used for prenatal care where available. If the clinic regularly makes a charge to the patient, the fee may be paid through these funds.

Infant care. Payment for infant care will be made only during the infant's first year of life. Pediatric care consists of two types:

Health supervision, which is limited to one visit per month for supervision or immunization or both.

Care of the sick infant.

The sick infant may be cared for in the home or in the hospital for a period limited to three weeks. Special authorization must be requested if the period is extended beyond this point.

Where local well child conferences, with at least monthly service, are available, health supervision may be given in the conference and the conference will be paid if it regularly charges a fee.

The physician giving pediatric care sends a report of services rendered in the case on a special form to the Division of Child Hygiene, with his bill for services. Payment will be made only on receipt of the bill and the report.

Nursing care. Only bedside care by nurses is covered or eligible for license in Massachusetts may be furnished under this plan. Prenatal supervisory visits are not included for payment.

The state district health officer receives a copy of each authorization from the Division of Child Hygiene. In this way the public health nursing supervisor for the district is able to provide adequate prenatal supervisory visits, as well as bedside nursing care for the mother or infant.

Hospital care. Hospital care furnished to mothers or infants is at ward rates only. The hospital must agree to accept no other payment for hospital care from any other source during the period when care is authorized by the Massachusetts Department of Public Health.

Fees for delivery rooms, anesthesia, blood transfusions, unusually expensive drugs, ambulances and so forth are extra items and payment will be made at rates usually charged to ward patients.

PAYMENTS AUTHORIZED UNDER THIS PLAN

The attending physician may be paid according to the fee schedule that is appended. Payment for service under this plan is not retroactive. The fees allowed cover only the period after the wife signs the application blank. In emergencies, the application must be sent so as to reach the Division of Child Hygiene within twenty-four hours after the beginning of the emergency. In such cases, authorization for payment may be issued if the request is in accordance with the approved regulations.

The cost of care by the intern and resident staff of a hospital is included in the ward cost, and these

physicians will not be paid for medical service rendered to ward patients. Payment may not be made to an attending physician for service customarily provided to ward patients without reimbursement.

According to the regulations of the Children's Bureau, a fee for any one operation may not exceed the total cost of care; for example, the fee for an obstetric operation cannot be more than \$50. The attending physician cannot be paid for an operation; he must call a consultant, who will either operate or designate a specialist to do the operation. A description of the consultant service under this plan will be published at a later date, with a list of the obstetric and pediatric consultants.

STANDARDS OF MEDICAL CARE

The standards of both maternal and infant care are supervised by technical committees. The standards published in the pamphlet *Prenatal Care*, published by the Children's Bureau must be followed for prenatal care.

The physician who is to be paid for maternal or infant care must be a graduate of a Grade A medical school. Graduates of other medical schools who have had training or experience in obstetrics or pediatrics that is approved by the technical committees may be paid.

TECHNICAL COMMITTEES

The technical committees are appointed by the Commissioner of Public Health. Each committee comprises six physicians who are diplomates in their special fields.

The personnel of the Technical Committee on Obstetrics is as follows:

Dr. R. L. DeNormandie, Boston
Dr. R. J. Williams, Lynn
Dr. Raymond Titus, Boston
Dr. Louis Phaneuf, Boston
Dr. Judson Smith, Boston
Dr. Thomas Almy, Fall River

The personnel for the Technical Committee on Pediatrics is as follows:

Dr. W. R. Sisson, Boston
Dr. Stewart Clifford, Boston
Dr. Robert Moulton, Salem
Dr. Arthur Kimberly, Worcester
Dr. R. M. Smith, Boston
Dr. James Baty, Brookline

* * *

FEE SCHEDULE*

MEDICAL FEES

Maternity Care:

Complete maternity care (at least five prenatal visits, delivery and post-partum care)..... \$50.00

*The bill for service and the report of each case are to be submitted on the letterhead of the physician, hospital or nursing organization to the Division of Child Hygiene, Massachusetts Department of Public Health, 73 Tremont Street, Boston, immediately after service is given.

Delivery and post-partum care only.....	35.00
Prenatal care only (in physician's office).....	15.00
Consultation service:	
Office visit	5.00
Hospital visit when consultant is on staff.....	5.00
Home visit or visit to any other hospital.....	10.00
Travel — allowance for 25 miles or more at 4½¢ per mile	
Telephone — allowance for long-distance telephone calls	

Operations:

Obstetric or nonobstetric operations (maximum)..... 50.00

Other fees to be set by the Technical Committee on Obstetrics as need arises.

The attending physician cannot be paid for any operation. If obstetric operation is indicated, he should call on a consultant for this service. If non-obstetric surgery or other special treatment is needed, the specialist may be chosen by the consultant who is called on the case.

Infant Care (during first year of life only):

Well infant (medical supervision):

Office of private physician for complete examination at initial visit or immunization, or both, per visit 2.00 |

At well-child conference, per visit..... 50

Will be paid only to conferences regularly charging a fee; bills should be sent when the amount reaches \$5.00.

Sick infant (diagnosis and medical care):

Initial authorization for care of the sick infant can be given for a period not to exceed three weeks. A request must be made for extension of service.

First visit:

At home (maximum)..... 3.00

In office or hospital..... 2.00

Additional visits:

At home 3.00 |

In office or hospital..... 2.00

Maximum payment for first week of illness..... 15.00

Maximum payment for second and third weeks, per week 6.00 |

Maximum payment beyond third week (after special authorization is given), per week..... 6.00

Consultation service:

Office visit 5.00 |

Hospital visit when consultant is on staff..... 5.00

Home visit or visit to any other hospital..... 10.00

Travel — allowance for 25 miles or more at 4½¢ per mile

Telephone — allowance for long-distance telephone calls

Operations (maximum) 50.00 |

Other fees to be set by the Technical Committee on Pediatrics as need arises.

The attending physician cannot be paid for any operation. If operation is indicated, he should call upon a consultant. When the services of a specialist are required, the consultant will designate the specialist.

HOSPITAL FEES

In accepting the case, the hospital agrees to make no charge to patient and to receive payment from the Massachusetts Department of Public Health at the following per-diem ward rates:

Metropolitan Boston \$4.00 |

Outside Metropolitan Boston 3.50 |

Delivery room, anesthesia and unusually expensive drugs may be paid for at minimum ward rates.

The cost of blood for transfusions may be paid for at the customary rate of the hospital for ward patients.

Cost of ambulance service may be paid for at the rate of \$3 for three miles and 50 cents per mile thereafter.

Maternity cases — minimum stay of ten days, maximum of fourteen days. Extension may be had when necessary with special authorization.

Sick infant — maximum allowance of three weeks on initial authorization. Extension may be had when necessary with special authorization.

Where the prenatal clinic regularly charges a fee, \$1.50 per visit will be allowed for prenatal care.

In an emergency, when the patient must enter a hospital without authorization, application for payment for services must be made to the Division of Child Hygiene, Massachusetts Department of Public Health, within twenty-four hours.

NURSING FEES

Post partum visits per visit	\$1 25
Home delivery (maximum)	10 00
Home visit for sick infant	1 25

CANCER SYMPOSIUM

In connection with the wartime conference of the American Public Health Association, to be held at the Hotel Pennsylvania in New York City, a one day cancer symposium will be held on October 11. The participants comprise the heads of the cancer programs in thirteen states and representatives of the American Society for the Control of Cancer and the National Cancer Institute, as well as several outstanding surgeons and educators. The morning session will be devoted to a discussion of the epidemiology of cancer. At a luncheon session (\$2.25), to be held at the Hotel McAlpin, administration will be discussed. Service to cancer patients will be the subject for the afternoon session, and education in cancer, that of the evening session.

A general invitation to attend the symposium is extended to all Massachusetts physicians. Those who are interested are requested to notify the Massachusetts Department of Public Health, Room 546, State House, Boston.

MISCELLANY

COLLEGE CAMPUSES IN FIGHT AGAINST TUBERCULOSIS

Out of 860 colleges and universities that received the annual survey questionnaire of the Tuberculosis Committee of the American Student Health Association, 488 replied and 311 reported tuberculosis case finding programs in operation. In view of the heavy losses in student health personnel and other serious disturbances experienced by many schools because of the war, this report represents encouraging progress in tuberculosis control among institutions of higher education. It is significant that colleges with a definite control program discovered new cases of pulmonary tuberculosis almost eighteen times as frequently as did those colleges with no program. The following paragraphs are abstracted from a recent article (Lees, H. D. Tuberculosis among college students. *Journal-Lancet* 63:98-101, 1943) covering this subject.

The twelfth annual report of the Tuberculosis Committee of the American Student Health Association gives striking proof of the value of a tuberculosis control program as a regular part of student health service. In the 311 progressive colleges and universities (total student enrollment, 558,075) reporting such programs, 744 new cases of tuberculosis were discovered, a rate of 1335 new cases per 100,000 students. At 177 colleges (total student enrollment, 146,000) which provided no such programs, 11 new cases came to light, a rate of 75 per 100,000 students. Twenty-two food handlers were found to have pulmonary tuberculosis, and among faculty and other

administrative officers, 40 new cases were discovered, thus bringing the total of new cases found in colleges during the school year 1941-1942 to 817.

Few diseases impose such costly and far reaching penalties for public or personal failure to provide early diagnosis as does tuberculosis, yet the majority of institutions of higher education in this country still fail to employ modern tuberculosis case finding methods, which are simple and not expensive. The years of disability and suffering and the financial costs involved will reach staggering proportions, and there will be numerous deaths when ever we neglect early diagnosis of tuberculosis.

It is estimated that the complete cost of finding an undiscovered case of tuberculosis among college students on now unprotected campuses might run as high as \$166. This may seem expensive to some, who do not take into

TABLE 1 Testing Techniques in 254 Colleges Reporting Tuberculin Testing Programs (1941-1942)

DATA	No. of COLLEGS
Testing method

account the social and economic values involved in the early diagnosis of the disease. Failure to provide modern case finding programs, however, will invariably prove far more costly to unfortunate individuals, families and communities, and can never redound to the credit of a negligent institution.

The tuberculin test provides the most sensitive and reliable index of the prevalence of tuberculous infection. In the young adult group, for the country as a whole, 21.8 per cent of students react to tuberculin, the East Coast and West Coast sections having a higher infection rate than other sections of the country.

Many of the older, largely exploded, ideas relating to tuberculosis seem still to be firmly lodged in the minds of many people. The belief is all too prevalent that early tuberculosis gives rise to early symptoms. Certain institutions report various procedures for the follow up of 'suspects'. "Weighing at frequent intervals and frequent temperature readings" are among the commoner of these. The suspects are usually those students who are markedly underweight. The committee therefore feels justified in emphasizing again the fact that the tuberculin test and the chest x-ray provide the only adequate means for the early detection of presymptomatic tuberculosis in the vast majority of cases.

Although it is not possible to speak in exact terms

of the incidence of tuberculosis as applying to the country's student population, reports available to the committee seem to indicate a decline of approximately 30 per cent in its prevalence among college students during the past six years. This may be on the conservative side, for during this period reports from many of the larger institutions conducting excellent case-finding programs indicate an extension of these procedures to include a higher percentage of their students. It is evident that more students are being examined each year and that the technics employed have improved and become more effective.

That there are various technics used in tuberculin testing is shown in Table 1. The Mantoux intradermal method continues to lead all others, while P.P.D. and O.T. are fairly even choices in testing materials. A com-

Fluoroscope used exclusively (chest x-ray when indicated)	12
Colleges reporting no tuberculin-testing program (57)	
Chest x-ray for all new students	22
Chest x-ray for all students annually	9
Other routine x-ray programs	26

paratively large number of colleges use the two-dose technic.

Sixty-six colleges report the ideal annual x-ray of positive reactors. The various x-ray procedures reported are indicated in Table 2.

During the school year 1942-1943 the committee enlisted the co-operation of a group of eastern colleges in a study of entering students approximating 10,000 in number. Information concerning each student includes age, home address, name and location of secondary school attended and whether a private, public or parochial school; tuberculin test technic and results; and x-ray findings. It is hoped that this survey may continue without interruption for a period of ten years or longer, thus providing data indicating differences in the prevalence of tuberculous infection among students from various states and various home communities, accurate yearly comparisons, as well as supplying an index of any changes in the prevalence of tuberculous infection among students in any area.—Reprinted from *Tuberculosis Abstracts* (September, 1943).

CORRESPONDENCE

ESSENTIAL PHYSICIANS

To the Editor: Many doctors regarded as essential—though not of necessity permanently essential—to the needs of Massachusetts have recently received letters asking them to apply for commissions and to have physical examinations. The letters which they have received emphasized that no essential man will receive a commission until he has been declared available by the Procurement and Assignment Service, and the latter has been ordered by the

War Manpower Commission to declare no essential man available until a satisfactory replacement for him is found

It is clear that as the war lasts, medical officers are likely to be invalidated out from the Army and Navy, and will filter back into civilian practice. It is anticipated that many such physicians, as they return, will be able to resume the positions that they held previously in the various communities, and that as they return they may be able to take the place of men now called essential, who will thus become available for military service.

It should be re-emphasized that essential men who now apply for commissions will not receive them until they have been declared available to do so by the Procurement and Assignment Service, and that Procurement and Assignment has been directed by the War Manpower Commission to declare no such men available until, in fact, satisfactory replacement for them can be found.

BOOK REVIEW

Psychoanalytical Method and the Doctrine of Freud. By Roland Dalbiez. With an introduction by E. B. Strauss, M.D. (Oxford), F.R.C.P. Translated from the French by T. F. Lindsay. 8°, cloth, Vol. 1, 415 pp. and Vol. 2, 331 pp. London: Longmans, Green and Company, 1941 \$9.00.

These two volumes, one of which is entitled "Exposition," and the other, "Discussion," are far too technical for an extended notice in this journal. Both the original French edition and the English translation have already been critically reviewed in psychiatric and psychoanalytic journals.

The general introduction by Dr. E. B. Strauss emphasizes that Freud's claim to enduring fame in the history of thought is securely established. The purpose of the author is to point out that the writings of Freud contain two serious defects. In the first place, Freud makes no clear distinction between his method and his doctrine, and secondly, the author claims that Freud is incapable of presenting his thought in a convincing form. Because of these alleged defects an attempt is made to give an objective statement of psychoanalysis.

The first volume discusses the psychopathology of everyday life, dreams, the sexual theory, the general theory of the neuroses and psychoses, the structure of the mental apparatus and the cultural applications of psychoanalysis. In the second volume, there is discussed at length the unconscious, the theories of sex and psychic causality. In both these volumes the author states that he is neither for nor against psychoanalysis, his purpose being, on the contrary, to distill from the psychoanalysis of today the results that will remain part of the science of tomorrow. His approach can, perhaps, be best summarized in his own words: "I believe that the metaphysical system which would most logically extend the results which Freud has reached, would, on the whole, be of the Aristotelean type."

NUTRITIONAL REQUIREMENTS IN TIME OF WAR*

RUSSELL M. WILDER, M.D.†

WASHINGTON, D. C.

WITH many foods in short supply, rationing—some prefer to call it enforced food sharing—is being undertaken. Without a rationing program the only people to get enough would be the ones who have the time to raid the stores when fresh supplies come in. Any course other than rationing would lead to queues and chaos. Failure to control the use of food supplies would make impossible the shipment of food to strengthen our allies, or even to provide what is needed by the United States armies in this country and all around the globe.

There simply is not enough to give everyone all the food he wants to buy. Yet the general food position in this country is not too bad—not now, at any rate. It may be worse before the year is out. If production goals are not attained we shall soon be scraping the bottom of many a barrel. If the machinery for distribution fails to function, we shall undoubtedly be in serious trouble. And we must brace ourselves against possible sudden and unpredictable demands for food that may arise out of opportunities for new invasions, out of unexpected needs on the part of our allies or out of the necessity of providing food to starving people in reoccupied territory, to secure their help in speeding the victory against our common enemies.

However, the food position, I repeat, is now not too bad, and with reasonable good fortune in production, reasonably good management and reasonable willingness on the part of most of us to adjust consumption habits, we the people of this country will undergo only bearable hardships, even allowing for increased military needs.

Government purchases of food to feed our military forces and to help sustain the fighting strength of our allies will amount this year to roughly 25 per cent of the total production of food in this

country. Production, however, has increased enough so that despite this requisition of many million tons of food, as much is being left for home consumption as was used in the years before the war. Some commodities, including milk and poultry, are in larger supply than they were then; others, notably butter and commercially processed fruits, are shorter in supply. The figure for red meat—strange as this may sound to the many who have almost forgotten the aroma of a well-cooked beefsteak—is almost the same as that for the period 1935-1939: 124.5 pounds per capita per annum now, 126.3 pounds then. Also, the average diet, judged in terms of the nutrients provided per capita per day, is essentially the same. Were the foods distributed with perfect equity—to each according to his needs—the calories, protein, minerals and vitamins provided would fully meet for everyone the recommendations of the Food and Nutrition Board of the Division of Biology and Agriculture, National Research Council, with something of every nutrient to spare.

Perfect equity of distribution, however, is not to be expected under any system and was not attained at any time before the war. In 1935-1936 some 35 per cent of the families whose purchases of food were studied by the Bureau of Home Economics had diets that were rated as less than fair, and were the recommended daily allowances of the National Research Council to be applied as the yardstick, this percentage would be much greater. There are at least three explanations for the defective diets in 1935-1936. First, a bad nutritional environment was in part responsible. Many foods as purchased were impoverished by methods of processing, notably products derived from bread grains and some processed fruits and vegetables. Furthermore, the consumption of sugar was excessive. In such an environment it is difficult to choose a good diet without more knowledge of nutrition than most persons have. Secondly, lack by the large majority of the population of the most elementary

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 26, 1943.

†Chief, Civilian Food Requirements Branch, War Food Administration, U. S. Department of Medicine, Mayo Clinic, Rochester, Minnesota (on leave of absence).

knowledge of how to select a good diet must have contributed to many defective diets. Lastly, the food supplies available, owing largely to the low purchasing power of a high percentage of the population, were unequally distributed.

The less expensive foods are in general more impoverished by processing than are other foods. The so-called "protective foods" like milk, meat and fresh vegetables and fruits are usually higher priced. With the better money wages earned by many persons in 1942, consumption of the more expensive protective foods was greatly increased. Yet even in that year of luxury consumption (1942), analyses of family food expenditures, based on a survey of family spending and saving in war-time as published by the Office of Price Administration, revealed that at least 20 per cent of the population were not receiving annual incomes large enough to purchase the food necessary for a good diet.

It has been stated above that the provision of nutrients per capita per day obtained from the total supplies of food available for consumption by civilians in 1943 compares favorably with that for the period 1935-1939. For a large proportion of the population the nutritional situation may actually be superior. Factors that may be expected to exert a favorable influence on the position are as follows:

First, methods have been introduced for improving the nutritive quality of several important staple commodities. Chief of these is the enrichment of flour and bread with vitamins and iron. It is estimated by the milling industry that 80 per cent of the white flour is now enriched with thiamine and niacin. An order of the Food Distribution Administration requires enrichment of all white baker's bread, and approximately 90 per cent of the margarine produced is now fortified with vitamin A. Because of the fact that the cheaper commodities contribute relatively more calories to the diets of persons in low-income groups, the restorative fortifications of flour, bread and margarine that were recommended by the Food and Nutrition Board of the National Research Council have effected a wider distribution of the vitamins and minerals involved. The curtailment of supplies of sugar to approximately 70 per cent of prewar consumption is also beneficial.

Secondly, an intensive campaign of education in nutrition has been under way since the National Nutrition Conference was held in Washington in May, 1941. This campaign, directed and coordinated by the Nutrition Division, formerly in the Office of Defense Health and Welfare Services but now a part of the Food Distribution Administration, has extended into almost every hamlet in this country. It has probably not reached down

into the lower levels of literacy. Nevertheless, its effects are making themselves apparent in many homes through the selection of better foods and diets.

Thirdly, increased employment and increased incomes for large sections of the population have resulted in consumption of more of the protective foods—milk, meat, vegetables, fruits and so forth—by many persons who previously could not afford these foods. One effect of this has been to create shortages, notably of meat and butter. This experience has demonstrated for all time that the supposed surpluses of foods in the years before the war were not surpluses at all but relative deficits that were masked by inequality of distribution.

Lastly, rationing of processed fruits and vegetables and of meats, fats and cheese should have the effect of diminishing waste of food, and thus lead in turn to more effective use of the food supplies available.

Factors the effect of which may be unfavorable for the food position, especially for that section of the population with low fixed incomes, are as follows: the relatively higher cost of many foods; the abandonment or limitation of direct distribution of food and the food-stamp plan; and difficulties attending the transition to controlled distribution procedure, together with associated "black markets" and discrimination on the part of legitimate distributors in favor of former and nearby customers. Lack of satisfactory machinery for obtaining information on consumption makes it impossible to judge the net result of these opposing factors. The importance of securing current surveys of consumption in different areas by geographic position, type of employment and income level is the subject of much discussion at the present time.

Precise evaluation of the amount of poor health attributable to bad nutrition is difficult to obtain, for reasons given in a report of a special committee of the Food and Nutrition Board.¹ What evidence existed up to 1941 pointed to less than satisfactory nutrition in a large segment of every population group that had been studied.

The average American diet has been steadily improving in many ways, although not in all respects, since the last war. This improvement is believed to be a major reason for the increased height and weight of children and soldiers. The average height of the Army inductees is reported as 1 inch greater than the average for United States soldiers in World War I. On the other hand, the proportion of men currently rejected on grounds of physical disabilities has been very large. What proportion of these rejections should be attributed to malnutrition is conjectural. In

my opinion, it is high. Besides the desired surveys on food consumption, there is need for the systematic current application of several clinical tests to groups of the population to obtain a periodic appraisal of the nutritive status of the Nation.

The staff of the Civilian Food Requirements Branch of the Food Distribution Administration is responsible for watching the food position from the standpoint of civilian needs. A representative maintains close contact with each of the several commodity branches of the Food Distribution Administration so that information concerning the supply position of every food commodity is regularly available. At quarterly intervals, or more frequently, an allocation board headed by the director of the Food Distribution Administration reviews the claims for food submitted by the Army, the Navy, the Civilian Food Requirements Branch, the Office of Lend-Lease Administration and other agencies. The decisions concerning allocations are based on the recommendations of this board. Mr. Hendrikson, director of the Food Distribution Administration, takes this position:

We want our own soldiers to have all the food they need, when they need it, and where they need it. We want to go just as far as we can in meeting the food requirements of our allies. But we also want to — and must — provide American civilians with the food required to do a good job on the home front. The principle that must guide and is guiding the division among these major claimants is this: "How will it help to win the war?" *Viewed in this light, the claims of all are well supported.*

The civilian requirement for each commodity depends on estimates of the physiologic needs of the population as a whole, with due regard to special needs and the requirements of industry and institutions; estimates of past consumption; and judgments concerning the physiologic effects of imposed restrictions on consumption. The estimation of physiologic needs involves continuous reviewing of the entire food position. We can, for instance, do with less red meat, than the present estimated supply of 2 pounds per capita per week if poultry, eggs, dairy products and fish are in adequate supply, but when they in turn are scarce, the requirement for meat becomes more pressing. The same applies to other groups of foods. The essential consideration, from the standpoint of needs, is not the food itself but the nutrients that the food provides — the calories, proteins, minerals and vitamins. However, as shortages develop in commodities now unrationed, — and presumably they will, — the necessity for withholding enough of the more essential foods to meet civilian needs will become increasingly more pressing. Furthermore, as other shortages appear

the foods involved must be added to the list of rationed foods. To arrange for rationing with the Rationing Division of the Office of Price Administration when shortages develop is also a responsibility of the Civilian Food Requirements Branch.

No system of rationing can be adjusted to satisfy perfectly the real or imagined special needs of everyone. Such a program would break down out of sheer complexity. Differential rationing has been avoided in so far as possible in every country where rationing has been tried except in Germany and Russia. Some degree of differential rationing, however, will undoubtedly be necessary for some commodities, and notably for milk. It is everywhere agreed that the need for milk is greatest in infancy and childhood, in pregnancy and lactation and in sickness. Children, pregnant and lactating women and invalids must have priority on milk even if the rest of the people go without.

This brings me to a subject in which we as physicians are professionally concerned. That is the dietary needs of invalids and hospitals. A division of the Civilian Food Requirements Branch is exclusively concerned with the problems presented by these needs. It is headed by Dr. Fred L. Adair, past chairman of the Department of Obstetrics of the University of Chicago. It has two sections. One deals with the dietary requirements of invalids and hospitals. This section will soon have the direction of a physician with experience in hospital management, who will be aided by expert dietitians. The other section deals with the requirements of pregnancy and childhood. It has been headed for some time by Dr. Sarah Deitrick, of the Children's Bureau.

The ration orders issued up to now permit wide discretion by the local rationing boards in providing supplementary rationed foods for invalids and hospitals. The door was left wide open, — although everyone has not yet discovered it, — but the time will assuredly come when abuses will necessitate correction of this situation. When this occurs, my office and the Food Rationing Division of the Office of Price Administration will want the most authoritative advice obtainable.

For this purpose the National Research Council, at the request of the director of the Food Distribution Administration, has appointed a group of eminent physicians who between them represent in an official capacity several of the professional sections of the American Medical Association; the American Diabetic Association is also represented by one of its officers. The group is called the Subcommittee on Medical Food Requirements. It is organized as a subdivision of the Committee on Drugs and Medical Supplies of the National Research Council. It will develop a procedure for

knowledge of how to select a good diet must have contributed to many defective diets. Lastly, the food supplies available, owing largely to the low purchasing power of a high percentage of the population, were unequally distributed.

The less expensive foods are in general more impoverished by processing than are other foods. The so-called "protective foods" like milk, meat and fresh vegetables and fruits are usually higher priced. Precise evaluation of the amount of poor health attributable to bad nutrition is difficult to obtain, for reasons given in a report of a special committee of the Food and Nutrition Board.¹ What evidence existed up to 1941 pointed to less than satisfactory nutrition in a large segment of every population group that had been studied.

The average American diet has been steadily improving in many ways, although not in all respects, since the last war. This improvement is believed to be a major reason for the increased height and weight of children and soldiers. The average height of the Army inductees is reported as 1 inch greater than the average for United States soldiers in World War I. On the other hand, the proportion of men currently rejected on grounds of physical disabilities has been very large. What proportion of these rejections should be attributed to malnutrition is conjectural. In

recovery of tubercle bacilli and the reported cases of termination in frank tuberculosis. Against this concept are the facts that tubercle bacilli usually cannot be demonstrated by culture or animal inoculation and that 60 to 80 per cent of cases fail to show positive skin reactions to tuberculin. The proponents of the theory explain this by an atypical or nonacid fast phase of the bacillus. Schaumann⁴ cultivated from the lesions a group of pleomorphic organisms that he believed to represent such a phase, and they have been observed to become acid fast on passage. Several other reports⁸⁻¹² give further support to the theory that sarcoidosis is due to an atypical tubercle bacillus and that its peculiar manifestations are due to lack of tuberculin allergy. In these cases the administration of BCG to patients with sarcoidosis failed to produce tuberculin sensitivity.

According to Filho,¹³ the entire sarcoid syndrome may be found in leprosy, including skin lesions, bone changes, lymphadenopathy and anergy to tuberculin. Longcope and Pierson¹⁴ were unsuccessful in their attempt to grow fungi from the lesions.

Williams and Nickerson¹⁵ prepared from proved skin lesions an antigen that they injected intradermally into patients suspected of having sarcoidosis. In 4 cases, an erythematous reaction appeared in twenty-four hours. Such a reaction may be nonspecific, however, and Harrell⁹ was unable to duplicate these results using an extract prepared from lymph nodes. The presence of eosinophils in the blood stream in some cases suggests an allergic state. The fact that neutropenia and leukopenia may be found in the disease suggests that a virus is the etiologic agent. Harrell thinks that these patients exhibit an exaggerated nonspecific response to small amounts of a lipid fraction of a single organism or a variety of organisms. This response is analogous to the necrosis, infiltration by polymorphonuclear neutrophils and edema of the familiar allergic reaction to proteins. At the present time, however, on the basis of existing evidence, the etiology is obscure.

PATHOLOGY

The pathologic picture is characteristic, and no matter what structures are involved, the lesions are identical. The typical lesion is about the size of a miliary tubercle and is composed of large, pale staining, polygonal epithelioid cells. Small lymphocytes may be found scattered among these cells. Between nodules there is little fibrosis, but in lesions of long duration the connective tissue may be hyalinized and the reaction to Congo red stains for amyloid on this type of tissue is occasionally positive.⁹ There is no peripheral inflammatory zone about the nodules, and caseation is absent. Although necrosis is not a frequent find-

ing, small areas are occasionally seen in the central cells. Giant cells are noted at times, but are rarely numerous. When present, they are very large, with as many as twenty pale nuclei, and contain peculiar inclusions that stain intensely with hematoxylin. Giant cells occur with special frequency in the presence of degeneration of the central cells.

The solitary tuberclelike lesions do not grow in size, but increase in number, at times so much so that they form shiny, pearly gray masses that are plainly visible to the naked eye and give the appearance of tumors in the skin or masses in the spleen, liver, heart or other organs. When the lesions regress, there is a tendency to fibrosis and hyalinization. The skin, lymph nodes, lungs, bones, liver and spleen are most commonly involved, but no organ in the body is exempt. Schaumann⁴ emphasized the frequency with which lymphoid tissue is affected.

CLINICAL DATA

Clinically, sarcoidosis is characterized by widespread involvement of one or more organs, with few constitutional manifestations. Many investigators have reported that the disease occurs most often among Negroes, Puerto Ricans and Indians, whereas according to others there is no special race incidence. The disease begins insidiously in early adult life or childhood and usually pursues an indolent course. The diversity of its clinical forms is explained by the association of lesions in multiple organs. Contrariwise, seldom are all the organs involved in the same patient. Although skin lesions are frequent, the disease may be widely disseminated in their absence. The skin lesions are of several types; painless, nonpruritic, violaceous plaques with no surrounding erythema or induration, occurring most frequently on the face, arms and legs, but at times widespread; localized nodular lesions, most commonly involving the eyelids, nares, fingers and ears, and combinations of these two. Destruction and distortion of the nares may occur. The nails may be striated and brittle, and the nail beds often show the lesions. The oral and nasal mucosa may be involved.

The commonest initial finding in sarcoidosis is enlargement of the superficial lymph nodes. The adenopathy may be limited or generalized, and varies considerably in degree. The nodes are firm, rubbery, discrete and usually painless and do not adhere to surrounding tissues. The nodes most frequently involved are the preauricular, postauricular, submaxillary, submental and epitrochlear. Lymph nodes along the course of the major lymphatic vessels in the arm may be palpable, and those of normal size or only slightly enlarged may show a typical sarcoid lesion.

Pulmonary lesions are common, and several types have been described. Marked bilateral, symmetrical enlargement of the hilar and peribronchial lymph nodes is commonly the only pulmonary manifestation. In other cases, dense radiations extend from the enlarged hilar nodes into the lung fields, most often along the medial portions of the lower lobes. A frequent type is a nodular infiltration distributed bilaterally, granular in appearance and resembling miliary tuberculosis. A soft infiltration resembling caseous pneumonic tuberculosis is found at times. Honeycombing and larger cavity formations may be present. Enlargement of the lymph nodes in the superior mediastinum, especially on the right, may accompany the pulmonary lesions. X-ray films of the chest are not a guide to the severity of the disease,¹⁶ since extensive pulmonary infiltrations may be accompanied by little evidence of a disseminated process, and may resolve completely, whereas slight pulmonary involvement may be associated with extensive lesions in other organs, resulting in serious disability. There is a tendency for the pulmonary lesions to clear completely or almost completely. In a series of cases cited by King,¹⁶ resolution occurred in 60 per cent in seven weeks to three years, with an average of twenty-two months. A return of pulmonary lesions is unusual after clearing has occurred. There is some disagreement whether fibrosis may result from the healing of lesions in the lungs.

Bone lesions occur in 10 to 20 per cent of cases, usually involving the phalanges, metacarpals and metatarsals. The tarsal and carpal bones and occasionally the long bones may, however, be affected. Circumscribed cysts without change in the density of the surrounding bone represent the usual type of involvement. In other cases the bone has a latticework or reticulated appearance, with thickened trabeculae contrasting with rarefaction in the rest of the bone. The periosteum and joints are not involved. The lesions are chronic, and may resolve or progress irregularly. They do not perforate and form fistulas, but there may be inflammation and tenderness of the overlying tissues.¹⁷ Deformities and even painless mutilation of the fingers such as occur in leprosy are seen. X-ray examination of the bones is rarely positive in the absence of some obvious deformity.

Any of the structures of the eye may be involved. Conjunctivitis, keratitis, iridocyclitis or more extensive uveitis may occur. The lesions in the cornea, iris or uveal tract may heal and leave scars and synechiae. The eye involvement is most often mistaken for syphilis or tuberculosis. In some cases the parotid gland may be affected along with the eye, giving rise to the syn-

drome formerly called uveoparotid fever. The other salivary glands, or the lachrymal and mammary glands may be the seat of sarcoidosis. Involvement of muscle, peripheral nerves and the central nervous system has been noted.

Little attention has been paid to the important effects that sarcoidosis produces on the heart. Salvesen¹⁸ first recorded a case of myocardial involvement resulting in bundle-branch block. Schumann¹⁹ observed that at times heart failure results. Longcope and Fisher¹⁹ report 5 cases of sarcoidosis that showed evidence of myocardial insufficiency during life. Heart failure, arrhythmias or significant electrocardiographic changes are reported in these patients. Invasion of the pericardium by sarcoid may also occur. Cardiac function may be secondarily affected as a result of extensive pulmonary involvement, with resultant strain on the right ventricle or even right-sided heart failure.

Localization in the liver, spleen, stomach, intestines, kidney and epididymis occurs. Rotenberg and Guggenheim²⁰ report a case of sarcoidosis in which renal insufficiency and hypertension may have been due to sarcoid invasion of the kidneys.

Cases with involvement of the pituitary gland have been reported. Diabetes insipidus was present in most of them. A case of insufficiency of the anterior lobe of the pituitary gland due to sarcoid infiltration has recently been reported.²¹

Owing to the fact that groups of organs may be involved in almost innumerable combinations, a great variety of clinical syndromes result. It is to be noted, however, that all the extracutaneous lesions are characterized by their latency and their tendency to spontaneous regression, in contrast to the much more chronic behavior of the skin lesions.

It has already been mentioned that sarcoidosis is accompanied by few constitutional symptoms. Occasionally weakness, fatigability, anorexia, weight loss or arthralgia occurs. These symptoms, however, are rarely prominent. Fever may be present, usually in association with uveoparotiditis or acute progressive phases of the disease. Longcope²² emphasizes that symptoms are caused by "mechanical interference with the function of organs rather than by any form of intoxication." The sarcoid lesions by exerting pressure on normal tissue displace or destroy it. When the lesions are in the skin or superficial lymph nodes, symptoms are lacking. The opposite is true, however, when the eye, mediastinum, heart, lungs, central nervous system or other important organs are the seat of sarcoid tumorlike masses. A puzzling feature of sarcoidosis of the lung is the paucity of symptoms and signs in the presence of extensive pulmonary involvement. However, dyspnea, cough and transient chest pain may be present. Hemoptysis occurs

but is rare.²³ Secondary infection resulting in bronchopneumonia is not uncommon. Tuberculosis often develops in cases of pulmonary sarcoidosis.

LABORATORY DATA

The laboratory findings, though not constant, may be of aid in supporting the diagnosis. Anemia is not often present. The white cell count is usually normal or below normal. Marked leukopenia suggests splenic involvement, whether or not the spleen is palpably enlarged. The only abnormality of any significance in the differential count is eosinophilia. Some cases, however, never have eosinophilia, whereas in others it is transient. Some observers consider eosinophilia an index of activity. Harrell⁹ observed that showers of large mononuclear cells were present if differential counts were often repeated. The rise occurs at the expense of the polymorphonuclear leukocytes. The sedimentation rate is usually elevated during the active stage of the disease. Since, however, hyperglobulinemia may be present, the sedimentation rate cannot be used to indicate activity, for hyperglobulinemia increases the rate.²⁴

Harrell and Fisher²⁵ have discussed the changes in blood chemistry. They found the blood calcium to be normal or above normal and the serum phosphatase usually increased in the active phase. The latter finding could not be correlated with the duration of the illness or the site or extent of the lesions. Nonprotein nitrogen and phosphorus levels are normal. The total cholesterol is low or normal. The plasma proteins show an interesting variation. The globulin fraction is commonly elevated sufficiently to raise the total plasma protein. When the total proteins are within normal limits, the globulin fraction is often larger than normal and in excess of the albumin fraction. The plasma albumin is normal or slightly decreased. The urine is usually normal, although Harrell⁹ in 2 cases found a substance resembling Bence-Jones protein in its solubility at the boiling point.

COURSE OF DISEASE

Sarcoidosis is characterized by a chronic, usually benign course and periods of remission. Complete cure may occur. The two shortest reported periods of recovery are five and twenty seven months. Recovery may be spontaneous, or simultaneous with the development of intercurrent tuberculosis. The prognosis is good, and the disease is usually not fatal except when vital organs are involved.

DIAGNOSIS

Sarcoidosis must be differentiated from Hodgkin's disease, lymphosarcoma, bronchiolitis fibrosa obliterans, erythema nodosum, leukemia, fungous

infection, tuberculosis, especially the noncaseous variety, and syphilis. The correct diagnosis is usually made by exclusion or biopsy. When enlargement of lymph nodes predominates, the disease must be differentiated from follicular lymphoma blastoma (giant lymph follicle hyperplasia).²⁶ This is a relatively benign disease of the lymphatic system characterized by lymphadenopathy (due to dimensional and numerical hyperplasia of the follicles), splenomegaly (60 per cent of cases), a normal blood picture, absence of cachexia, a long course and a prompt response of the lymph nodes and spleen to x-ray therapy in the early stages of the disease. The pathologic picture is characteristic.

TREATMENT

Various types of treatment have been advocated. Arsenicals, iodides, leprosol, tuberculin, hyperpyrexia, gold salts, roentgen rays²⁷ and radium have been used without great success. Carbon dioxide snow and x-ray therapy have, however, been of some value in the treatment of skin lesions. Longcope²² has observed a favorable effect of ultraviolet irradiation on the skin lesions and superficial lymph node enlargement. Others have noted no benefit from its use. As a matter of fact, it is difficult to evaluate any form of therapy in view of the natural tendency of the disease to undergo spontaneous remission. Until more is known of the etiology and pathogenesis of sarcoidosis, treatment must remain empirical.

CASE REPORTS

CASE I. A 19-year-old Negroess developed a mild upper respiratory infection. For the ensuing 2 weeks, she had moderate weakness, nonproductive cough and considerable dyspnea even while at rest. X-ray examination of the chest led to a diagnosis of pulmonary tuberculosis and the patient was sent to a sanatorium. While there, she continued to be weak and dyspneic. Examination of the sputum was repeatedly negative for tubercle bacilli and fungi. Intradermal tuberculin tests with PPD (purified protein derivative), first and second strengths were negative. A splenic puncture was negative. After 1½ months, the patient was transferred to the Gallinger Municipal Hospital for further studies.

Her past history disclosed that she had been frail and short of breath for as long as she could remember. As a child, she had been unable to play with other children because of dyspnea.

At the time of admission to the hospital, the patient appeared asthenic. While she was lying flat in bed, the breathing was rapid and shallow. The temperature was 99°F, the pulse 80 and regular, and the respirations 36. A firm movable lymph node 1.5 cm in diameter was felt 7 cm above the middle third of the right clavicle. The heart was normal. Subcrepant rales were heard over the upper halves of both lungs, and there was bronchial breathing over the upper portion of the right and left lower lobes and over the right middle lobe. The

spleen was felt one fingerbreadth below the costal margin and was firm and smooth.

An x-ray film of the chest (Fig. 1) showed diffuse infiltration and mottling throughout both lungs. In the

FIGURE 1. Case 1.

Note the diffuse infiltration and mottling with small areas of cavitation in the upper lobes and prominent hilar shadows.

upper lobes there were small areas of cavitation. The hilar shadows were prominent. Films of the hands and feet were negative. The red-cell count was 5,530,000, and the white-cell count 5800, with 64 per cent neutrophils, 30 per cent lymphocytes and 6 per cent monocytes. The serum albumin was 3.39 gm., and the serum globulin 3.02 gm. per 100 cc. Urinalysis was negative. Biopsy of the cervical lymph node resulted in a diagnosis of sarcoidosis.

The patient's course was uneventful until the 17th hospital day, when she suddenly became orthopneic and cyanotic. The temperature rose to 103°F. and the pulse to 150. On the following day, the liver was tender and extended four fingerbreadths below the costal margin. The venous pressure was 220 mm. of saline solution and rose to 270 mm. on pressure in the right upper quadrant. The arm-to-tongue circulation time, measured with 10 per cent magnesium sulfate, was 31 seconds. The dyspnea and cyanosis continued and the patient died on the 18th hospital day.

Autopsy. The right ventricle of the heart was hypertrophied and dilated. The right auricle was dilated. There was no evidence of sarcoid involvement of the myocardium. The pericardium was normal. Both lungs were studded with grayish masses. On sectioning the lung, these masses were not necrotic and at the apices small cavities with smooth walls were seen. There was no evidence of caseation. The microscopic sections showed typical sarcoid lesions. Occasional giant cells were seen in these sections. The spleen weighed 550 gm. and contained numerous large gray masses 1 to 3 cm. in diameter. Microscopic examination showed evidence of sar-

coidosis. The liver weighed 1700 gm. Small gray masses about 0.5 cm. in diameter were seen on the surface and on a cut section. The lesions of sarcoidosis were seen on microscopic examination. The pancreas, adrenals and gastrointestinal and genitourinary tracts were normal.

Comment. This case represents sarcoidosis involving several organs. The clinical and pathological findings suggested chronic strain of the right ventricle due to severe pulmonary disease, and the immediate cause of death was acute failure of the right ventricle.

CASE 2. A 22-year-old Negro developed a mild, non-productive cough and dyspnea on exertion 3 weeks before admission. On the advice of his physician, an x-ray film of the chest was taken, and on the strength of this the patient was referred to the hospital with a diagnosis of far-advanced pulmonary tuberculosis. The past history was negative except for a corneal ulcer at the age of 10.

At physical examination the patient looked well developed, well nourished and healthy. The only positive

FIGURE 2. Case 2.

Note the bilateral enlargement of the hilar nodes and diffuse mottled infiltration throughout both lungs.

findings were a right corneal scar 0.3 cm. long, bilaterally palpable epitrochlear lymph nodes 1 cm. in diameter and occasional sibilant rales in the right hemithorax.

The red-cell count was 4,900,000, and the white cell count 4000, with 57 per cent neutrophils, 39 per cent lymphocytes, 3 per cent monocytes and 1 per cent eosinophils. Examinations of six sputums and one gastric washing were negative for tubercle bacilli. The intradermal tuberculin test with P.P.D., first strength, was negative, but the test was slightly positive with P.P.D., second strength. The serum calcium was 12 mg. per 100 cc., the serum albumin 5.27 gm., and the serum globulin 3.35 gm. An x-ray film of the chest (Fig 2) showed bilateral enlargement of the hilar lymph nodes and a diffuse, mottled infiltration throughout both lungs.

Biopsy of an epitrochlear lymph node revealed findings typical of sarcoidosis.

As the patient felt well, he was discharged to return each month for a check up examination.

Comment This case is quite typical of sarcoidosis with diffuse pulmonary involvement, few symptoms and no constitutional reaction. The corneal ulcer at the age of 10 may have been due to sarcoidosis.

Case 3 A 42-year-old Negress was admitted to the hospital complaining of cough and fever. Ten days previously, she had a severe chill followed by fever. For the ensuing 10 days, she remained in bed because of weak

fingers were deformed. There was slight dullness over both upper lobes anteriorly. Over the right hemithorax and left upper lobe, sibilant and sonorous rales were heard. Bronchial breathing and subcrepitant rales were present over the right upper lobe. At both bases subcrepitant rales were heard.

The red-cell count was 3 500 000 and the white cell count 7000, with 58 per cent neutrophils, 23 per cent band forms, 12 per cent monocytes, 6 per cent lymphocytes and 1 per cent eosinophils. Urinalysis was negative. The serum albumin was 2.17 gm and the serum globulin 4.76 gm per 100 cc. Intradermal tuberculin tests with PPD, first and second strengths were negative. The sputum was negative for tubercle bacilli on six occasions. An x-ray film of the chest (Fig. 3) showed diffuse mottling and fibrosis throughout the greater portion of the right lung and the upper half of the left lung. There were many small cavities in the left upper lobe and a large fluid-containing cavity 4 cm in diameter in the right upper lobe. X-ray films of the hands and feet (Fig. 4)

FIGURE 3 Case 3

Note the diffuse infiltration and cavity formation most marked in the upper halves of both lungs

ness, dyspnea and a severe, dry cough. There were no chest pains, hemoptysis or night sweats.

The past history revealed that the patient had been short of breath for 1 year. The dyspnea had become progressively but only slightly worse until the onset of the present illness, when it became so severe that the patient could not lie flat in bed. Six years before admission a nodular rash had appeared on the cheeks and nose. A biopsy of the skin taken at the Dermatology Clinic of the Georgetown Hospital had established the diagnosis of sarcoid.

At physical examination the patient looked seriously ill. The temperature was 102.5°F, the pulse 120 and respirations 40. On both cheeks and spreading across the bridge of the nose was a dark red nodular lesion. The nares were enlarged and distorted. A similar lesion was present on the right upper eyelid, the right side of the lower jaw and the right elbow. Several submaxillary lymph nodes were enlarged, firm and freely movable. The right index finger and the left ring finger were broader than the others. The distal phalanges and nails of these

FIGURE 4 Case 3

Note the many sharply punched-out areas most marked in the phalanges of the right index and left ring fingers

showed many sharply punched-out areas indicating bone resorption in the phalanges of the right index and left ring fingers and in several of the carpal and metacarpal bones. An electrocardiogram showed low T waves in Leads I and 4, which were suggestive of myocardial damage.

The patient was given sulfadiazine. After 4 days the temperature, pulse and respirations were normal. The chest findings were unchanged except for the disap-

pearance of the basal rales. Re-examination of the chest by x-ray 10 days after admission showed no appreciable change except that the cavity in the right upper lobe was empty. The temperature remained normal and the patient was symptom free at discharge on the 25th hospital day.

Comment. This is a case of sarcoidosis with skin, bone and pulmonary lesions and a superimposed pneumonia that responded to chemotherapy.

CASE 4. A 46-year-old Negro had transient pain in the left side of the chest in May, 1941. The pain was dull and slightly intensified by deep breathing. A physician sent him to the District of Columbia Chest Clinic, where an x-ray film of the chest was taken. He was then sent to the Glenn Dale Sanatorium.

The past history revealed a loss of 20 pounds during the preceding 5 months. This the patient attributed to hard work as a laborer. He had been in a tuberculosis sanatorium for 5 months in 1931 because of "swollen glands" in his neck. At that time he noticed a skin lesion above the left clavicle.

He remained at the Glenn Dale Sanatorium until November, 1941, and left against advice. While there he gained 17 pounds and was symptom free. All sputum examinations were negative for tubercle bacilli. From November, 1941, until May, 1942, the patient stayed at home and continued to feel perfectly well. During this

FIGURE 5. Case 4.

Note the numerous areas of infiltration and honeycombing throughout the greater portion of the left lung and the middle third of the right.

period frequent sputum examinations were negative for tubercle bacilli. In May, 1942, he was advised to enter the Gallinger Municipal Hospital for further study.

At physical examination the patient was slightly obese and appeared to be in excellent health. There were dark-red skin lesions in patches above the left clavicle. The lesions were nonscaly, nonindurated and raised in plaques. There was slight diminution in breath sounds over the left lower lobe. The remainder of the examination was negative.

An x-ray film of the chest (Fig. 5) showed numerous areas of infiltration and honeycombing throughout the greater portion of the left lung and middle third of the right lung. At the left base there was evidence of thickened pleura. X-ray films of the hands and feet were negative. Examinations of the sputum and gastric washings were repeatedly negative for tubercle bacilli. Sputum culture for fungi was negative. An intradermal tuberculin test was positive. The sedimentation rate (Ernst-Rourke method) was 1.55 mm. per minute (normal, 0.35 mm.). The serum albumin was 2.92 gm., the serum globulin 5.16 gm., and the serum calcium 11.8 mg. per 100 cc. The red-cell count was 4,000,000, and the white-cell count 5600, with 39 per cent neutrophils, 51 per cent lymphocytes, 7 per cent monocytes, 2 per cent eosinophils and 1 per cent basophils. A biopsy of the skin lesion showed sarcoid.

Comment. This is a case of sarcoidosis with skin and pulmonary lesions. The diagnosis was suggested by the evidence of diffuse pulmonary disease resembling tuberculosis in the absence of symptoms and signs of that disease.

CASE 5. A 24-year-old Negro was admitted complaining of swollen femoral and axillary lymph nodes. Ten months previously, he noticed slight, painless swelling of the femoral lymph nodes on both sides. A short time later, he noticed similar swelling of the axillary lymph nodes. These groups of nodes gradually became larger. The bulging of the femoral nodes through his trousers caused him considerable embarrassment, and for this reason he sought admission to the hospital.

At physical examination the patient looked well developed, well nourished and healthy. The preauricular, axillary, cervical, epitrochlear, inguinal and femoral lymph nodes were enlarged. They were discrete, rubbery, movable and nontender. The axillary nodes were about 3 cm. in diameter and the femoral nodes about 6 cm. in diameter. Over both knees and the back of the neck were hard, salmon-colored plaques 0.5 to 1.0 cm. in diameter. The remainder of the examination was negative.

An x-ray film of the chest (Fig. 6) showed bilateral enlargement of the hilar lymph nodes. Films of the hands and feet were negative. The red-cell count was 5,580,000, and the white-cell count 3600, 69 per cent neutrophils, 27 per cent lymphocytes, 3 per cent eosinophils and 1 per cent basophils. Urinalysis was normal. The corrected sedimentation rate (Wintrobe method) was 38 mm. per hour. The serum albumin was 4.85 gm., and the serum globulin 3.96 gm. per 100 cc. Intradermal tuberculin tests (P.P.D., first and second strengths) were negative. A biopsy of a lymph node revealed sarcoid.

The patient was given x-ray therapy to the chest and femoral regions, with resultant slight reduction in the size of the lymph nodes. Six weeks after the completion of x-ray therapy the patient noticed some newly enlarged inguinal lymph nodes. At that time, however, the nodes were very painful and tender. They were fluctuant, inflamed and draining a sanguinopurulent fluid. The temperature was 102°F. There was no penile lesion. A Frei test was strongly positive. The drainage continued for 2 weeks, during which time the temperature fluctuated between 100 and 102°F. At the end of this period the lymph nodes were hard and fixed. Biopsy of one of the inguinal nodes resulted in a diagnosis of lymphopathia venereum.

Comment This case represents one of sarcoidosis with superimposed lymphopathia venereum. The lymph nodes in sarcoidosis do not break down and the overlying skin does not show evidence of inflammation. In lympho-

FIGURE 6 Case 5

Note the bilateral enlargement of the hilar lymph nodes and mediastinal nodes

pathia venereum, there is also an elevation of the serum globulin, which has suggested to some observers an etiological background similar to that of sarcoidosis. In Longcope's²⁰ series of cases, however, Frei tests were done in 8 cases with a positive result in only 1.

CASE 6 An 18-year-old Negress was admitted complaining of cough and mild chest discomfort of 24 hours duration. Her cough was productive of mucoid sputum that was occasionally blood tinged. Slight dyspnea on exertion had been present since the onset of the present illness. Her appetite had been poor for 3 months, and during this time she had lost an unspecified amount of weight.

Physical examination revealed a well developed and fairly well nourished patient who was moderately dyspneic. The temperature was 99°F, the pulse 100, and the respirations 36. The blood pressure was 110/60. The scleras were icteric. Examination of the chest was negative except for slight diminution of breath sounds over the right upper lobe. The remainder of the examination was negative.

X-ray examination of the chest showed no definite evidence of infiltration of the lungs, but there was a generalized accentuation of the bronchovascular shadows. Overlying the right upper lobe there was a hazy density that was interpreted as due to a pleural reaction. X-ray films of the hands and feet were negative. A blood Kahn reaction was ++. Sputum examinations were repeatedly negative for tubercle bacilli. Intradermal tuberculin tests

(PPD, first and second strengths) were negative. The urine showed a strong reaction for bilirubin. The red cell count was 5,300,000, and the white cell count 6850, with a normal differential count. The Van den Bergh reaction was direct, and there was 8.4 mg of bilirubin per 100 cc of blood. The icteric index was 60. The serum albumin was 2.53 gm, the serum globulin 2.26 gm, and the blood cholesterol 166 mg per 100 cc.

The cough and chest pain subsided after 2 days. The temperature became normal on the 3rd day. At that time the patient was entirely symptom free except for slight dyspnea. Two weeks after admission an x-ray film of the chest (Fig 7) showed diffuse irregular areas of infiltration throughout both lung fields. She felt quite well and a physical examination was negative except for slight icterus. The icteric index was 28. Subsequent x-ray examination of the chest 10 and 20 days later showed no change from the second examination.

FIGURE 7 Case 6

Note the diffuse irregular areas of infiltration throughout both lungs

The patient was discharged on the 45th hospital day without any symptoms or signs, but with x-ray evidence of diffuse pulmonary infiltration. She returned at 3 week intervals for check up examinations. After leaving the hospital she continued to feel perfectly well. X-ray examination of the chest showed no change.

Comment In this case of sarcoidosis the pulmonary lesions developed while the patient was under observation. Although no acute symptoms are attributed to pulmonary sarcoidosis, few cases have been observed during the period of development of the lesions. The symptoms in this case may have been due to sarcoidosis or may have been manifestations of a superimposed inflammatory process.

CASE 7 A 39-year-old Negro was admitted because of cough and dyspnea. Six weeks before admission, he coughed up a small amount of blood streaked sputum for the first time. Three weeks later, he developed a cough,

productive of mucoid sputum that was occasionally blood tinged. He continued to work for the next two weeks and then was forced to stop because of several episodes of chilliness, profuse perspiration and dyspnea.

The past history was entirely negative except for the loss of 15 pounds during the preceding year.

At physical examination the patient appeared well developed and well nourished but moderately dyspneic. The

FIGURE 8. Case 7.

Note the small nodular areas of infiltration throughout both lungs.

temperature was 102°F., the pulse 100, and the respirations 36. There were numerous subcrepitant rales over the lower halves of both lungs. The remainder of the examination was negative.

An x-ray film of the chest (Fig. 8) showed discrete and coalescent small nodules symmetrically distributed throughout both lungs. X-ray films of the hands and feet were negative. Examinations of the sputum and gastric washings were negative for tubercle bacilli. A culture of the sputum was negative for fungi but showed sputum Types 10 and 18 pneumococci. Urinalysis was negative. The red-cell count was 4,000,000, and the white-cell count was 4200, with 61 per cent neutrophils, 36 per cent lymphocytes and 3 per cent monocytes. The serum albumin was 5.75 gm. and the serum globulin 4.11 gm. per 100 cc. An intradermal tuberculin test with P.P.D., first strength, was negative, but with second strength it was weakly positive.

The temperature remained elevated for the ensuing 2 weeks, ranging between 103 and 100°F. The cough and dyspnea improved. An x-ray film of the chest showed the same discrete nodules throughout both lungs. The coalescence previously described was no longer present. Examination of the chest at this time was negative.

During the next week the patient felt entirely well except for slight dyspnea on exertion. He remained under observation for the next 4 months, with no change in the chest x-ray or physical examination. During this period he was symptom free and gained 10 pounds. He was

discharged and went back to work as a garbage collector. He has since been seen at monthly intervals. When last seen 7 months after discharge he was feeling entirely well and had gained 20 pounds. X-ray examination of the chest showed slight clearing of the discrete nodular areas of infiltration.

Comment. This is a case of pulmonary sarcoidosis with a superimposed acute inflammatory process that subsided after 2 weeks.

CASE 8. A 52-year-old Negress was admitted because of dyspnea. She had been in excellent health until 1 year before admission, when she noticed dyspnea following exertion. She consulted a physician, who attributed the dyspnea to heart failure. No benefit resulted from treatment with digitalis. The dyspnea became more severe, and she was admitted for further study.

The past history was negative except for a loss of 16 pounds during the year preceding entry.

Physical examination was completely negative.

An x-ray film of the chest (Fig. 9) showed diffuse in-

FIGURE 9. Case 8.

Note the diffuse mottled infiltration throughout both lungs.

filtration throughout all portions of both lungs. Films of the hands and feet were negative. Examinations of the sputum and gastric washings were repeatedly negative for tubercle bacilli. A culture of the sputum was negative for fungi. The red-cell count was 4,730,000, and the white cell count was 4400, with 39 per cent neutrophils, 52 per cent lymphocytes, 9 per cent monocytes, 1 per cent eosinophils and 2 per cent basophils. Urinalysis was negative. The serum albumin was 2.5 gm., the serum globulin 4.3 gm., and the serum calcium 12.5 mg. per 100 cc. An intradermal tuberculin test with P.P.D., first strength, was negative, but with second strength it was weakly positive.

The patient remained symptom free except for dyspnea on exertion. X-ray films of the chest taken 2 and 4 months after admission showed no change.

CASE 9. A 27-year-old Negro had a chest x-ray film taken as a part of a routine examination. He had no

complaints and his physical condition seemed excellent. The film (Fig. 10) showed bilateral symmetrical enlargement of the hilar lymph nodes and small discrete nodules throughout both lung fields. There were also enlarged lymph nodes in the superior mediastinum on the right

FIGURE 10. Case 9.

Note the bilateral symmetrical enlargement of the hilar lymph nodes and the small nodules throughout both lungs.

side. The x-ray examination was repeated 2 and 4 months later and showed no change, and the physical examination remained negative.

Examinations of the sputum and gastric contents were negative for tubercle bacilli. The red-cell count was 5,000,000, and the white-cell count 5200. The serum globulin was 2.5 gm., and the serum albumin 4.5 gm per 100 cc. The sedimentation rate (Ernstene-Rourke method) was 1.1 mm. per minute. Intradermal tuberculin tests (P.P.D., first and second strengths) were negative.

Comment. Although in this case and in the three preceding cases the diagnosis of sarcoidosis was not proved by biopsy, the clinical course and x-ray findings in each case favored this diagnosis.

CASE 10. A 20-year-old Negress developed a nonproductive cough and dyspnea on exertion in June, 1942. She was seen by a physician, who said that she had whooping cough and prescribed various cough medicines. The cough and dyspnea continued, but were not very disturbing. In October, 1942, the patient experienced lower abdominal pain, a vaginal discharge and fever. A diagnosis of acute salpingitis was made by a physician, and one of the sulfonimide drugs was administered. Within 5 days the manifestations of acute pelvic inflammatory disease subsided. During the ensuing 4 months the cough and dyspnea became more severe. The weight in June, 1942, was 196 pounds and in February, 1943, it was 141 pounds. Because of this weight loss, cough and dyspnea, the patient was referred by her physician to a hospital. Following x-ray examination of the chest she

was transferred to the Gallinger Municipal Hospital with a diagnosis of milary tuberculosis.

The past history revealed "rheumatism" at the ages of 13 and 15. Since the age of 17 the patient had had episodes of polyarthritus lasting several days. An appendectomy had been performed at 13 years of age, and a tonsillectomy at 14. She had had a 6-month spontaneous abortion at the age of 16.

At physical examination the patient was well nourished and well developed and did not appear to be ill. She was slightly dyspneic and coughed every few minutes. The temperature was 98.6°F, the pulse 100, and the respirations 35. The only positive findings were occasional subcrepitant rales over the lower halves of both lungs and bilaterally palpable epitrochlear and axillary lymph nodes 1 cm. in diameter.

An x-ray film of the chest (Fig. 11) showed diffuse, discrete and coalescent milary nodules throughout both

FIGURE 11. Case 10.

Note the milary nodules throughout both lungs.

lungs. In the right superior mediastinum there was a large lymph node and in both hilar areas the infiltration was more homogeneous. X-ray films of the hands and feet were negative. The red-cell count was 4,980,000 and the white-cell count 6100, with 51 per cent neutrophils, 31 per cent lymphocytes, 5 per cent eosinophils and 1 per cent basophils. Examinations of five sputums and one gastric washing were negative for tubercle bacilli. Culture of the sputum was negative for fungi. Intradermal tuberculin tests (P.P.D., first and second strengths) were negative. The serum calcium was 11.2 mg., the serum albumin 4.77 gm, and the serum globulin 3.72 gm. per 100 cc. Urinalysis was negative. The sedimentation rate (Ernstene-Rourke method) was 0.6 mm. per minute. A blood Kahn reaction was negative. A biopsy of the right epitrochlear lymph node showed the typical findings of sarcoid.

The patient remained in the hospital for 7 weeks. During that time she gained 10 pounds and felt well except for exertional dyspnea and cough. The temperature was normal throughout her stay. One week after discharge she returned to the hospital complaining of severe malaise,

fever, sore throat and headache of 24 hours' duration. On the evening before admission she had had a shaking chill.

At physical examination the patient was seen to be acutely ill. The temperature was 104°F., the pulse 160, and the respirations 70. Subcrepitant rales were heard throughout both lung fields. A culture of the sputum showed Type 7 pneumococcus, and a blood culture was negative. The remaining laboratory studies showed no significant change from the previous admission. X-ray examination of the chest showed no appreciable change from the previous examination with the exception of a slightly greater degree of coalescence of the nodules.

The patient was given sulfadiazine, and within 48 hours the temperature was normal, the pulse 100 and the respirations 34. She has remained afebrile and asymptomatic with the exception of slight cough and exertional dyspnea.

Comment. This case shows the ease with which sarcoidosis may be mistaken for miliary tuberculosis from the roentgenologic point of view. On the other hand, the absence of severe constitutional manifestations in the presence of diffuse pulmonary disease should lead one to the correct diagnosis. The superimposed bronchopneumonia is not an uncommon finding in sarcoidosis. The polyarthritis may also have been due to sarcoidosis.

SUMMARY

The concept of sarcoidosis as a generalized systemic disease is traced in the literature, and its cause and manifestations are discussed.

Arguments for and against a tuberculous origin of the disease are presented. The syndrome is also found in leprosy.

The fact that neutropenia and leukopenia may occur suggests that a virus is the etiologic agent, but the etiology remains obscure.

Clinically, sarcoidosis is characterized by widespread involvement of organs, with few constitutional manifestations. The commonest initial finding is enlargement of lymph nodes. Pulmonary and bone lesions are common. There is wide variation of syndromes.

The laboratory findings, course, diagnosis and treatment are discussed.

Ten typical cases are briefly reported.

CLINICAL NOTES

THE USE OF DALIBOUR'S WATER IN THE TREATMENT OF SKIN DISEASES

GEORGE E. MORRIS, M.D.*

BOSTON

DALIBOUR'S water has been used by French dermatologists in the treatment of traumatic wounds and pyogenic infections of the skin for almost two hundred and fifty years. A weak solution of copper sulfate and zinc sulfate, it is an excellent astringent, bacteriostatic and deodorant. It deserves more widespread use in this country than it is receiving, both because of its obvious intrinsic worth and because in dermatological therapy it can be substituted with advantage for many of the other heavy metals—aluminum, silver and so forth—that are needed in the war effort.

The name has been spelled many different ways, including "Auillebourst," "D'alibourst" and "D'alibourt." In all official papers, however, the spelling has been "Dalibour," and the latest edition of the French pharmacopoeia has reaffirmed this form.

The water or solution was first described by Jacques Dalibour in 1700.² The formula of the "*l'eau de merveille*" was kept a family secret until 1812, when its composition was revealed in the *Formulaire Magistrale*. It is as follows:

R	Copper sulfate	0.1 gm
	Zinc sulfate	0.4 gm
	Safranine	0.1 gm
	Camphor water	10 cc
	Water	q s ad 100.0 cc

Sig Dilute with three or four parts of water and apply as a wet dressing or compress

When large quantities are to be used, a ten-times concentrated solution is more convenient and economical. This should be diluted before use with twenty to forty parts of water.

The solution is clear, odorless and pink, is as astringent, and has a mild metallic taste. The pH varies from 5.3 to 6.3.

Combes³ has said

The logic of Dalibour's reasoning in compounding this solution is simple and clear. The local therapeutic value of copper sulfate and zinc sulfate was recognized by physicians many centuries before boric acid and aluminum acetate were known. Blue or Roman vitriol water in the fourteenth and fifteenth centuries was extolled as a local wet dressing in cutaneous inflammations and impetigo. The same may be said of white vitriol, which found its broadest use as a

collyrium in inflammations of the conjunctiva. Copper sulfate, in addition to possessing local stimulating and astringent properties, even in high dilutions is bacteriostatic and fungicidal.

Camphor is highly prized in the household as a local sedative. Aqua sedativa is an old item in the *National Formulary*, its antipruritic and sedative properties being dependent upon its camphor content . . .

The simultaneous application of copper and zinc sulfates and camphor by means of Dalibour water affords us an effective bacteriostatic, astringent and sedative solution for use as a wet compress.

Many modifications of the original formula are possible. The addition of 1 per cent gentian violet or 1 per cent brilliant green increases the bacteriostatic properties. Omission of the safranine permits the dispensing of a light blue solution. From 0.5 to 1.0 per cent of formalin may be included to enhance the astringent effect, or alcohol may be substituted for part of the water to further the solution's drying and astringent characteristics. Many similar alterations can be made and will readily come to mind.

When employed in the form of a wet dressing or wet compress, Dalibour's water is an effective remedy for superficial pustular infections of the skin. It is especially useful in the therapy of secondarily infected epidermophytosis, scabies or pediculosis corporis. It is equally valuable in the treatment of impetigo contagiosa, nummular eczema, superficial erosions and varicose ulcerations. Such use effects prompt control of the infectious process, thus permitting early definitive therapy for the underlying condition—scabies, epidermophytosis and so forth.

The water can be incorporated readily in such widely used preparations as lanolin, zinc oxide paste N F, and bentonite paste, or in one of the newer oxycholesterin or glyceryl monostearate creams. The following formulas are suggested:

R	Copper sulfate	0.04 gm
	Zinc sulfate	0.15 gm
	Water	3.00 cc
	Lanolin	10.00 gm
	Zinc oxide paste N F	q s ad 30.00 gm

Sig Apply to oozing parts

R	Copper sulfate	0.3 gm
	Zinc sulfate	0.9 gm
	Urea	12.0 gm
	Aerosol OT (25 per cent)	0.2 gm
	Bentonite	20.0 gm
	Water	q s ad 120.0 cc

Sig Apply to ulcers

As a deodorant it is unsurpassed for the therapy of severe odorous cancerous lesions, condyloma acuminatum or epidermophytosis. In weak dilutions, either as a compress, in a vanishing cream or applied by atomizer to the axillae before bed-

*Junior visiting dermatologist Boston City Hospital, assistant in dermatology Massachusetts Memorial Hospitals

time two or three times a week, it is effective in the relief of hyperidrosis and bromidrosis.

A mixture of copper sulfate and zinc sulfate may be prescribed in powder form for the bath. Thirty parts of copper sulfate and 90 parts of zinc sulfate are mixed and pulverized, and from a teaspoonful to a tablespoonful of the powder is dissolved in water and added to the bath. Such baths are astringent and bacteriostatic and efficiently remove odor from patients suffering with pemphigus vulgaris, ulcerating cancer or other malodorous conditions. The patient is allowed to remain in the tub from ten to thirty minutes. Since elderly patients may develop cerebral anemia and may faint in prolonged warm baths, they should be watched constantly. Unlike potassium permanganate, Dalibour's powder does not permanently stain the tub or skin. Patients who have taken both permanganate and Dalibour baths strongly prefer the latter.

It must not be thought that Dalibour's solution is a panacea for skin diseases. It has proved of no value in deep-seated pustular follicular diseases, such as acne vulgaris, sycosis vulgaris and furunculosis. Solutions of aluminum acetate and silver nitrate have proved better therapeutic agents where astringency is primarily desired, as in non-infected dermatitis venenata, eczema and so forth. Despite these shortcomings, however, Dalibour's water and its many possible modifications are valuable therapeutic agents and deserve more widespread use.

"DRY ICE" BURN OF THE HYPOPHARYNX

REPORT OF A CASE

JOSHIAH E. QUINCY, M.D.*

BOSTON

THE following case of a burn of the hypopharynx is reported because of its unusual

*Assistant otolaryngologist, Faulkner Hospital; assistant surgeon, Massachusetts Eye and Ear Infirmary.

etiology. "Dry ice" (solid carbon dioxide) is a caustic agent, to be classed with lye, in that it may be as dangerous as the latter when it attacks the mucous membranes, particularly in the airway and esophagus. Two similar cases were found in the literature.^{1,2} In the first one, tracheotomy was performed, whereas in the second one, as in the case reported below, the patient recovered without serious complications.

CASE REPORT

W. H., an 11-year-old boy, was admitted to the Faulkner Hospital on May 31, 1942, within 30 minutes after swallowing a teaspoonful of "dry ice" in an effort to imitate his elders smoking. Marked vomiting and expulsion of most of the "dry ice" followed promptly, but considerable difficulty in swallowing and some labored respiration persisted.

Examination of the mouth was negative. There was marked edema of the base of the tongue, hypopharynx and arytenoid cartilages. The vocal cords were normal, and respiration was adequate.

Treatment consisted of absolute bed rest. One teaspoonful of albolene was given by mouth every 4 hours. The taking of food and water by mouth was stopped. Frequent mouth washes with dilute Dobell's solution were given. The patient was closely watched, and a tracheotomy set was kept at hand in case of continued edema of the larynx.

Subsequent progress was satisfactory and the edema subsided within 4 days. Since there was considerable secondary infection, a culture showing hemolytic streptococci, with some elevation of temperature, 1 gm. of sulfadiazine was given every 4 hours, beginning on the 3rd day. After a blood level of 4.0 mg. per 100 cc. had been obtained, the dose was reduced to 0.5 gm. three times a day for 2 days, and then stopped. The patient was discharged June 7 with the temperature normal; he was able to swallow small amounts of fluids with comfort.

Two weeks after the onset, x-ray and fluoroscopic examination of the esophagus showed only a possible delay in swallowing. Since the patient was eating strained vegetables and soft solids with no discomfort, no further examination of the esophagus was made. Indirect laryngeal examination 3 weeks after the onset was negative. The patient felt well, had returned to school, and was eating as usual. Fluoroscopic and film x-ray examinations 3 months after the accident showed no deviation from normal.

MEDICAL PROGRESS

CHEMICAL FACTORS IN INFLAMMATION AND CELLULAR INJURY*

VALY MENKIN, M.D.†

BOSTON

OWING to limitations of time, the following discussion will be confined to certain aspects of recent studies on inflammation in this laboratory. The subjects to be dealt with are the concept of increased capillary permeability and the mechanism involved, which has led to the identification of leukotaxine in inflammatory exudates; the studies on the isolation of the leukocytosis-promoting factor; some chemical factors that condition the cellular picture in inflammation; and a brief review of the latest studies on the factor concerned in explaining the basic pattern of cellular injury in inflammation, which has led to the view that the stereopattern reaction of injury in inflammation is referable to the liberation of necrosin.

Inflammation is a manifestation of severe cellular injury, and as such represents the basis of all infectious processes. It can be readily defined as the complex vascular, lymphatic and tissue response on the part of vertebrate tissue to the presence of an irritant.^{1‡} An irritant may be considered to be any agent that interrupts normal cellular metabolism. It may be physical in nature, chemical or viable, as in the case of micro-organisms.²

Inflammation consists of a number of interdependent sequences that lead to the localization and ultimate disposal of the irritant. These phases are often grouped under the somewhat loose term "inflammatory reaction." Initially, there is a disturbance in fluid exchange, manifested by an alteration in the normal equilibrium of capillary filtration. There is at first, as shown by Landis,³ a transitory increase in capillary pressure, and this is followed by more permanent changes in the structure of the endothelial wall structure—namely, augmentation in its permeability.⁴ The enhancement in permeability can be readily demonstrated by introducing trypan blue into the circulating blood of a rabbit. The area of injury is rapidly stained blue owing to the outward passage

of the dye.⁵ The magnitude of increase in permeability is such as to allow particulated material to pass into the extra-capillary spaces.⁵ The extent of increased capillary permeability is subject to measurement. A number of years ago it was shown that, on introducing a dye into the ventricle of a pithed frog with its mesenteric capillaries exposed on the stage of a microscope,—one could evaluate with an appropriate scale the rate of change of concentration of the dye as it passes out into the extra-capillary spaces.⁶ It was found that with inflammation caused by certain irritants the permeability of capillaries is enhanced about twofold.

LEUKOTAXINE AND THE MECHANISM OF INCREASED CAPILLARY PERMEABILITY

The mechanism of increased capillary permeability in inflammation is an important factor, for it is the pivotal reaction on which all subsequent sequences depend. Lewis⁷ about twenty years ago, stimulated by the work of Ebbecke, postulated that the phenomenon is referable to the liberation of histamine or at least to a substance so closely allied to it that he termed it the "H-substance."⁷ The argument utilized by Lewis is fraught with difficulty, for it is largely one of analogy. For this reason the whole problem was reinvestigated several years ago in this laboratory. It was readily shown that the exudative fluid recovered from the site of inflammation contains a factor in turn capable of eliciting an increase in capillary permeability.⁸ This could be readily demonstrated by the seepage of a dye from the circulation into an area of skin previously inoculated with a sample of exudative material. Subsequently, chemical extraction was undertaken by first eliminating the protein fraction of exudates by treatment with pyridine and acetone. The acetone supernatant phase after desiccation is treated with butyl alcohol. The active material when kept at a low temperature comes down in the butyl alcohol phase after concentrating the latter. The material usually appears in the form of doubly refractive aggregates that at times and with proper desiccation from an aqueous medium appear in the form of needle crystals.⁹ This powerful substance, capable

*The articles in the medical-progress series of 1941 have been published in book form (*Medical Progress Annual*, Volume III, 678 pp. Springfield, Illinois: Charles C Thomas, 1942. \$5.00).

‡Assistant professor of pathology, Harvard Medical School.

The references cited herein pertain primarily to the various studies of the writer. A more complete bibliography appears elsewhere.²

of inducing an increase in capillary permeability in a dilution of 1:100,000, or even in greater dilution, has been termed "leukotaxine." It is evidently not a protein. It has an α -amino group and an indole nucleus. There is evidence that it is a polypeptide to which a prosthetic group may be attached.

Leukotaxine readily diffuses out of a cellophane tube. It has none of the properties of histamine, thereby throwing considerable doubt on the view of Lewis that H-substance is primarily concerned in the mechanism of increased capillary permeability in inflammation. The whole exudate elicits the capillary reaction. Laborious extraction yields a crystalline-like substance that reproduces exactly a pattern similar to that caused by the untreated exudate. Yet the substance has none of the properties of histamine. This to a large extent invalidates the Lewis hypothesis. Leukotaxine, in contrast to histamine, fails to contract the isolated segment of guinea-pig intestine.⁹ Extracting leukotaxine for the possible presence of histamine by the method of Barsoum and Gaddum¹⁰ fails to yield any evidence that the latter is present.¹¹ Leukotaxine fails to depress the blood pressure in a cat, in contrast to the marked depressant effect of histamine.¹² It is evidently not histamine, or acetylcholine, since it fails to lower blood pressure. The following test indicates that it is probably not an adenylic compound. Parnas and Ostern¹³ have reported that adenosine induces heart block in the frog. Leukotaxine completely fails to induce any such arrhythmia.¹² Leukotaxine can evidently induce an increase in the permeability of cells in general, even among lower invertebrates. This is of significance, for it indicates the wide biologic value of this substance. For instance, it increases by about 50 per cent the permeability of the ova of the sea urchin (*Arbacia punctulata*) to sea water. This superficial effect doubtless induces a minor degree of cellular injury, for the fertilization of such eggs is followed by a retardation in cleavage development, together with atypical cleavage.¹⁴ In such ova the fertilization membrane is closely adherent to the cell, and numerous sperms are firmly attached to the membrane.

The increase in capillary permeability induced by leukotaxine has been found to be counteracted by only one substance—namely, the extract of the adrenal cortex—and to a certain extent by some of the steroid compounds derived from the adrenal cortex.¹⁵⁻¹⁷

Leukotaxine is concerned with another fundamental manifestation in inflammation—the migration of polymorphonuclear leukocytes to the site of injury.¹⁸ This is often referred to as chemotaxis. The ideas of Abramson¹⁹ on the subject, al-

though perhaps attractive as such, have unfortunately received little experimental support, either in his hands or in those of other investigators. The conclusions are primarily unsupported assumptions. The views of this worker consist in assuming that negatively charged leukocytes in an electronegative blood stream readily migrate, as in a cataphoretic chamber, into a positively charged area of connective tissue that has previously been injured. Leukotaxine does not as yet explain the exact intrinsic cellular mechanism concerned in the motion of leukocytes, but it at least stands out as a concrete substance, liberated in exudates, that is definitely chemotactic. This fact in itself offers the distinct possibility of attacking the problem further in an endeavor to determine how leukotaxine specifically affects the mobility of white cells so as to induce their migration to the site of inflammation. Whether electric charges have anything to do with the phenomenon remains to be proved. The end product of blood serum extracted for leukotaxine yields no activity so far as cell migration is concerned. On the other hand, leukotaxine derived from exudates is definitely chemotactic, for its injection into tissues induces not only a marked increase in capillary permeability but also a distinct migration of polymorphonuclear cells outward into the area of injury. The chemotactic property of leukotaxine can be easily demonstrated by in vitro observations.² The placing of leukotaxine crystals on a slide containing a drop of exudate is soon followed by migration and clustering of cells at the periphery of particles of leukotaxine. No such effect is observed with either carbon particles or reduced iron powder.

In conclusion, leukotaxine extracted from inflammatory exudates offers a reasonable explanation for two of the basic sequences in inflammation—namely, the mechanism of increased capillary permeability and the local migration of polymorphonuclear leukocytes. Besides these two functions, leukotaxine appears to be relatively innocuous so far as the induction of any appreciable tissue injury is concerned.

THE MECHANISM OF LEUKOCYTOSIS WITH INFLAMMATION

The leukocytosis-promoting factor is another potent biologic substance recently isolated from the site of inflammation. Leukotaxine introduced into the circulating blood fails to alter the number of white cells.²⁰ Yet it is well known that in numerous inflammatory processes the level of circulating leukocytes is considerably elevated. The leukocytosis has been shown to be referable to a chemical unit.²⁰ The injection of whole exudative material into the blood stream of a dog induces a prompt leukocytic response. Neither leukotaxine nor blood

serum is capable of eliciting such a reaction. The evidence indicates that there is a leukocytosis-promoting factor present in inflammatory exudates. This factor in contrast to leukotaxine is nondiffusible, and it is thermolabile.²⁰ Its injection is accompanied by a discharge of immature leukocytes into the circulation. Chemical extraction of exudates

anism of leukocytosis accompanying numerous inflammatory processes. Its marked growth effect on some of the elements of the bone marrow obviously may prove to have clinical implications. These require no further comment.

CYTOLOGIC SEQUENCE IN INFLAMMATION

Another fundamental sequence in the development of the inflammatory reaction is the initial infiltration of polymorphonuclear leukocytes, which are subsequently replaced by macrophages. This is an almost invariable cytologic sequence.²⁷⁻²⁹ With some irritants the polymorphonuclear phase may be lengthened and the macrophage one correspondingly shortened—for example, staphylococcal abscess—or vice versa—for example, the tubercle. Nevertheless, the same basic principle is maintained. Several years ago it was observed

FIGURE 1.

This drawing of a section through the femoral bone marrow of a dog that had received several days previously an injection of the pseudoglobulin fraction derived from normal blood serum shows that the marrow is essentially normal.

yields activity in the pseudoglobulin fraction.²¹ Other protein fractions such as albumin and euglobulin are ineffective in inducing a state of leukocytosis. The material is absent in normal blood serum, but can be recovered from the serum of an animal with a concomitant inflammation.²² This fact suggests that it reaches the bone marrow by way of the blood stream. The material can be obtained from the exudates of dogs and rabbits² and of human beings.²¹

The most recent finding in connection with the leukocytosis-promoting factor is its capacity not only to discharge immature granulocytes into the circulation but also to induce a marked and specific growth effect in the bone marrow.^{25, 26} The result is a conspicuous hyperplasia of some of the hematopoietic elements, notably the granulocytes and the megakaryocytes (Figs. 1 and 2).

In brief, the leukocytosis-promoting factor of exudates offers a reasonable explanation for the mech-

FIGURE 2.

This drawing of a section through the femoral bone marrow of a dog that had received several days previously an injection of 87 mg. of leukocytosis-promoting factor derived from exudative material shows an extensive hyperplastic response replacing the usual areas of adiposity. A mitotic figure is in evidence. The factor seems to stimulate primarily the growth of granulocytic elements and of megakaryocytes.

that this phenomenon is referable to a developing local acidosis at the site of an acute inflammation.³⁰ In earlier studies it was demonstrated that the local circulation in an inflamed area is markedly impaired.³¹ The lymphatic outlets become occluded, and in time thrombi are also found in

the smaller vascular channels. Thus, the area of inflammation becomes, so to speak, shunted from the rest of the organism. It develops its own hydrogen-ion concentration, its own circulation and its own metabolism. The polymorphonuclear leukocytes brought to the site of injury through the action of leukotaxine, as described above, are unable to survive below pH 7.0, whereas the mononuclear phagocytes appear fairly normal at pH 6.9 to 6.8. At a somewhat lower pH all types of leukocytes tend to be injured. The result is a state of suppuration. Pus is virtually a function of the hydrogen-ion concentration. For instance, a twenty-four-hour exudate from the pleural cavity of a dog previously injected with turpentine is primarily composed of polymorphonuclear leukocytes, whereas an exudate of several days' duration at pH 6.5 reveals an absence of normal polymorphonuclear cells. The rise in hydrogen-ion concentration tends to precede the change in the differential leukocyte picture. On the other hand, if the reaction remains alkaline during the development of the inflammatory reaction, the cellular picture is characterized throughout by a predominance of polymorphonuclear leukocytes. That the general effect is an inability on the part of polymorphonuclear leukocytes to survive at an acid reaction has been demonstrated by subjecting leukocytes in vitro to buffers at various hydrogen-ion concentrations.³² In this way it is readily shown that these cells tend to cluster and become swollen with coarse granulation at about pH 6.5. When supravitaly stained, the nuclei take up the dye, indicating severe injury. These changes are absent in cells exposed to pH 7.4.

It is of importance to determine the mechanism of local acidosis with inflammation if one is to comprehend the forces at work in conditioning the cytologic picture at the site of an acute inflammation. The alkali reserve of the exudate tends to decrease with the developing local acidosis.³³ This in itself might be expected to occur, for it is another means of expressing the rise in hydrogen-ion concentration. Incidentally, it is well to emphasize again that all the biochemical changes are local; the reaction of the blood remains essentially unaltered.

The local acidosis seems to be primarily referable to a glycolytic process.³³ The result is a true lactic acid acidosis. Several chemical variables have been studied in the exudate during the progress of the inflammatory reaction. These include the concentration of sugar and of lactic acid and the measurement of the pH, correlated in turn with the cellular picture. The conversion of glucose to lactic acid induces a local acidosis,

with the resulting effect on the leukocytes described above.

In conclusion, the cellular picture in inflammation is primarily conditioned by the hydrogen-ion concentration, which in turn seems to be referable to a disturbance in the intermediary carbohydrate metabolism. The lymphocytes appear to be unaffected—at least directly—by the changes in hydrogen-ion concentration. The function of the latter cells is still somewhat obscure. The studies of McMaster and Hudack³⁴ and the more recent work of Ehrich and Harris³⁵ suggest their possible role in the formation of antibodies.

DIABETES AND INFLAMMATION

The biochemical studies on the relation of hydrogen-ion concentration to the cellular picture at the site of an acute inflammation have led to further extensive investigation in an attempt to unravel the mechanism concerned in the intensifying of the diabetic state when there is a superimposed inflammation in depancreatized dogs.³⁶ Time forbids discussion of the details of this work. Suffice it to say that an inflamed area is a focus of proteolysis. At the site of inflammation in a diabetic animal the breakdown of proteins is considerably exaggerated. Local gluconeogenesis from the deaminated part of the protein molecule readily explains the heightening in blood sugar following the diffusion of glucose previously formed at the site of injury. Close analysis indicates that in general, even in nondiabetic animals, glucose is capable of being formed by injured cells.³⁷ Such cells are therefore potentially foci of gluconeogenesis. The process is merely exaggerated in the diabetic animal. There is also some additional evidence that urea, besides originating in the liver, is likewise formed at the site of an acute inflammation.³⁷

THE CHEMICAL BASIS OF INJURY IN INFLAMMATION

The last phase of the most recent studies to be considered here is the presence of a fundamentally stereopattern of injury in the development of the inflammatory reaction, irrespective of the irritant. The latter and the anatomic location of the lesion may modify its ultimate appearance. Nevertheless, close scrutiny reveals a basic pattern of injury. For instance, damaged cells may show granular elements strewn through their cytoplasm; the cells may be vacuolated; the collagenous bundles may appear swollen; and the nuclei may reveal various degrees of pyknosis. Another evidence of tissue injury found in a variety of acute inflammatory lesions is displayed by the fibrinous occlusion of lym-

phatics and also by the presence of small thrombi in the blood vessels of an inflamed area.¹

It may be asked whether the mechanism that accounts for the basic pattern of injury in inflammation is referable to a chemical unit. Leukotaxine scarcely induces any degree of injury to cells except for an augmentation of cellular permeability. The leukocytosis-promoting factor elicits essentially no injury to tissues. Recent studies, however, have indicated that the euglobulin fraction of exudates is highly injurious to the cutaneous structures of the rabbit and to some extent to those of the dog.³⁸ There is thus an accumulated body of evidence that either in the euglobulin fraction of exudates or else associated with it there is present an injury factor capable *per se* of reproducing the noxious effects seen in inflammation. This substance or factor has for the sake of convenience been termed "necrosin."³⁵ Its injection into the skin of rabbits is accompanied by intense redness, edema and usually a central area of necrosis. No other fractions of exudate appear to be capable of inducing any such effect. Furthermore, the euglobulin fraction of normal blood serum elicits absolutely no appreciable lesion in the skin of rabbits. On the other hand, the same fraction from the serum of a dog with a concomitant acute pleural inflammation frequently induces a severe inflammation. This observation suggests that the toxic substance is absorbed from the site of inflammation into the circulation, whence it can be recovered. This fact is perhaps of significance in re-evaluating the concept of a focus of infection and its far-reaching repercussions to other organs.

Necrosin induces an acute inflammation with blockade of the lymphatics. A section through such an area reveals zones of dense leukocytic infiltration in which the lymphatic channels may be occluded by thrombi.³⁹ Small vascular channels may also show evidence of thrombosis. On the other hand, the euglobulin fraction of normal serum leaves the lymphatic channels essentially patent. About ten minutes after the injection of necrosin into the skin of rabbits the collagen bundles often appear to be swollen, with a tendency to fuse together. The latter seems to be one of the first morphologic evidences of the injurious effect of necrosin on supporting structures.

As stated previously, necrosin can be recovered from the blood serum of an animal with an acute inflammation. This interesting observation, which may reasonably explain the toxic effect of a lesion on organs at a distance, has suggested the necessity of examining the generalized effect on organs of an intravenous injection of necrosin.³⁹ Although several organs, such as the gastrointestinal tract, may show evidence of injury, or various lymphoid structure may reveal signs of enlargement and

congestion, it is nevertheless only the liver and to some extent the kidneys that seem most frequently to exemplify signs of damage. Many of the parenchymatous cells of the liver appear swollen and contain many fat vacuoles. There are interspersed foci of leukocytic infiltration, reminiscent of hepatic focal necrosis. The liver on gross examination is streaked with what seems to be yellowish or whitish foci. In some cases the cell outlines have disappeared and the liver cords are stippled with coarse, black-stained granules that do not take the iron stain. The epithelial lining of the kidney tubules may show irregularities and vacuolation, and foci of leukocytic infiltration separating some of the tubular structures may also be present.

Various investigators^{40, 41} who have studied the problem of traumatic or surgical shock have arrived at the conclusion that one or several toxic substances are absorbed into the circulation from the site of acute injury. It is indeed quite conceivable that in the syndrome of shock there are several such substances, and furthermore that the clinical picture of shock is to a large extent due to some of these substances in addition to superimposed systemic neurologic factors and to an alteration in the blood volume. At any rate, necrosin *per se* fails to depress the blood pressure in a cat, in contrast to the action of histamine.³⁹ It is quite conceivable that in shock the fall in vascular tension is referable to histamine, whereas the other noxious effects are due in part to the liberation of necrosin at the site of injury.

There are two additional properties of necrosin that indicate its significance to the student of pathology. Its intravenous injection into a dog is accompanied by severe toxic manifestations, including vomiting and diarrhea. For a while the animal lies on its side and appears somewhat prostrated. Of greater significance is the abrupt fall in the number of circulating leukocytes, which is usually extremely marked. The white-cell count may fall in an hour or two from about 10,000 to 1000 or 2000. After several hours the dog appears to be clinically improved and the white-cell count rises. Subsequently or on the following day a leukocytosis may ensue. It is conceivable that the latter is a secondary effect caused by the initial injury of various organs by necrosin, which thus allows the release of the leukocytosis-promoting factor. The inability of other fractions of exudate to induce leukopenia suggests that the liberation of necrosin at the site of injury and its absorption into the blood stream are actively concerned in the mechanism of the developing leukopenia accompanying certain infectious processes.

Of perhaps even greater interest is the fact that the intravenous injection of necrosin in dogs is accompanied by a marked rise in temperature simul-

taneous with the developing leukopenia, possibly of 3 to 5°F. The early studies of Grafe⁴² suggested that in infectious processes the fever is referable to the absorption of products of cellular disintegration. Other protein fractions of exudate—for example, the leukocytosis-promoting factor or the euglobulin fraction of normal serum or of ascitic fluid—are all incapable of inducing any fever when injected into the circulating blood of a dog. The fact that necrosin seems to be the only fraction to have this capacity suggests strongly its possible role in the production of fever with inflammation.³⁹

SUMMARY AND CONCLUSIONS

The presence of leukotaxine, the leukocytosis-promoting factor and necrosin in inflammatory exudates offers a reasonable explanation for the development of a fundamental pattern in inflammation. Observations suggest that an irritant irrespective of its nature severely injures cells, which in turn, as a result of their deranged metabolism, liberate various common denominators—for example, leukotaxine, the leukocytosis-promoting factor and necrosin. These substances, which are to be regarded as constant products of marked cellular injury, are responsible for the recognized pattern of the inflammatory reaction.

The salient sequences in inflammation besides the basic injury caused by the presence of necrosin may be recapitulated as follows²:

(1) *Disturbance in local fluid exchange.*

(a) Increase in capillary permeability, which is primarily referable to liberation of leukotaxine.

(b) Initial increase in lymph flow.

(2) *Localization of the irritant (fixation).*

Time has prevented any discussion of this earlier work, which has led to the view that inflammation is the regulator of bacterial invasiveness through its ability to induce blockade¹ of the lymphatics. Thus, the dissemination of a micro-organism bears in large part an inverse function to the induced degree of local injury and a direct function to time.

(3) *Migration of leukocytes.*

(a) The diapedesis of polymorphonuclear leukocytes is referable to the liberation of leukotaxine.

(b) The cytologic sequence at the site of an acute inflammation is conditioned by the local hydrogen-ion concentration.

(c) The leukocytosis in the circulating blood stream is referable to the liberation at the site of inflammation of a pseudoglobulin, the leukocytosis-promoting factor.

The interplay of the foregoing sequences favors the localization and the ultimate disposal of the irritant. This leads to the final reparative phase of the injured area. There are suggestive observations that repair may also be due to the liberation of growth-promoting factors by mildly injured cells.⁴³ Necrosin seems to be released by the cell that is severely injured by an irritant, and thus the appearance of necrosin initiates the inflammatory process. Its chemical separation from the rest of the exudative fluid becomes a necessity in any endeavor to determine whether proliferative or reparative factors derived from probably less severely injured cells are likewise present in exudates. Such studies are now under way.

CASE 29381

PRESENTATION OF CASE

A fifty-one-year-old man, a factory worker, entered the hospital because of acute abdominal pain.

One week prior to admission the patient developed upper abdominal "distress," the nature of which he was not able to describe well. It was apparently not related to food. There was no associated back or shoulder pain, nausea or vomiting, but he was forced to stop working. His bowel movements had been fairly normal with a laxative prescribed by his physician. At the onset of his present illness he contracted a "cold" after removing storm windows. There were no chills, fever, urinary disturbances or chest pain. He had remained in bed more or less constantly. On the night before admission the pain in the abdomen became worse and he developed chilly sensations. He was given a hypodermic by his doctor and sent into the hospital. There was no vomiting. His last bowel movement had been two days before admission, at which time he had two loose stools. He had not passed gas by rectum since then.

Physical examination disclosed a moderately obese man with questionable cyanosis of the lips and fingernails. The skin was moist. The heart was not enlarged. A short systolic murmur was heard in the aortic region, which was not transmitted. The aortic second sound was greater than the pulmonic. The heart rate was regular and of good quality. The lungs were clear. The abdomen was flat. No peristalsis could be detected anywhere. There was voluntary spasm all over, but when the muscles were relaxed by flexion of the legs, there was variable response to palpation—once it was "sore," then "no pain," then "a little tender" and so on. No definite masses were felt. There was no costovertebral tenderness. Rectal examination showed no tenderness or masses. The prostate was slightly enlarged. There was no edema or ascites.

*On leave of absence.

The blood pressure was 158 systolic, 80 diastolic. The temperature, pulse and respirations were not recorded.

Urine examination was negative. Examination of the blood showed a white-cell count of 16,200, with 84 per cent neutrophils. Three hours later the white-cell count was 11,300. A blood Hinton test was negative. An electrocardiogram was interpreted as showing normal rhythm, at a rate of 80, with low T₂ and total inversion of Lead 3; Lead 4 was normal.

A roentgenogram of the abdomen showed considerable gas and fecal material in the proximal colon. The colon distal to the splenic flexure was collapsed. A film taken on the following day in the prone and upright positions showed several dilated loops of small bowel on both sides of the midabdomen as well as a large, single loop of bowel that appeared to be small intestine. There was also a small amount of gas in the colon in the region of the splenic flexure. An upright film showed fluid levels within several of the loops on the right side of the abdomen. There was no air beneath the diaphragm. A barium enema on the second hospital day revealed the passage of barium to the cecum and the terminal ileum without delay. There was a moderate amount of fecal material within the colon that somewhat hindered the examination. No gross evidence of obstruction or definite evidence of ulceration or of a filling defect could be seen. There were two loops of slightly dilated air-filled small bowel in the left midabdomen. Barium passed through the ileum to the air-filled loops of bowel, and one loop gave the appearance of partially encircling a mass over the left side of the lumbosacral junction; the loop in question was somewhat narrowed and irregular in outline.

An electrocardiogram on the third hospital day was normal.

On the third hospital day the patient had a spontaneous bowel movement. Peristalsis was audible, and the abdomen flat. On further questioning it was brought out that the patient had had two former episodes of substernal pressure with radiation down the left arm, lasting three to five minutes and coming on while he was working on a chair. These attacks had been diagnosed as angina pectoris and the patient was advised to live a moderately restricted life. Since then the patient had had no similar episodes.

A gastrointestinal series on the fifth hospital day showed that the passage of barium through the pylorus was very slow. A large residue of barium was seen in the colon, especially in the region of the cecum, which was dilated. There was considerable gas in the hepatic and splenic flexures. Hourly films showed slow passage of

barium to the small bowel, and for a period of three hours no progression was seen. The stomach was almost completely empty at three hours, and all the barium was found to be in a few loops of small intestine on the left side of the abdomen in the region where the air filled loops were visible on the previous examination. At four hours, however, barium had passed through the narrowed loops previously described. Spot films taken over this region showed no definite evidence of ulceration. The narrowing was believed to have been due to extrinsic pressure. At four hours the head of the barium meal was in the region of the ileocecal valve, but had not entered the cecum. No mass could be definitely visualized.

Following the gastrointestinal series the patient was given an enema, with good results. He was seen twice that evening and appeared well. At about 4:00 the following morning he began to complain of gas pains, and another enema was given. Soon after that the patient was found to be sweating profusely. The blood pressure could not be obtained. The abdomen was slightly distended. The pulse was about 120. Examination of the blood revealed a white cell count of 29,800, with 87 per cent neutrophils. Intravenous fluids were given, and a Miller-Abbott tube inserted. The patient's condition apparently improved throughout the day. The following night he passed 50 cc of bright red blood.

The white cell count on the seventh hospital day was 22,300, with 91 per cent neutrophils. The urine showed a ++ test for albumin. The non-protein nitrogen was 44 mg per 100 cc, the protein 58 gm. The chloride was 928 milliequiv per liter, the carbon dioxide combining power 20.6 millimols. The serum amylase was normal. A portable film of the abdomen showed no demonstrable air filled small intestine. The stomach was filled with air, and the colon contained a large amount of barium and considerable gas.

A film taken on the eighth day showed the tip of the Miller-Abbott tube in the second portion of the duodenum. There appeared to be a small amount of gas in the slightly dilated bowel. A large amount of barium was seen in the large intestine. The right side of the diaphragm was elevated, and there were linear areas of atelectasis in the right lower lung field. The abdomen remained somewhat distended. The Miller-Abbott tube was passed to the jejunum, as confirmed by x-ray, and the stomach was kept decompressed by a Levine tube.

The white cell count on the eleventh hospital day was 31,300, the hemoglobin 12.6 gm. The blood protein was 6.0 gm per 100 cc, and the chloride 97.2 milliequiv per liter. A portable film now

showed considerable air in the stomach and some gas filled bowel, presumably the colon. The Miller-Abbott tube lay over the lumbosacral articulation.

The following day the patient passed dark blood by rectum and had some bloody drainage through the Miller-Abbott tube. He became pulseless, comatose and died.

DIFFERENTIAL DIAGNOSIS

DR CARROLL C MILLER. This case seems to be covered with mystery and confusion concerning several of its details. A large part of the discussion concerns itself with the x-ray findings, none of these prove anything, and so far as I can figure out they do not help particularly in making a diagnosis. There are two points that we must ascertain in diagnosing such a problem: the location of the trouble and whether it is intrinsic or extrinsic in relation to the gastrointestinal tract. If it is intrinsic, is it an infectious condition or is it a vascular disturbance? If it is extrinsic, has it ulcerated into the bowel so as to provide us with an explanation of the symptoms and signs? We should like to know about the presence of abdominal tenderness and pain. The temperature is not recorded. The pulse was essentially normal when the patient first came in, but after the shocklike episode on the sixth day the pulse rose to 120. According to the chart before us, five or six days after admission the temperature rose from the normal to 101°F by rectum and stayed more or less at that level without any appreciable change. There was a concomitant rise in pulse and respirations. So we do not have a definite picture of a rising curve or of an intermittent spiking one. We do not know what the hemoglobin was when the patient was first seen, so that we have no way of comparing the last note of 12.6 gm with the former condition.

Since so much space in the abstract has been given to discussion of the x-ray films it might be interesting to see them now.

DR LAURENCE L. ROBBINS. These films are arranged more or less according to the time relation in which they were taken. I have left out those that are not particularly pertinent. It might be said that perhaps the diagnosis should have been made by x-ray. I am not at all sure about that, however.

This is the appearance at the time the patient entered the hospital, with a large amount of fecal material on the right side of the colon. The next day, probably after enemas, we notice that the colon is fairly well cleaned out and that there is this air filled small bowel. The following day a barium enema was given, and the colon is apparently normal. These are the loops of small bowel that

were described as air containing, and you notice that the barium passes up to a point close to the air-filled loops. This loop of ileum appears to go around something (Fig. 1). In the same area

DR. MILLER: How far away from the ileocecal valve would you say this was?

DR. ROBBINS: About 75 cm. An exceptionally large amount of Larium passed into the small

FIGURE 1. X-Ray Film following a Barium Enema.

The abnormal loop of ileum appears to be partially surrounding a mass over the left side of the lumbosacral junction.

you see another loop of ileum that appears to overlie the questionable mass. This loop of bowel is definitely abnormal, I should say. So far as one can tell it is small and probably has some mucosal swelling. I cannot see anything that indicates a definite ulcer. Later films of the small bowel more or less confirm these findings except that there is nothing on which one can make a positive diagnosis of a mass at this time, and the suggestion of the loop of bowel constantly going around something is lost (Fig. 2). In this area, however, the mucosa again appears abnormal and that is confirmed by this spot film. I have seen a similar appearance in the mucosa of the sigmoid in a case of periarteritis nodosa. I am not trying to lead anyone astray, but that is the only similarity I have seen.

bowel. I think you can be sure there is definite abnormality of the mucosa of the ileum.

DR. MILLER: Because of the repeatedly high white-cell count and the high percentage of neutrophils, we must assume that something fairly acute in the way of either sepsis or necrosis was going on, and because of a variation during the investigation, at times distention and at times collapse of the bowel, and also because of the terminal episode of hemorrhage into the intestine, we must presuppose that something was going on intraluminally, which allowed blood to escape into the bowel. It will be hard to make a diagnosis that satisfies both these conditions.

There are several things to think of, but we do not have enough evidence to rule them entirely in or out. A sigmoidal diverticulitis with abscess

and rupture might account for localized peritonitis and for subsequent bleeding from the bowel. A mesenteric thrombosis would account for the signs of necrosis in the small intestine, accompanied by

hemorrhage coming from a mesenteric thrombosis or an internal hernia with strangulation.

The mass that this loop of bowel encircles might be either abscess or retroperitoneal tumor. It is

FIGURE 2. X-Ray Film following a Barium Meal.

The abnormality of the loop of ileum is still visible, but the apparent mass has disappeared.

a high white-cell count and some degree of fever. The chart is possibly consistent with that. It would also account for the terminal bleeding episode. It is not likely that this condition is malignant disease. In the first place, there was no previous history. The man was in reasonably good condition; in fact he was described as being somewhat obese. No masses were felt. However, acute abdominal emergencies are sometimes simulated by extensive metastatic lymph-node involvement in the abdomen because of sudden spread or rupture.

An internal hernia with strangulation of a loop of bowel might account for intermittent obstruction and eventual necrosis of that segment of the bowel, with intraluminal bleeding. I should like to think of the terminal episode as being due to

not likely that any retroperitoneal tumor would also so involve the small intestine as to produce this picture. An abscess can involve the wall of the bowel causing obstruction and bleeding, although it is not likely.

A condition that we often forget but which occurs fairly frequently is a Meckel's diverticulitis. In a Meckel's diverticulum there may be bleeding from a peptic ulcer, and it may also become infected, with rupture. From the x-ray picture it is possible that an abscess had formed around a diverticulum of the small intestine and that the loop of bowel had become involved in that area; there might still have been a communication into the lumen of the bowel to account for bleeding by rectum and by the Miller-Abbott tube.

I think we must postulate an infectious process

in the form of an abscess, with involvement of a loop of small bowel. I think as a best bet I shall say that this patient had a Meckel's diverticulum or a diverticulum of the sigmoid—a solitary one that was not seen by x-ray—accompanied by abscess and hemorrhage through erosion of a large mesenteric vessel.

DR. ROBBINS: I am not at all sure I made myself clear to you, Dr. Miller. The small-bowel studies do not confirm the presence of the mass suggested by the barium enema; the films are not characteristic of bowel going around a mass.

DR. MILLER: Nevertheless, there is a loop that is abnormal, either by distortion or extrinsic pressure.

DR. ROBBINS: It may be intrinsic disease.

DR. MILLER: Of course, a localized regional enteritis is possible, although it is not commonly seen so far back in the ileum as this. Furthermore, I do not believe that in cases of terminal or regional ileitis one often observes a terminal episode such as this patient had, with almost no cachexia or general disturbance.

DR. EDWARD B. BENEDICT: I do not see why this would not go with regional enteritis.

DR. ROBBINS: Would one have acute episodes with it?

DR. BENEDICT: No.

DR. MILLER: One does not as a rule see such a massive lesion as this man had. Furthermore, such patients are usually younger.

DR. RICHARD H. SWEET: As Dr. Miller clearly brought out, I believe there must have been some necrosis of the loop of bowel to explain this picture.

CLINICAL DIAGNOSES

Small-bowel obstruction.

Volvulus?

Intussusception?

DR. MILLER'S DIAGNOSIS

Meckel's or sigmoidal diverticulitis, accompanied by abscess and hemorrhage.

ANATOMICAL DIAGNOSES

Mesenteric venous thrombosis.

Infarction of small intestine.

Hemorrhage into intestinal tract.

Peritonitis, acute, fibrinous.

Hemoperitoneum.

Coronary thrombosis, old.

Arteriosclerosis, marked, generalized.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: At the autopsy we found 3000 cc. of hemorrhagic fibrinous fluid and

blood in the abdomen. The entire jejunum and most of the ileum, to within about 150 cm. (6 feet) of the ileocecal valve were covered with bluish fibrin. Parts of the bowel were obviously gangrenous, and other parts showed beginning infarction. The cause of this gangrene was a mesenteric venous thrombosis. The arteries and arterioles were uninvolved. There was no periarteritis nodosa. The entire intestinal tract was filled with old and recent blood, apparently arising from the massive necrosis of the small bowel, which had terminally perforated into the abdominal cavity.

Most of the cases of mesenteric occlusion that we see are arterial in type and are caused by emboli. The venous type is uncommon and little is known about its etiology. In contrast to the arterial it does not usually come on suddenly with severe abdominal pain.

DR. ROBBINS: Could you find evidence of old infarction?

DR. CASTLEMAN: The thrombi were of various ages, and in some there was definite organization.

The patient also had an old thrombosis of the left descending coronary artery, which accounted for the anginal attacks.

CASE 29382

PRESENTATION OF CASE

A fifty-two-year-old man entered the hospital because of severe pain under the xiphoid.

Five years prior to admission the patient suffered his first attack of sharp upper abdominal, midline pain that lasted four or five hours. He entered a community hospital, where extensive studies were done and reported to be negative. He was discharged after two weeks.

Four years and three years prior to admission he had similar attacks of epigastric pain that radiated to both shoulders and to the upper anterior chest. These lasted six and fourteen hours and spontaneously cleared. Seven weeks prior to admission he re-entered the same hospital because of an attack of pain, but since repeated studies were again negative he was promptly discharged. He continued to have these attacks, and six days prior to admission he collapsed during one of them. These episodes had no relation to meals. At times he found that milk and doughnuts partly relieved the pain, and for several years he had drunk 4 to 5 quarts of milk a day. During the previous three months the pain had often been relieved by induced vomiting. There was no nausea, vomiting, anorexia, fever, chills or jaundice. The stools were never tarry, bloody or clay colored. During the previous year constipation had become bothersome but had always been relieved by cathartics.

The patient had lost 15 pounds during the three months prior to admission.

The family and past histories were noncontributory.

Physical examination disclosed a 250 pound man who seemed very restless. The lungs and heart were normal. The abdomen was markedly distended and tympanitic, but peristalsis was normal. No masses were felt, and no tenderness was elicited.

The blood pressure was 110 systolic, 70 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood revealed a hemoglobin of 90 per cent, and a white-cell count of 10,200, with 77 per cent neutrophils. The urine was nor-

FIGURE 1. Portion of Film Showing an Ulcerated Lesion in the Second Portion of the Duodenum.

mal. The stool was guaiac negative on two occasions. The blood Hinton test was negative. The nonprotein nitrogen was 14 mg. per 100 cc., the protein 75 gm. per 100 cc., and the chloride 990 milliequiv. per liter. The van den Bergh reaction was normal.

A Graham test was negative. A gastrointestinal series disclosed a normal esophagus. The stomach was high and transverse in position but normal in form and function. The duodenal bulb filled to a normal contour. Just beyond the bulb, along the

posterior and lateral aspects of the second portion of the duodenum, there was an ulceration 1 by 2 cm. in size. About this area, and extending downward along the second portion of the duodenum for a distance of 7 cm., there was a rigid area of narrowing, and laterally there seemed to be a rather sharply outlined 2-by-4-cm. defect encroaching on the duodenum, in which the ulcer lay

FIGURE 2. Spot Film Demonstrating the Ulcerated Lesion with Surrounding Edema.

(Figs. 1 and 2). Beyond this the duodenum was of rather unusually large caliber. There was no obstruction to the flow of barium through this area. No definite fistulous communications were observed. There were opacities along the course of the colon, probably residue of opaque material previously given.

A barium enema passed readily from the rectum to the cecum and outlined a normal large bowel.

An operation was performed on the thirteenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. EDWARD B. BENEDICT: Practically the only positive finding we have is that seen on the x-ray film. It seems to me that the case is either extremely simple or extremely difficult, and judging from the comments and the strange looks that the people to whom I have talked about it have given me, it looks a little complicated.

The pain radiating to both shoulders seems unusual, so I spoke to Dr. Chester M. Jones about it since he has written a book on digestive tract pain. He mentioned various possibilities. The heart, from

what I am told, will occasionally give pain radiating to both shoulders, although it is unusual. In this case the heart was entirely normal. Hiatus hernia or other disease of the esophagus with spasm may give pain radiating to both shoulders, but the esophagus was normal by x-ray. Volvulus of the stomach also gives this type of pain, but we have no evidence of that. Gallstones may do it, but the Graham test was negative. The second portion of the duodenum is a rare place for a peptic ulcer, but it may occur.

The fact that there was rigidity of the second portion of the duodenum makes one think of malignant disease in addition to a simple ulcer, but the five-year history is long for malignant disease. It is noted in the x-ray report that the ulcer was situated posteriorly and laterally. Posteriorly the second portion of the duodenum is in relation to the kidney, and it makes one think that possibly this might have been a kidney lesion; but the urine was negative and there were no other signs pointing to a kidney lesion. Laterally the right colic flexure is in relation to the second portion of the duodenum, but the barium enema was negative, which appears to rule out a lesion of the colon that might have perforated into the duodenum. Again, we have the long-standing history that makes a malignant lesion quite unlikely.

Concerning lesions of the pancreas, common bile duct and ampulla of Vater, these organs are all medial, and this lesion was lateral and posterior. Moreover, with a lesion of the pancreas, common bile duct or ampulla, one would naturally expect jaundice. This patient had not been jaundiced. A retroperitoneal lesion other than the kidney, such as sarcoma, might be considered, but the duration seems to have been too long, and I do not believe that I have ever seen one ulcerate into the duodenum.

So we come down to the possibility of simple ulcer of the second portion of the duodenum. These do occur, although they are rare, and everything in the history goes with it. I believe that a peptic ulcer of the duodenum can give pain radiating to both shoulders, which is relieved by milk and doughnuts. He had lost only 15 pounds, which is compatible with a benign peptic ulcer. The physical examination and the laboratory findings contributed nothing. The repeated area of narrowing bothers me, but I think that can go with a cicatricial stenosis associated with a duodenal ulcer. As my first diagnosis, I shall put down benign peptic ulcer of the second portion of the duodenum with cicatricial stenosis, bearing in mind that a carcinoma in that region is also a possibility.

May we now see the x-ray films?

DR. MILFORD SCHULZ: These films of the esophagus and stomach are normal and probably rule out hiatus hernia. The ulcer, which is seen to better advantage on the spot films, lies in this rather constant rounded defect in the second portion of the duodenum.

DR. BENEDICT: Where would you place the ampulla of Vater?

DR. SCHULZ: It should be lower than where the ulcer is, and more medial. This area of narrowing remains quite constant throughout the examination.

DR. BENEDICT: Do you think that it is consistent with a cicatricial stenosis? Or has it got to be a malignant lesion? Or is that not a fair question?

DR. SCHULZ: I should think that either a tumor mass or a scarring of long standing could produce this type of narrowing and constant deformity.

DR. BENEDICT: You are sure it is not medial? It could not be an ulcerating carcinoma of the pancreas?

DR. SCHULZ: No.

DR. BENEDICT: Ulceration of the pancreas is rather unusual on the opposite side of the duodenum. I cannot think of anything else. I shall stick to my original diagnosis.

DR. RICHARD H. SWEET: On a statistical basis would not carcinoma be more frequent than benign ulcer in that location?

DR. BENEDICT: I put that in as a second possibility.

DR. SWEET: I was merely going on the statistical frequency.

DR. BENEDICT: What about the five years' duration?

DR. SWEET: I do not know.

DR. JACOB LERMAN: What about an ulcerating polyp in the duodenum?

DR. SCHULZ: The lesion does not look like a polyp in the x-ray film. It may be a tumor, or it may be just edema of the duodenum.

DR. BENJAMIN CASTLEMAN: The surgeon made leiomyosarcoma of the duodenum as his preoperative diagnosis. Have you anything to say about that?

DR. BENEDICT: I do not believe that I have ever seen one. They are extremely rare.

DR. CASTLEMAN: We have had a few intramural tumors of the second and third portions of the duodenum, but they certainly are not so common as carcinoma or even as peptic ulcer.

DR. FRANCIS D. MOORE: The striking thing about the patient preoperatively was the terrific pain, which was unrelieved by ordinary measures. The diagnosis of leiomyosarcoma was a far-fetched

attempt on the part of the service to reconcile the long history with the existing lesion, with the idea that it might have been a leiomyoma for a period of years and had then undergone malignant degeneration. Dr. Leland S. McKittrick operated on the patient and found a mass in the duodenum that was the size of an orange, a great deal of it apparently being tumor with superimposed inflammatory change. There were no lymph-node or liver metastases. A Whipple operation was performed, the duodenum being removed, the gall-bladder anastomosed to the jejunum, a gastrojejunostomy performed and the end of the pancreas closed off. The specimen was opened and showed an ulcerated lesion with raised margins, which appeared to have invaded the surrounding tissue.

CLINICAL DIAGNOSIS

Leiomyosarcoma of duodenum.

DR. BENEDICT'S DIAGNOSIS

Peptic ulcer of duodenum.

ANATOMICAL DIAGNOSIS

Peptic ulcer of duodenum.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: In the gross we found, 1.5 cm. above the papilla of Vater, a sharply demarcated ulcerated lesion approximately 2.5 cm. in diameter with slightly overhanging edges. As Dr. Moore has said, there was a lot of induration around it, which extended into the surrounding fat. We cut one section through the center of the lesion for microscopic examination and found what looked like a perfectly benign peptic ulcer. Since a peptic ulcer is extremely rare in that location, we went back and made numerous sections of the whole lesion. No evidence of cancer was found, and the final diagnosis was a benign peptic ulcer.

THE GREAT ARCHITECT

His name is Time. He determines what shall survive, be improved or be developed, and what shall be destroyed, be removed or be relegated to a position of social insignificance. He calls to consult with men on all their projects, and even though he is frequently opposed by individuals, with their wealth and their legacies, his opinion eventually prevails. Man has respect for him, and reverence for the endowments that he has the power to bestow. Man watches his track and measures his passage with the utmost precision, in seconds, minutes, hours, days and years. As the years span into longer periods, arbitrary units

are marked off as standards by which men judge their own accomplishments, and with which they vouchsafe the promise of the future.

Tufts College Medical School is now completing such a unit of time; it is fifty years old. Starting as one of many, it has survived to become one of few—there were one hundred and sixty medical schools in this country in 1900, whereas there are but seventy-seven today. Its fifty years have been tumultuous ones in medical education, but from them it emerges an approved school, recognized by all state and national authorities, training one third of the students who enter approved medical schools from the states of Maine, Massachusetts, New Hampshire and Rhode Island, and already backed with a large and vigorous alumni body. Time has firmly established Tufts in the medical life of the country, especially that of New England.

Under other circumstances this fiftieth birthday would be worthy of more pretentious observation than can be accorded it this year. A simple program has been announced, which includes a short series of addresses and a few more intimate occasions, in which there will be participation by students, faculty, graduates and public representatives. A book that permanently records the first fifty years will be issued, and Time will then begin to draw his plans for the second half century.

Having been similarly and generously blessed by the largess of this great architect, the *Journal* extends to Tufts College Medical School hearty congratulations, and best wishes for the years to come.

WARTIME ACTIVITIES ARE DIFFERENT

THE Directing Board of the Procurement and Assignment Service, War Manpower Commission, in its release reprinted elsewhere in this issue of the *Journal*, calls attention to the critical shortage of nurses for wartime needs and to changes in our practices necessitated thereby. As with many other groups it is manifestly impossible to train sufficient nurses soon enough to meet the needs we are about to face. The present likelihood

that we shall be spared the bombing meted out to so many other parts of the world (yet justifiably feared by us a year ago) should not permit anyone to imagine that the national crisis has yet been reached—let alone passed.

The circumstance that so many people have so much more money than they have ever had before, with so much less to spend it on, has operated to produce an increase in demand for medical and nursing services. The only deterrents are the distinctly limited number of physicians and nurses available to supply these services, and the effect of public opinion on those tempted to indulge themselves unnecessarily in the luxuries of being ill. Both these deterrents are effective, but they can and should be made still more effective if the Nation is to muster its full potential effort. The disappearance in Great Britain of all forms of civilian psychoneurosis indicates the degree to which any population may aspire in restricting itself to bare essentials.

The statement that more changes must be planned and executed to place nursing on a wartime basis seems to be an inevitable truth. The American Red Cross has accepted the responsibility of recruiting 36,000 nurses during the coming year, and certain important duties have been assigned to the recently organized Nursing Division of the Procurement and Assignment Service. That pressure may be brought to bear by the War Manpower Commission has been amply demonstrated in other fields, and the Procurement and Assignment Service will undoubtedly reach a point at which its opinion of availability or essentiality for certain nurses will not agree with that of the nurses themselves. When this point is reached, other measures must be devised. These will be more difficult in the case of women than the various ways that have been suggested to coerce men under comparable conditions. When coercion needs to be invoked, however, the method is immaterial: the country has begun to scrape the bottom of its barrel, and there is never much of value to be found among the dregs.

All the changes being brought into field after field by this war are not going to be temporary; they may endure beyond the duration. The thought that "the service of two part-time nurses can equal that of one full-time one" has a corollary, namely, that one full-time nurse can cover the jobs of two part-time ones. It is going to be as painful to decelerate as it has been to accelerate our activities—and there will undoubtedly be some that will remain accelerated. What this war is doing, primarily, is breaking down traditions—both good and bad. The good can be restored; the bad had better remain broken. In the meantime, he who resists the changes of today must prove to the rest of the world that he is not old and decrepit.

MEDICAL EPONYM

GEE-HERTER'S DISEASE

This was described by Samuel Gee (1839-1911), physician to Saint Bartholomew's Hospital, London, in his paper "On the Coeliac Affection," which appears in *Saint Bartholomew's Hospital Reports* (24: 17-23, 1888). A portion of the article follows:

There is a kind of chronic indigestion which is met with in persons of all ages, yet is especially apt to affect children between one and five years old. Signs of the disease are yielded by the faeces, being loose, not formed, but not watery, more bulky than the food taken would seem to account for, pale in colour, as if devoid of bile, yeasty, frothy, an appearance probably due to fermentation, stinking, stench often very great, the food having undergone putrefaction rather than concoction . . .

To diarrhoea alba add emaciation and cachexia, and we have a complete picture of the disease.

Twenty years later, Christian Archibald Herter (1865-1910), professor of pharmacology and therapeutics at Columbia University, wrote a book entitled *On Infantilism from Chronic Intestinal Infection* (New York, 1908). The following summary is found on page 113:

1. There is a pathological state of childhood marked by a striking retardation in growth of the skeleton, the muscles and the various organs and associated with a chronic intestinal infection characterized by the overgrowth and persistence of bacterial flora belonging normally to the nursing period. To this condition may be applied the term "intestinal infantilism."

2. The chief manifestations of intestinal infantilism are arrest in the development of the body; maintenance of good mental powers and a fair development of the brain; marked abdominal distension; a slight or moderate or considerable degree of simple anaemia; the rapid onset of physical and mental fatigue; irregularities of intestinal digestion resulting in frequent diarrhoeal seizures. . . .

R. W. B.

MASSACHUSETTS MEDICAL SOCIETY
DEATHS

STETSON—HALBERT G. STETSON, M.D., of Greenfield, died September 15. He was in his seventy-sixth year.

Dr. Stetson received his degree from the College of Physicians and Surgeons of Baltimore in 1895. Since 1921, he had served as medical examiner, and he was also chairman of the Greenfield school board and president of the Franklin County Public Hospital Corporation. Dr. Stetson was a former president of the Franklin County Medical Society, the New York and New England Association of Railway Surgeons, the Connecticut Valley Medical Association and the Massachusetts Medical Society. He was a fellow of the American Medical Association.

WYLIE—EUGENE C. WYLIE, M.D., of Dorchester, died September 15. He was in his seventy-second year.

Dr. Wylie received his degree from Harvard Medical School in 1895. He had been a practicing physician in Dorchester for over forty-eight years and a member of the staff of the Children's Hospital for twenty years. He was a member of the Massachusetts Medical Society and the American Medical Association.

A brother survives.

WAR ACTIVITIES

PROCUREMENT AND ASSIGNMENT
SERVICE

Under the caption "Wartime Nursing Is Different," the Directing Board of the Procurement and Assignment Service, War Manpower Commission, has recently released the following statement.

It is utterly impossible to provide the necessary volume of wartime nursing service on a peacetime basis. Places where nursing is going on as usual must share with others. Nurses who have not made adjustments to wartime needs for their service should understand the necessity for their participation.

The National Nursing Council has pointed out that the value of any national plan must be judged by its usefulness at the local level, that is, where nurses live and work—in the country and in the villages, towns and cities of the Nation.

Wartime nursing is different! That inescapable fact must be generally accepted by nurses, by physicians and by hospital administrators. Energy and motion now spent in resistance to change must be released for the attack on war-created needs.

Nurses have wrought many changes, but not enough,

in the pattern of nursing service since Pearl Harbor. "We just do the best we can" is heard more frequently than "This is our plan." Generally speaking, educational programs have received more thought than service programs. Acceleration of the basic course in nursing is an outstanding example. State boards of nurse examiners have initiated others.

The principles of good nursing have not changed, but nurses are learning to concentrate on the essentials. In the analysis and administration of nursing service, radical changes are being made. Tremendously valuable assistance in caring for patients is being secured from the Red Cross nurse's aides and other volunteers as well as from paid auxiliary workers.

Thus far nursing service has not been rationed; such rationing would be complicated by the differences in individual nurses and by the degree of essentiality of needed services. Furthermore, the sharing of services is more difficult than the sharing of goods. A critical shortage of nurses exists. Over 36,000 nurses are now with the armed forces and the Red Cross has accepted responsibility for the recruitment of an equal number by June 30, 1944. Our men are receiving skilled medical care of a high order, as shown by the high percentage of recovery from injury. Skilled nursing is an important factor in such care. Then, too, the very presence of nurses near the bases of military operations has repeatedly been described as a potent force in maintaining morale.

There has been an unprecedented increase in the use of civilian hospitals. Hospitals gave 14,250,000 more days of care in 1942 than in the preceding year, and the trend still is definitely upward. This is in keeping with the rapid growth of Blue Cross (group-hospitalization) plans and the Children's Bureau hospitalization program for the care of the families of service men.

Nursing is essential to the nation's health. The national nursing inventories of nursing resources in 1941 and 1943, made by the United States Public Health Service, offer a comparison of data for the two years (Table 1).

TABLE 1. *National Nursing Inventories.*

CLASSIFICATION	1941	1943
Active:		
Institutional	81,708	77,704
Public health	17,766	18,900
Industrial	5,512	11,220
Private duty	46,793	44,299
Other ..	21,276	18,476
Inactive but available	25,252	38,746*
Inactive and not available	90,979	49,829
Totals	289,286	259,174
In Nurse Corps of Army and Navy	6,371	36,000†

*Of these, 23,576 are married and under forty.
†Precise data are not available.

The total number of nurses graduated in the intervening two years is well in excess of the number withdrawn for military service; this fact is not apparent in the inventory. The returns are apparently incomplete. Active nurses who did not return their questionnaires apparently did not realize the profound importance of the information requested. This information is the basis for present planning and safeguarding the future. The relatively small decrease in the number of institutional nurses is much less significant than the increased use of hospitals in

creating the serious shortage of nurses. The increased number of nurses in industrial nursing is, of course, not surprising.

The large number of inactive nurses who reported themselves available is encouraging. But, — they are available for what, — full time or part time? These nurses and others who are still "hidden" can make a valuable contribution to nursing resources. Although it requires a little more planning, the service of two part time nurses can equal that of one full time one. Wartime nursing puts a tremendous burden on all the administrative nurses.

The program of the recently organized Nursing Division of the Procurement and Assignment Service is as follows: to determine the availability for military service or the essentiality for civilian service of all nurses eligible for military service and to submit such determinations to the American Red Cross for use in the procurement of nurses for the armed forces, to promote plans for maximum utilization of fulltime nurses and those who are able to serve only part time, to develop and maintain a roster of all graduate registered nurses, and to develop and encourage sound methods of supplementing the work of nurses with nonprofessional personnel.

Through the War Manpower Commission, nursing will not only have the benefit of the experience in the procurement and assignment of physicians, but means will be found to interpret wartime nursing to physicians and to secure their co-operation in effecting desirable wartime adjustments.

CORRESPONDENCE

BOARD OF REGISTRATION IN MEDICINE

To the Editor: At a meeting of the Board of Registration in Medicine held on July 16, 1943, Dr. H. Quimby Gallup, of Waltham, was re-elected secretary of the Board and Dr. Edward A. Knowlton, of Holyoke, was elected chairman.

Governor Saltonstall recently appointed Dr. George L. Schacht, of Springfield, as a member of the Board to fill the expired term of Dr. Harry L. Stevens, of New Bedford, and Dr. William F. O'Reilly, of Lynn, as a member to fill the unexpired term of Dr. Francis R. Mahony, of Lowell, deceased.

H. QUIMBY GALLUP, M.D., Secretary

Boston

ASPIRATION OF PLEURAL EFFUSIONS AND OF HEMOTHORAX WITH AIR REPLACEMENT

To the Editor: An article in the June 12 issue of the *Journal of the American Medical Association* reflected a dependence in our armed forces on the Potain aspirator, and a device was described for aspiration by means of a piston syringe. Apparently forgotten, however, is the time tested and satisfactory use of a simple siphon tube by which the fluid is made to flow from the chest to a basin on the floor by force of gravity alone.

All that is necessary is an aspirating needle attached to a rubber tube and a clamp or plug to occlude the distal end. The needle and tube are then filled with water and

the tube stopped before sterilizing. After sterilizing, the stopped end of the water filled tube is allowed to rest in a basin on the floor by the bedside, the needle is inserted in the chest, then the clamp or plug is removed and the chest fluid flows down into the basin.

This method was devised by Dr. W. W. Gannett at the Massachusetts General Hospital and was in constant use on his service during my internship in 1902. It has been employed by me, and presumably by many others, ever since in preference to the clumsy and unreliable Potain aspirator.

If one prefers, the process may be started by drawing on a piston syringe attached to the distal end of the tube. This has the advantage of yielding specimens undiluted with water. But when the tube is filled and siphonage established it is much better to allow the flow to continue steadily and gently by gravity alone rather than by intermittent manipulation of the syringe.

It is commonly recognized that in the hemothorax of through-and-through gunshot wounds it is inadvisable to apply simple aspiration with re-expansion of the wounded lung. On the other hand, there is probable advantage in removing the accumulation of defibrinated blood, provided this can be done without expanding the lung. Thus, aspiration with simultaneous creation of artificial pneumothorax is practiced. The following method, which I devised while on duty with the Harvard Unit at General Hospital No. 22, B.E.F., in 1916, was found to be practical and was used extensively at that hospital.

The principle involved is that if a closed, air-containing bottle on the floor is connected with the fluid-containing pleural cavity by two tubes and needles, and if a flow by siphonage from chest to bottle is started in one of these tubes, an automatically equal amount of air will be transferred from the bottle to the chest through the other tube. Thus the fluid in the chest will be replaced by air, but throughout the process the intrathoracic pressure will remain constant.

All that is necessary is a glass bottle of 2-quart size or larger, a two-hole rubber stopper with glass tubes, fitting without air leaks, and two rubber tubes 3 or 4 feet long with an aspirating needle at one end of each, the other ends connecting with the glass tubes of the bottle. The whole assembly is sterilized together.

Some means of starting the siphonage must be provided. The simplest way is to fill one of the tubes with water and to clamp it near the bottle end before sterilizing. An alternative is to insert a three-way stopcock or T-tube and aspirating syringe in the course of the tube through which the outflow is to be started.

For use, the assembled and sterilized apparatus is placed at the bedside. Two points on the chest are marked and infiltrated with novocain — one rather low, and the other about two spaces higher. If any uncertainty concerning the correctness of their location exists, it is well to prove the productiveness of both by puncture with an ordinary syringe and needle. Then the needle of the tube through which outflow is to be established is inserted in the chest at the lower point, the bottle is lowered to the floor and the flow is started. If the water-filled tube method has been employed, one merely releases the clamp after lowering the bottle, and siphonage by the water in the tube will insure a continuous flow from the chest to the bottle. If aspiration by syringe is applied, the tube is pinched or clamped below the T-tube and fluid is drawn into the syringe, then, the tube being released, ex-

pulsion of fluid from the syringe will start the siphonage, which continues by force of gravity. The fluid of hemothorax is so thoroughly defibrinated that the flow is rarely interrupted.

Commonly, in practice, the heart is markedly displaced, so that it may be well to defer insertion of the second needle until this displacement has been somewhat reduced. Soon, however, the air replacement is started by inserting the second needle at the higher puncture-point. By listening with a stethoscope, one can hear the bubbles of entering air, which proves that the system is operating satisfactorily. In due course the physical signs of hydro-pneumothorax appear—tympany above a horizontal level of flatness. The cough of pulmonary edema, which is the usual signal for terminating simple aspirations, seldom occurs, so that usually the flow may be allowed to continue until it ceases.

Both these procedures operate by means of the negative pressure induced by a column of fluid equal in height to the distance between the chest and the floor. Variations in intrathoracic pressure, as measured by a water manometer, are surprisingly slight so that this degree of aspirating force is adequate to maintain a constant flow, since it exceeds by a wide margin any negative pressure that may occur in the chest. Moreover, the steady, gentle flow by siphonage is far less apt to cause disagreeable reactions than is the irregular, more forcible aspiration by other methods. In my opinion, aspiration by siphonage deserves general adoption, not only under primitive conditions for its simplicity but also in the best hospital practice for its other advantages.

FRANCIS W. PALFREY, M.D.

24 School Street
Boston

BOOK REVIEWS

From Witchcraft to Chemotherapy. By Sir Walter Langdon-Brown, M.D., D.Sc. (hon.), F.R.C.P. The Linacre Lecture, 1941. 12°, paper, 60 pp. Cambridge, England: Cambridge University Press, 1941. 60c.

This is a brief but thoroughly interesting story of the increasing means of healing employed in medicine from early witchcraft to the latest triumph of chemotherapy. Dr. Brown shows that the homeopathic dictum that like cures like may be traced to the sympathetic form of magic and that the forerunner of plasters and poultices was a form of contagious magic. He further points out that the old wives' tales concerning magical cures are based on witchcraft, which in turn arose from the fertility cults of organized religion. Herbal remedies were in use because chemistry had not advanced sufficiently to form any basis for rational therapeutics. Only gradually did therapeutics evolve to its present triumphant position. College libraries should find this small book a valuable addition to their shelves.

A Study of the Blood in Cancer, with Special Reference to the Needs of the Tumor Clinic. By O. Cameron Gruner, M.D. (Lond.). 4°, cloth, 100 pp., with 40 illustrations, 4 plates and 32 tables. Montreal: Renouf Publishing Company, 1942. \$4.00.

This is an odd book. It has evidently been written by a man with so passionate an interest in the diagnosis of

cancer that he will sit for long hours in the laboratory studying the many minute characteristics of blood films—fresh, stained, dark-field and so forth. Unfortunately this laudable enthusiasm has probably far outstripped the importance of these hematologic minutiae in the diagnosis and prognosis of cancer.

The author states that by studying the following features of the blood, one may arrive at a tentative diagnosis of cancer and its degree of severity: viscosity (*v*), that is, ease of spread of the blood smear; crenation of red cells (*c*); fibrin formation (*f*); granular matter (*g*); ameboid movement of the leukocytes (*a*); leukocytosis (*l*); pattern formed by the red cells (*t*); agglutinating tendency of red cells (*ag*); rouleaux formation (*ro*); auto-hemolysis (*h*); size of the red cells (*s*). The matter of intracellular granules is also discussed. These features are then qualified by degrees, and one may then arrive at a formula such as the following, which is stated to be an example of cancer:

$$v^5 c^3 f^2 g^5 a^6 l^1 - t^3 (ag^3 ro^6) li^2 s^3$$

That all the above abnormalities may occur in various other conditions, that they are extremely variable and that they depend in large part on technic, cleanliness of glassware and so forth is not overemphasized.

The actual relation of these widely dissimilar features to cancer is by no means proved either statistically or clinically. To confirm or disprove the author's contentions would require years of study and careful statistical analysis. One doubts that it is worth the effort.

Infant and Child in the Culture of Today: The guidance of development in home and nursery school. By Arnold Gesell, M.D., and Francis L. Ilg, M.D. In collaboration with Janet Learned, M.A., and Louise B. Ames, Ph.D. 4°, cloth, 399 pp. New York and London: Harper and Brothers, 1943. \$4.00.

Dr. Arnold Gesell is director of the Yale Clinic of Child Development and has made notable contributions in this field since the clinic was established in 1911. Furthermore, it has become the habit of those working with children to turn to Dr. Gesell's publications constantly for authoritative information about the mental growth of infants and young children. In his latest publication the author has brought together in compact form much of the experience based on the research conducted at the clinic.

The book is divided into three parts. The first is concerned primarily with the broader aspects of the relation of growth to environmental and cultural factors. The second is a detailed description of the growing child. The third is a discussion of growth guidance, and includes much wise counsel in the training of children.

Dr. Gesell portrays throughout this book his sound philosophy concerning children and their relation to the world in which they must live. The book should be of immense value to physicians, to teachers and to anyone interested in children. One rarely finds so much sound scientific information combined with practical guidance as in this book. It can be unreservedly recommended.

Victories of Army Medicine Scientific accomplishments of the Medical Department of the United States Army By Edgar E Hume, MD, DPH, DTM and LLD 8", cloth, 250 pp, with 79 illustrations Philadelphia J B Lippincott Company, 1943 \$3.00

Colonel Hume is well known for his many contributions on the history of the Medical Department of the United States Army. This book is based on lectures given before the College of Physicians of Philadelphia and Johns Hopkins University and on the Beaumont Lecture before the Wayne County Medical Society, Detroit. The volume covers the complete record of the Medical Department and the Medical Museum of the United States Army.

Beginning in 1775, with the War for Independence and extending through World War II up to the present time, details are given in regard to the history of army medicine. Subsequent chapters deal with the *Index Catalogue of the Army Medical Library*, the Medical Museum and the School of Preventive Medicine. Colonel Hume has added, moreover, an analysis of the contributions of the Army to surgery, physiology and epidemiology and to the discovery of various diseases. Naturally, emphasis is put on the work of Walter Reed and William Beaumont, but Colonel Hume has dug out from the records numerous other contributions by various men connected with the service who perhaps are not so well known.

The book is well written, and there are numerous excellent illustrations. Title pages of important books are given as well as photographs of men grouped into certain categories, such as medical bibliographers, pioneers in photomicrography, vital statisticians, ornithologists and meteorologists. An excellent account is given of Colonel John Shaw Billings, one of the greatest of military surgeons. The appendix carries tables, giving a list of the directors of the Medical Department of the United States Army from 1775, of librarians of the Army Medical Library, of curators of the Army Medical Museum and of others. There is also a list of general hospitals, each being named for a physician who served the Medical Department. The place and time of his service and the nature of the work that he did are indicated.

In general, this is an excellent book, covering the field as it has never been covered. Although there have been histories of the Medical Department of the United States Army, particularly the one published in 1929 by Colonel Ashburn, Colonel Hume has written a different type of book—an illustrated history in a semipopular manner, based on sound facts. The book should appeal not only to the medical profession but also to the general public.

Manual of Industrial Hygiene and Medical Service in War Industries Issued under the auspices of the Committee on Industrial Medicine, Division of Medical Sciences National Research Council. Prepared by the Division of Industrial Hygiene, National Institute of Health United States Public Health Service, and edited by William M Gafner, DSc 8", cloth, 508 pp, with 20 illustrations and 5 tables Philadelphia and London W B Saunders Company, 1943 \$3.00

This manual has been prepared by the Division of Industrial Hygiene, National Institute of Health, of the

United States Public Health Service, and presents a comprehensive discussion of industrial health problems involving organization, operation, the prevention and control of disease and the problems associated with manpower shortages. Sixteen well-qualified specialists in various fields of industrial medicine and public health have contributed to the volume, which is a desirable handbook for all engaged in caring for large groups of workers.

A Surgeon's Fight to Rebuild Men An autobiography By Fred H Albee, MD With a foreword by Lowell Thomas 5" cloth, 349 pp, with 10 illustrations and a frontispiece New York E P Dutton and Company Incorporated, 1943 \$3.50

This is an interesting autobiography by a man who has played a distinct part in the development of orthopedic surgery in this country. He is well known for his contributions to bone graft surgery and the development of numerous mechanical devices that have made operations on bones easier and more efficient. His life moreover, has had a certain dramatic quality particularly in his early days for Dr Albee has not been without criticism from his colleagues, while at the same time receiving honors both from scientific bodies and from the public.

The author was born in 1876 near Wiscasset Maine of English and French Huguenot stock. From his grandfather Houdlette, who was an expert cabinetmaker young Albee learned much about mechanical problems and the use of his hands in delicate work. Such problems interested him all his life, and it is not surprising that he became a highly skilled manipulator of orthopedic apparatus with a finely developed sense of surgical technique. He earned his way through Bowdoin College and later attended Harvard Medical School. While there he had intimate contacts with some of the professors and writes about Richard Cabot, J J Putnam R H Fitz A T Cabot and M H Richardson. Under Dr Cabot's direction he worked for Dr Putnam in the old Colby Hydrotherapy Institute, taking blood pressures on patients who were being treated. Dr Richardson kept an eye on this young, green lad from the East, to use Albee's own expression, and made him prisoner with John Homans, in preparation for Dr Richardson's lectures.

After leaving the Massachusetts General Hospital he began practice in Waterbury Connecticut. While there he went to New York City every week to attend orthopedic clinics particularly at the Hospital for the Ruptured and Crippled and the New York Postgraduate Hospital. He soon became well known even abroad and while still in Waterbury, in 1906 he fused the hip joint of a patient by a bone graft. This new method of arthrodesis brought him into the limelight and he was invited to go to Budapest in 1909, while still a very young man, to demonstrate his operation. There he was received with acclaim.

After coming home he worked hard on orthopedic surgery, particularly at the animal laboratory in Cornell Medical School where he was soon made professor of orthopedic surgery. In 1911 he first used living bone as a bone graft in the treatment of Pott's disease. Having his operation on two sound principles that have largely been widely accepted in the first place, Albee stated that the graft must be so fitted that a sound blood supply is re-

sured, and secondly, that the graft must come from the same species.

The rest of Albee's life is possibly of less medical interest although more important, perhaps, to the public. He served in the Army during World War I and afterward. In addition he took an active part in the development of orthopedic surgery, not only in this country but abroad, and helped to establish international orthopedic congresses in collaboration with his foreign colleagues. In 1929, when he was president of the American Orthopaedic Association, he arranged a joint meeting with the British Orthopaedic Association in London. Subsequently Dr. Albee established a private clinic in Florida.

The book is fairly well written, but there are a number of minor typographical errors. The illustrations are in general excellent and facts of considerable historical importance are contained in this volume, particularly in the early chapters.

Brucellosis in Man and Animals. By I. Forest Huddleson, D.V.M., Ph.D. Revised edition. 8°, cloth, 379 pp., with 42 illustrations and 36 tables. New York: The Commonwealth Fund, 1943. \$3.50.

The first edition of this excellent monograph, issued in 1934, carried on the frontispiece the following prediction made by Alice C. Evans in 1918, when she discovered that *Brucella melitensis*, the causative agent of undulant fever, and Bang-Striholt's bacillus, which produced epizootic abortion in cattle, showed a hitherto unsuspected kinship: "Considering the close relationship between the two organisms, and the reported frequency of virulent strains of *Bact. abortus* in cows' milk, it would seem remarkable that we do not have a disease resembling Malta fever prevalent in this country." These words have been replaced by the equally divinatorial ones of Charles Nicolle: "Mediterranean [undulant] fever is a disease of the future."

Keeping the same title Dr. Huddleson's primitive compilation of methods for the diagnosis and study of brucellosis has grown up to a treatise giving, besides detailed technical information, a complete presentation of the historical developments and of the data gathered in recent years concerning the nature, treatment and control of the disease. The book relates that in the United States the reported cases of brucellosis in man have steadily increased from 24 in 1925 to 3427 in 1941. The prophecies quoted above are on their way to realization, since Dr. D. W. Giltner warns that brucellosis in cattle has become already three times as prevalent as was tuberculosis at the time its eradication began.

This edition ought to be read by all public-health officers, since the section dealing with sanitary problems is written by Dr. Giltner, whose qualification in this field is unmatched. Other important improvements have been introduced and recent contributions not heretofore published have been included.

The 1939 edition paved the way from the booklet issued in 1934 to the 1943 monographic presentation, which by no means contains all the information available, since many data and investigations related to immunity have not been included. In this connection, attention is called to a review on immunity that appeared in the June, 1942, issue of *Bacteriological Reviews*. A melting of both sources of information would provide a valuable body of

references. The bibliography, though yet incomplete, already embraces 500 titles. The 1943 revision is not considered by Huddleson himself as the *dernier mot* on the matter treated; however, the untiring efforts of a man who has been studying a disease for more than a quarter of a century deserve the keen interest of and a warm welcome from the research as well as the professional worker.

Synopsis of Pathology. By W. A. D. Anderson, M.D. 12°, cloth, 661 pp., with 294 illustrations and 17 color plates. St. Louis: The C. V. Mosby Company, 1942. \$6.00

This synopsis of pathology concentrates in a brief survey a tremendous number of facts. It shows that the author is able to differentiate essentials and nonessentials, and the restricted bibliographic references at the end of each chapter are well chosen. By means of frequent tables, he makes an excellent synoptic presentation, particularly in the fields of hematology and lymphatic diseases. The chapter on parasites, however, needs some amplification since no mention is made of Bilharzia and cysticercosis.

The illustrations are in general well chosen and well reproduced, but one would prefer for the demonstration of tuberculosis to students a spleen with smaller tubercles than the one which has been chosen and which so closely resembles the illustration of the spleen in Hodgkin's disease. For the purpose of ordinary demonstration of miliary tuberculosis, which is manifest with three to five magnifications, is perhaps the best.

The opinion of the reviewer approaches somewhat that of the old gambler: "Don't gamble, but if you do, take the bank." Thus, the best advice seems to be to use a standard textbook in pathology. A good synopsis, such as that of Anderson, may satisfy the student and prevent his going to the more complete sources of information.

Man in Structure and Function. By Fritz Kahn, M.D. Translated from the German and edited by George Rosen, M.D. 2 vol. 8°, cloth, Vol. 1, 341 pp., with 207 illustrations, and Vol. 2, 397 pp., with 253 illustrations. New York: Alfred A. Knopf, 1943. \$10.00 (set).

This is a popular account of the anatomy and physiology of man, illustrated by a series of remarkable pictures. Based on sound scholarship, a thorough knowledge of physiology and a style suitable for the general public, nothing of its kind has ever before been written. In the reviewer's opinion, the book is by far the best of its type. The pictures are perhaps the most remarkable part of it, and any physician in looking them over is sure to gain knowledge of some of the complex physiologic processes of the body not directly in his special field of activity.

For the public these volumes are indeed a welcome addition to the literature. The book was first published in Switzerland in 1939, and it is greatly to the credit of the publisher that he had the foresight to issue this elaborate two-volume work at the present time. A sound knowledge of the body was never more needed by the American public than now, when the problems of nutrition are in the forefront. The translation from the German is excellent, and the price of the volumes is entirely justified by the contents.

MODERN PHARMACY AND THE MEDICAL PROFESSION*

HOWARD C. NEWTON, Ph.D.†

BOSTON

IT is unique in the meetings of your society for a representative of the pharmaceutical profession to address it. It was only a little more than a year ago—April 6, 1942, to be exact—that for the first time the American Medical Association and the American Pharmaceutical Association met in joint conference at Cleveland to discuss their mutual problems. It is, I believe, this conference that has led to the recent fuller recognition of the value of co-operation between the organizations of the two professions. Medicine and pharmacy have many common objectives, all revolving about the central theme, the preservation of the public health. Active co-operation of the professions will surely aid in accomplishing these objectives.

There is evidence that indicates the concern of each profession for the work of the other in their early days in Massachusetts. It is interesting to learn that the first pharmacist to locate in Massachusetts, Giles Firmin, was the father of the physician who delivered the first medical lectures in this locality.

Giles Firmin, Sr., came to this colony in 1633 from Sudbury, England, where he had practiced as an apothecary. His son, Giles, Jr., had come to this country in 1632 to practice medicine. The father was a valued member of the new community, serving as a selectman and as a deacon of the Boston church. His service was not long, however, as in less than a year he became ill and died.

Giles Firmin, Jr., practiced his profession in and around Ipswich, and it was he who delivered the first lectures in anatomy to students in this country. After some seven years of medical practice he decided that it was not sufficiently lucrative, so he undertook the study of theology. He wrote to John Winthrop about this decision, "I am strongly sett upon to studye diviinitie, my studies

else must be lost; for physick is but a meene help." It is recorded that he completed his studies in theology and returned to England, where he was ordained and settled as a rector. It is not recorded whether he found this occupation sufficiently lucrative, but presumably he did.

A study of the history of Massachusetts in the time of the Firmins reveals that pharmacy, medicine and theology were all highly regarded professions practiced by leaders in the community. The limitations of the practice of each profession were not sharply defined, and in those early times it seems that the pharmacists practiced medicine as well as pharmacy, the physicians practiced pharmacy as well as medicine, and the ministers practiced all three. The point to be emphasized is that the professions of pharmacy and medicine were very close to each other in these early days of Massachusetts.

If one continues to peruse the local history of the two professions, one discovers that the Massachusetts Medical Society made an outstanding contribution to pharmacy when on October 3, 1805, it voted to prepare a pharmacopoeia, which was published three years later. This was undoubtedly one of the events that stimulated the work resulting in the publication of the first edition of the *United States Pharmacopoeia* in December, 1820. The present twelfth revision of this publication is a striking example of accomplishment through the co-operation of the two professions.

The greatly increased interest in drugs and medicines and in uniform standards for them that accompanied the publication of the first *United States Pharmacopoeia* resulted in another important step in the progress of pharmacy in Massachusetts—the founding of the Massachusetts College of Pharmacy in Boston in 1823, the second such institution to be established in this country. This created a substantial basis for the future progress of the profession. Dr. Ephraim Eliot was the dynamic organizer and the first president of

*Presented at the annual meeting of the Massachusetts Medical Society, Boston May 26, 1943.
†Dean, Massachusetts College of Pharmacy

the institution, which was to become the largest college of pharmacy in the world.

In both medicine and pharmacy, education and training at that time were accomplished by the apprenticeship system. It was many years before a formal course of instruction was required for admission to their practice. This apprenticeship system, which may have been excellent in its time, became outmoded with the tremendous advances in the field of science. The professions in Massachusetts were slow in realizing this, and both medicine and pharmacy suffered from such tardiness in recognizing the obvious means by which they could continue to meet their obligations to the public. Medicine finally saw what should be done, and made the completion of a standard medical curriculum the minimum requirement for admission to its practice. Just at that point medicine in Massachusetts began to outdistance pharmacy, which until very recently has been forced to proceed without any such requirement. This has brought about the present condition in which we find that approximately half the practicing pharmacists of Massachusetts have not had the advantage of a good professional education and training in an accredited college of pharmacy. The "poor boy" or "Abraham Lincoln" argument has always been used to influence legislators to keep the requirements for admission to pharmacy as low as possible, in fact the lowest in the United States.

I cannot refrain from chiding the medical profession for its failure in past years to aid in securing sound legislation in the field of pharmacy. It was not until 1941 that a law was enacted that makes graduation from an approved college of pharmacy a prerequisite to admission to the licensing examinations. And even at that late date, at the public hearing held on the proposed legislation, a prominent member of the medical profession appeared against its enactment. The effective date of this law has not been reached, but it is to be hoped that the medical profession now recognizes the value of such legislation and will do all that it can to encourage its enforcement.

You may well ask how it is that without the benefit of favorable legislation the Massachusetts College of Pharmacy has been able to progress through the years and to become the largest college of pharmacy in the world. There are many reasons for this, but perhaps the most spectacular one is to be found in the biography of a prominent citizen of Boston.

It was during one of the final years of the Civil War that a seventeen-year-old boy whose father had been killed in the war came to Boston from the little town of Acton in search of a job. He was hired as office boy and clerk by the drug firm of Weeks and Potter. Showing remarkable ability

and industry, he earned promotions rapidly, and in some nine years he became a member of the firm. His unusual business talent and keen judgment soon led him to organize the Potter Drug and Chemical Corporation, of which he became president. Meanwhile his investments in Boston real estate had grown until he became the city's largest taxpayer. His company became an international organization, and its products under the name of Cuticura were known in all parts of the world. This man, as you have doubtless surmised, was George Robert White.

In 1916, when the Massachusetts College of Pharmacy had outgrown its quarters at the corner of St. Botolph and Garrison streets, its alumni started a campaign for funds for a new building. Mr. White was interested in this campaign and its objective and, realizing that his great fortune had originated in the pharmaceutical field, he first subscribed \$50,000 to the fund. Then, when the alumni had subscribed some \$50,000 more, he became enthusiastic over the possibilities of the project and volunteered to assume the whole cost of the building. His offer was accepted and he personally supervised the construction of the main building of the college on Longwood Avenue, which reflects his artistic taste throughout its halls of marble and bronze. This building cost Mr. White somewhat more than \$850,000.

In order that this fine structure might be permanently and properly cared for, Mr. White donated a valuable piece of downtown business property, the income from which could be expected to be ample for this purpose. Mr. White was not married, and when he died much of his fortune was left to his sister, Mrs. Bradbury. When Mrs. Bradbury died, she bequeathed \$1,000,000 to the college to aid in ensuring that her brother's gift should be maintained and operated as he wished it to be. Thus the Massachusetts College of Pharmacy became the most richly endowed college of pharmacy in the world and has been enabled to offer superior courses of instruction at a moderate cost to its students. It has made it possible for the poor boy as well as the boy of financial means to secure an excellent education and training for the practice of pharmacy.

Pharmaceutical education has made marked and substantial progress during the last twenty-five years, leaving behind it the outgrown apprenticeship and preceptorship, just as did medical education in previous years. The regular undergraduate curriculum of the colleges of pharmacy, as the result of long, careful study and development, is now one of four years and of at least thirty-two hundred hours of intensive classroom and laboratory work. The outline of the curriculum is re-

vised and published under the title, *The Pharmaceutical Syllabus*, and this is respected by educators as a work that is based on an excellent foundation. The content of the curriculum has been derived functionally from a study of the needs of the profession.

Pharmacy today is one of the most important agencies engaged in the preservation of the public health. Its responsibility is to prepare and make available all the medicines, new and old, that the medical profession may require in the scientific treatment of disease, or that may be safely employed by the public as household remedies. In order to discharge this responsibility, a tremendous modern industry has been established requiring pharmacists educated and trained to take their places in manufacturing plants, research laboratories and governmental inspection bureaus, in addition to the distribution outlets such as the thousands of drugstores, the hospitals and the public dispensaries. The modern practice of pharmacy requires a modern education and training in a college of pharmacy that has adequate facilities for its work, comparable to those of the medical school in its field. The pharmaceutical curriculum has been developed with full consideration of these responsibilities and requirements.

First, it is recognized that a good background of knowledge of chemistry is essential for those who would practice pharmacy intelligently. The curriculum provides for this with full courses in inorganic chemistry, organic chemistry, analytical chemistry, qualitative and quantitative, both gravimetric and volumetric, and finally biochemistry. These courses constitute a major subject for the student. Secondly, it is recognized that an equally good background of knowledge of biological science is necessary. This is furnished through full courses in zoology, botany, physiology and bacteriology. Thirdly, there are the courses in pharmacognosy, pharmacology and public health, in which the knowledge of chemistry and the biological sciences is applied directly to the study of drugs. Fourthly, the curriculum has a large group of courses that apply all the previously mentioned divisions of knowledge to the actual preparation of medicines. These are the courses designated under the title of pharmacy, with dispensing pharmacy as the culmination of all of them. This group of courses, as would be expected, constitutes another major subject. Finally, there are included sufficient courses in English, physics and mathematics to enable the student to carry on his studies satisfactorily.

A student who completes this curriculum has the basic education and training required to enter the practice of the profession but in addition nearly all states require at least a year of supervised practice

or internship before entrance to the state licensing examinations. The student who wishes to specialize in some particular phase of the practice may continue his studies in the colleges, take graduate courses, engage in research and earn the highest of graduate degrees.

Even from this brief résumé of the principal features of the pharmaceutical curriculum, it may be readily concluded that modern pharmaceutical education is comprehensive, carefully planned and worthy of the profession for which it prepares practitioners. Further, it may be concluded that these practitioners are educated and trained to assume their share of the great responsibility of those engaged in the preservation of health.

More than ever before, the profession of pharmacy is prepared to render the following services that are of particular interest to the members of your society: to have available in every community an adequate supply of high standard drugs and medicines; to have available the knowledge, skill and equipment necessary for the extemporaneous preparation of medicines prescribed by the medical profession; to have available such a knowledge of the drugs and medicines that, through proper advice, the dangers of misuse may be averted; to have available accurate and reliable information about public health; to participate in research so that new and improved medicinal agents may be made available to the medical profession.

It is on this last division of service that I should like to comment briefly. When one thinks of research, one is inclined to think of the great foundations devoted to it or of the large manufacturers' laboratories that have come into prominence in this field. Sceldom does one dwell on the possibilities of research in connection with the everyday dispensing of prescribed medicines. Yet this form of research, so helpful to the physician and his patient, is a part of the service that modern pharmacy provides, as well as the major research of the large laboratories.

In order to acquaint the members of your society with the scope of this service, the Massachusetts State Pharmaceutical Association, with the cooperation of the Massachusetts College of Pharmacy, is conducting a professional exhibit at this meeting where you may see some of the results of this work. In it you may have observed how a sticky, black tar ointment may be prepared so that it can readily be removed from the skin with warm water, when its removal is desirable. You may have seen how the ordinary sulfur lotion can be prepared so that the particle size of the sulfur is extremely small and the chemical is thus made more effective. You may have visited or tried the

odor of syrup of orange so prepared that it has the attractive, aromatic qualities of the fresh fruit. You may have noticed the solutions for the eye, prepared so that they are isotonic with lachrymal secretions and thereby more satisfactory for use. You may have seen a group of medicines made so that the diabetic patient can take them without difficulty. All these and other medicines in this exhibit are the results of pharmaceutical experimentation and research in connection with the improvement of medicines that you may frequently prescribe.

Colleges of pharmacy are offering this service and are educating and training their students so that they may provide it for the medical profession. Through refresher courses, the colleges are also endeavoring to inform practicing pharmacists of the improvements in compounding that have been discovered, so that they may make use of them.

* * *

In this brief outline of some of the features of modern pharmacy I have attempted to take

you "behind the scenes" of the practice, showing you some of the factors that have retarded its progress and some that have aided it. I have endeavored to show you the objectives of the practice and the nature of the preparation of the practitioners who are expected to accomplish these objectives. I have told you of these things because unfortunately they are not obvious even to many within our own profession. But there are strong forces at work in the right direction, and this direction is definitely toward true co-operation in the preservation of the public health.

With more than 20 per cent of the members of both our professions in military service, the care of the civilian population is a job that can be well done only by co-operative effort; and the same is true of the planning for their care in the postwar period. Both the present war and the future peace dictate the necessity for full co-operation among the medical and related health services.

To the professions of medicine and pharmacy in Massachusetts I commend the motto *Alterum alterius auxilio eget* [Each needs the help of the other].

STUDY ON EFFECTIVENESS OF DIETARY CONSULTATION*

HERBERT T. KELLY, M.D.,† AND MYRTLE SHEPPARD, A.B.‡

PHILADELPHIA

THIS study was undertaken in 1942 among private patients in order to determine the effectiveness of dietary consultation in the correction of poor habits of diet. Eighty-five adult patients, both male and female, of varying ages, selected at random, were chosen for study.

For each of the patients, there was compiled a dietary history that included a record of food habits, dislikes, intolerances and cravings. In addition, each patient was instructed to record his weekly food intake at two different periods. The purpose in having these two questionnaires filled out was, first, to determine the value of dietary consultations and, second, to study food habits. The questionnaire contains a detailed list of types of food, with spaces for the kind and amount for each meal, as well as blanks for food and drinks taken between meals. Notes explain how the amounts are to be recorded, and additional questions cover how foods such as meat, fish, eggs and vegetables were prepared and what amounts of salad dressing were used. Each patient was

given seven such sheets, one for each day, on which to record dietary intake during one week. The first questionnaire was given to the patient at his first visit, and he was shown how to fill it out, meal by meal. When the patient returned the completed food questionnaire, it was reviewed with him, with careful attention to whether the food intake was recorded properly. The patient was then given a proper diet, adapted to his needs and based on the dietary pattern revealed in his week's record. In other words, we used as the building stones for the new diets the former good food habits and, whenever necessary, substituted good food habits for the faulty ones.

A few weeks later, the patient was given the second questionnaire, which he was requested to keep for one week, as he had done previously, recording everything consumed even if all suggestions for dietary improvement had not been followed. When this was returned, dietary suggestions were again made to the patient. It is interesting that, in the case of the second questionnaire, the patients were not nearly so co-operative as with the first. Many were reluctant to record their weekly food intake for a second time, an attitude that we interpret as a challenge

*This study was made possible by a grant from the White Laboratories, Incorporated, Newark, New Jersey.

ures, the dietary findings are not completely accurate and are approximated. However, we believe we have obtained a true picture of each patient's dietary pattern.

pute the dietary amounts of fat and carbohydrate, or of minerals and vitamins, other than those for which human requirements have been established, since the Food and Nutrition Board of the Na-

tional Research Council has not recommended optimum daily allowances for these nutrients.

We then classified the data on these 85 patients to determine how many diets were deficient, before and after consultation, in protein, calories

than did any other group, probably because they had been chronically ill and wished to correct their inefficiency in the daily pursuit of their duties.

We also considered it worth while to determine from the two series of questionnaires how many

FIGURE 1. Dietary Pattern before and after Consultation.

and so forth (Table 1). In the case of niacin (nicotinic acid), we have merely given the number of diets that fell into certain numerical ranges, since data are not available for the niacin content of all foods.

RESULTS

Figure 1 illustrates the improvement in diets after consultation. In all but 8 cases the final dietary pattern was better than the original. Four of the patients whose dietary pattern was not improved by consultation were on reducing and diabetic diets and failed to adopt the dietary recommendations because of previous alcoholism and a craving for rich desserts. Another patient had a respiratory infection and could not follow the suggestions; another, who had cerebral arteriosclerosis, did not understand the therapeutic diet; still another was emotionally disturbed and had phobias regarding the consumption of rare meat (one of the "high-emotional foods"), and of vegetables unless puréed; and the remaining patient was old, with an unchangeable dietary pattern that included the consumption of too few vegetables and too much alcohol.

Interesting was the fact that the male patients co-operated more than did the female patients in submitting the second set of questionnaires. Moreover, those who were intent on gaining weight seemed to follow more of the dietary suggestions

patients daily consumed a pint of milk, one serving of meat and so forth (Table 2). In short, we were interested in knowing how many patients' diets conformed to the dietary yardstick of the

TABLE 2.

CONSUMPTION	BEFORE CONSULTATION		AFTER CONSULTATION

Food and Nutrition Board of the National Research Council, as well as determining several other points of general import.

The various reasons why our patients did not eat enough of the essential nutrients include allergies, ignorance of the importance of particular

foods, indigestibility of a food, constipating or laxative effect of a food, adherence to food fads, supposition that certain foods are fattening and so forth.

In this respect, the survey made by the Committee on Food Habits² regarding reasons for lack of consumption of meat is pertinent. Twenty-one per cent of 5200 subjects questioned, representing a cross section of Americans, thought meat hard to digest; 50 per cent thought some or all meat fattening.

Likes and dislikes of foods are influenced by economic background, esthetic training, traditional conflicts, national, regional, religious and age differences and differences in child-training.³ Why certain persons like one kind of food that is disliked by others is a matter that should concern the clinician and nutritionist interested in improving the nutritional status of those whom they encounter.

Even though 8 of the patients studied did not respond well to nutritional suggestions, the results may be considered good, for in 77 of 85 subjects dietary improvement followed consultation. It is significant that the patients were adults of varying ages many of whose food habits had existed for a long time, since most adult eating habits are extensions of habits formed in earlier years, usually in childhood. According to Dorcus,⁴ "Why one eats or does not eat certain foods and how these habits are modified are questions that raise problems having ramifications that lead ultimately into at least five distinct fields of psychology—physiological, social, comparative, abnormal and that concerned with the process of learning." Today the clinician, being more and more concerned with the psychology factor—since psychogenic disturbances cause so many ills—should record the patient's food dislikes and intolerances and attempt to discover whether the cause is somatic or

psychologic. In endeavoring to change food habits, one should realize that the selection of food is determined by its taste, by its ability to meet a physiologic need and by its novelty.

The results of this study show the importance of the patient's keeping a dietary record that will be reviewed by the physician. We do not consider it important that a second set of questionnaires be submitted. From time to time, it may be worth while for the physician to check the patient's diet to make certain that the changes previously suggested have been put into practice. In fact, such periodic interrogation doubtlessly acts further to encourage patients to correct faulty food habits.

SUMMARY AND CONCLUSIONS

In this study of 85 private patients the prevalence of dietary deficiencies was compared before and after dietary consultation, in order to determine the effectiveness of consultation and to study the food habits of the patients. In all but 8 cases the dietary pattern was improved after consultation. In spite of a second dietary check-up, however, there were still many dietary deficiencies, although the number had decreased considerably. Interestingly, the patients who were underweight were the most co-operative of all those studied.

Although this study was done on only 85 patients, we are convinced that dietary consultations, with check-ups from time to time, are advisable in formulating a good basic diet and in substituting good food habits for faulty ones.

POTASSIUM SULFOCYANATE THERAPY IN ESSENTIAL HYPERTENSION*

ETHEL FANSON, M.D.,† DERA KINSEY, M.D.,‡ COMMANDER ROBERT S. PALMER (MC), U.S.N.R.§

BOSTON

ANY drug whose therapeutic efficacy has been discovered, discredited and rediscovered¹⁻⁴ for forty years, and which is today widely used but is not yet included in *New and Nonofficial Remedies*, bears careful scrutiny, especially since its pharmacology is a subject of some dispute.⁴ Our experience with potassium sulfocyanate therapy covers the past thirteen years.⁵ Without reference to blood levels, the drug when first used was cautiously pushed to obtain a hypotensive action. A satisfactory fall in the blood pressure was regularly obtained in about a third of the patients under well-controlled conditions.⁵ By careful follow-up, toxic reactions were kept minimal in number, although they were at times severe in single cases. The hypotensive action was dependent on continuous exhibition of the drug. Because of the inconvenience of meticulous follow-up and the less than 50 per cent hypotensive effectiveness, potassium sulfocyanate was not regularly used until Barker⁴ and Wald⁶ pointed out the possibility of controlling the relation between toxic and therapeutic effects by following the blood cyanate level.

During the past five years we have followed 100 patients on sulfocyanate therapy for periods varying from a few months to four years. The sex distribution was 62 females and 38 males. The age range was from thirteen to sixty-eight years, 61 per cent of the patients being between thirty and fifty years of age and 20 per cent between fifty and sixty years; 12 per cent were under thirty, and 7 per cent were over sixty.

The patients were classified as Grade I (41 per cent), Grade II (37 per cent), Grade III (14 per cent) and Grade IV (8 per cent), on the following basis:

Grade I (early or mild): There is variable hypertension, the blood pressure ranging from 150 to 200 systolic and from 100 to 120 diastolic, in 23 per cent of cases falling to normal levels (140 systolic, 90 diastolic, or less) with rest or sedatives, and occasionally under stress going above the limits noted. The fundi show

minimal, if any, changes, as represented by narrowing of arterioles. The heart or kidneys show minimal, if any, changes.

Grade II (moderate): There is variable hypertension, the blood pressure ranging from 170 to 250 systolic and from 110 to 130 diastolic, usually at the lower levels, occasionally even lower, but in 11 per cent of cases falling to normal with rest or sedatives. The fundi show arteriovenous compression, narrowing, and caliber changes in the arterioles. The heart shows slight enlargement or prominence in the region of the left ventricle up to moderate enlargement, but no symptoms or signs of actual or impending failure. The urine shows no change or a slight grade of albuminuria and minimal numbers of formed elements in the sediment. The renal function is normal or slightly impaired by concentration and intravenous phenolsulfonephthalein tests.

Grade III (late benign): There is variable hypertension, with the blood pressure almost always over 170 systolic and 110 diastolic, but in 8 per cent of cases falling to normal levels. The fundi show arteriovenous compression, caliber changes in the arterioles, wide light reflexes and exudates or hemorrhages in the retinas. The heart is usually enlarged, often with symptoms of congestive or anginal failure. The urine often shows albumin and casts. The renal function is often impaired, but actual failure (uremia) is unusual. Cerebral accidents sometimes occur. This grade of hypertension is as a rule of many years' standing.

Grade IV (malignant): The blood pressure, especially the diastolic, is usually very high. The symptoms are often of recent onset in a patient almost always under fifty and often under forty, the cardinal signs being edema of the optic disks, with or without exudate and hemorrhage. Cardiac enlargement and congestive or anginal heart failure are often present. Renal impairment and failure are common.

All studies were completed at the initial and subsequent visits during the first one to three months. During this time therapeutics was confined to rest, mild sedation, — usually $\frac{1}{4}$ gr. of phenobarbital four times daily, — diet — often restricted fat and salt — and simple psychotherapy. The last cannot be stressed too much. Close interest was taken in the patient's problems and future. Rather than a brief, general reassurance, an attempt was made to instill doubt into the patient's minds about the fears for his future with which he had been as a rule preoccupied. An optimistic and hopeful attitude on the part of the physician usually engendered the same attitude in the patient. These efforts in 40 per cent of the cases resulted in a fall of 10 to 50 in the systolic pressure and 10 to 30 in the diastolic pressure.

‡Assistant in medicine, Massachusetts General Hospital, attending physician, New England Hospital for Women and Children.

§Instructor in medicine, Courses for Graduates, Harvard Medical School; assistant physician, Massachusetts General Hospital (on leave of absence).

After this initial period of rest, sedative, diet and psychotherapy, potassium sulfocyanate (5 gr one to three times daily) was prescribed, and the blood level was checked at weekly to monthly intervals and, after an established tolerance, once in one to three months. Toxic reactions were carefully explained, the usual ones being written down for the patient's reference.

Taking the group as a whole, an excellent hypotensive action (a fall in blood pressure to below 150 systolic and below 100 diastolic) was obtained in 12 per cent of the cases. A sustained decrease of 30 to 50 systolic and 20 to 30 diastolic was obtained in an additional 16 per cent. Thus, 28 per cent of the cases showed a definite hypotensive action in addition to any fall as a result of diet rest, sedatives and psychotherapy during the initial period. A hypotensive effect was more frequent in females (32 per cent) than in males (21 per cent). The favorable effects occurred in the different grades of hypertension as follows: Grade I 14 of 41 patients (34 per cent), Grade II 8 of 37 patients (21 per cent), Grade III 3 of 14 patients (21 per cent), and Grade IV 3 of 8 patients (38 per cent).

The most notable observation in this series was the additional symptomatic improvement from potassium sulfocyanate therapy after the usual regime of rest, diet, sedative and psychotherapy. This symptomatic improvement occurred in 53 per cent of the cases, and was greatest in Grade I hypertension. The commonest symptom and the one most effectively relieved was headache, usually hemispheric of the migraine type. Often intractable headache unaffected by other measures was brought under control. Other subjective sensations relieved were dizziness, lightheadedness and faintness, such relief being accompanied by an improvement in well being.

Approximately 20 per cent of the patients exhibited toxic effects, for the most part mild, the females showing such effects in a higher percentage (28 per cent) than the males (17 per cent). Patients were repeatedly instructed to omit the drug on the appearance of any untoward subjective sensation. As a result, the blood cyanate level was often lower than the optimum therapeutic level specified by Barker and others.^{4,7} Nevertheless toxic manifestations were kept at a minimum and were inconvenient rather than serious, and maximal symptomatic relief was as commonly obtained with blood levels of less than 8 mg per 100 cc as with those above 8 mg. Of the patients not obtaining additional symptomatic relief from potassium sulfocyanate the majority received the drug in sufficient dosage to obtain a blood cyanate level of 8 to 12 mg per 100 cc and frequently higher.

The hypotensive action of the drug occurred at blood levels less than 8 mg per 100 cc in slightly over half the cases showing this reaction. Frequently the hypotensive action was as marked at lower levels as it was when the level was 12 mg or even higher. On the other hand, of the patients showing no significant response in the blood pressure, 40 per cent showed maximum blood cyanate levels of 8 mg or more and 18 per cent levels of over 12 mg.

The following is an abstract of a case showing a typical hypotensive effect.

CASE REPORT

R D (M G H U 256413) a 35-year-old man was first seen on June 24, 1940 with complaints of headache, blurring of vision and edema of the ankles. The blood pressure was 190/120. The heart was enlarged with a gallop rhythm. There was dyspnea on exertion. Paroxysmal nocturnal dyspnea with red streaked sputum had been present for 3 months. The patient had had acute glomerulonephritis 9 years previously. At later visits over a period of 3 months on phenobarbital, digitalis and aspirin the blood pressure varied from 190 to 220 systolic and from 110 to 130 diastolic. On this therapy headaches continued to be almost intractable. Potassium sulfocyanate therapy (5 gr daily) was begun after 5 months on other therapeutic measures that caused no reduction in blood pressure and no relief of the headaches. At the following visit 2 weeks later there was no reduction of blood pressure but there had been no headaches. The blood cyanate level was 3.9 mg per 100 cc.

Over a period of 1 year on potassium sulfocyanate the blood pressure fell gradually from 210/140 to 140/110 (Fig 1). At no time was the blood cyanate level over 8.3 mg per 100 cc. At the end of that time however great enlargement of the thyroid gland was noted.

The patient was admitted to the hospital and studied exhaustively by the Thyroid Clinic. There was lid lag. The thyroid gland had a very hard consistency. The basal metabolic rate varied from 13 to -17 per cent. Slight exophthalmos was noted. There were a thrill and a bruit over the gland. The patient complained of excessive sleepiness. Biopsy showed an extremely hyperplastic and extremely vascular gland.

At that time potassium sulfocyanate was withdrawn. Two weeks after withdrawal the headaches were severe and the blood pressure had risen to 177/127. Aspirin failed to control the headaches. In 1 month the thyroid gland was distinctly smaller and in 2 months no goiter was palpable and the basal metabolic rate was +6 per cent.

Four months after potassium sulfocyanate was discontinued it was recommenced. The headaches at once improved at a blood cyanate level of 4.2 mg per 100 cc. In 1 month the blood pressure had fallen from 172/127 to 147/99 but the thyroid gland had again begun to enlarge diffusely. In 2 weeks more it was three times normal size. The skin was normally moist but the patient was sensitive to cold. The blood pressure was 136/96.

After 2 months potassium sulfocyanate was again discontinued. Within 1 week the patient had lost his sensitivity to cold, the skin was normal, there was some exophthalmos and the thyroid gland had receded. In another

week the gland was normal in size. The patient was more alert and he was still without headache.

After another month the headaches had returned and the blood pressure was 164/108. Potassium sulfocyanate was again instituted, with prompt relief of the headaches

ing and optimistic and to utilize all resources of simple psychotherapy persuasion, suggestion, advice and direction. In this way the effect of psychotherapy has been separated from the action of

FIGURE 1.

This chart shows the systolic and diastolic blood-pressure levels, the cyanate level in the blood and the potassium sulfocyanate dosage during fourteen months of therapy.

at a blood cyanate level of 3.7 mg. per 100 cc. In 2 weeks the patient felt tired and was intolerant to cold, and lid lag was present. The blood pressure was 140/102. The thyroid gland was two to three times normal size. Again potassium sulfocyanate was stopped, the blood pressure rose, and the headaches returned.

In the past year on the advice of the Thyroid Clinic this patient has taken potassium sulfocyanate together with $1\frac{1}{2}$ to 3 gr. of thyroid daily without enlargement of the thyroid gland and with a blood pressure of 140 to 150 systolic and 90 to 108 diastolic. He has been free from headaches.

In the 3 years since the first examination the blood pressure has been controlled. The patient was given digitalis as well as potassium sulfocyanate, and there have been no notable symptoms of congestive failure, although possibly a slight loss of cardiac reserve. He has tolerated moderate work and even heavy lifting, and is continuously employed.

SUMMARY

One hundred patients with essential hypertension have been treated with potassium sulfocyanate during the past five years. This drug was given after a careful control period during which all the usual therapeutic measures were employed. Since patients with essential hypertension usually appear to be susceptible to suggestion, both favorable and unfavorable, an effort was made during the control period to be reassuring, encourag-

ing and optimistic and to utilize all resources of simple psychotherapy persuasion, suggestion, advice and direction. In this way the effect of psychotherapy has been separated from the action of the drug. The latter has been used cautiously and toxic effects have been kept to the minimum—20 per cent of the patients—but the hypotensive action has not been notable. A fall to normal or near normal occurred in only 12 per cent of the cases, and a sustained fall, although by no means to normal levels, was obtained in 16 per cent, a total of 28 per cent.

Symptomatic relief ascribable to potassium sulfocyanate alone was obtained in over half the patients, and the symptom most effectively relieved was headache, especially the very severe, intractable sort. The relief of headache is in our opinion the most valuable attribute of the drug.

Our care to avoid the toxic effects of what we consider a dangerous drug whose action is incompletely understood often prevented us from obtaining what others consider optimum therapeutic levels. Nevertheless, of the patients in this series who did not obtain additional symptomatic relief from potassium sulfocyanate, the majority attained blood cyanate levels of between 8 and 12 mg. per 100 cc. and frequently higher. Furthermore, the hypotensive action occurred in blood cyanate levels of less than 8 mg. in slightly over half of those showing this reaction. Also, of the patients showing no hypotensive action, 40 per cent

attained blood cyanate levels of 8 mg. or more, and 18 per cent levels of over 12 mg.

The case reported illustrates the better sort of result on the level of the blood pressure and on the symptoms, maintained over a three-year period during exhibition of the drug. During this time, with the additional help of digitalis, congestive failure has been controlled and at this writing the patient is gainfully employed at moderately heavy work. This case illustrates also the goitrogenic effect of potassium cyanate, the details of which are fully discussed elsewhere.⁸

Only 2 of the cases of goiter were observed in this series, both of which receded promptly after withdrawal of the drug and did not recur on readministration of the drug.

CONCLUSIONS

Potassium sulfocyanate is a potentially dangerous drug because its pharmacologic properties are

not fully understood and because the therapeutic and toxic blood levels are too close and vary too widely in different patients.

The greatest usefulness of potassium sulfocyanate therapy in essential hypertension consists in the relief of severe, migraine-like headache.

MEDICAL PROGRESS

PHYSIOLOGY*

HEBBEL E. HOFF, M.D.†

MONTREAL, CANADA

PROBLEMS confronting a physician in wartime are not always new, but are often old ones acquiring new significance from the necessity of pushing personal performance far beyond the limits of normal peacetime activity, as, for example, in aviation. The attention they attract may also arise from the increased importance of certain types of disability. Thus, seasickness, which may only occasion distress in peacetime, may endanger life or may threaten the success of a military venture.

The problem of fatigue is important for both the above reasons. There is an increased and increasing demand for exertion, so that one may expect the incidence of fatigue to rise, and the costs of fatigue in terms of output and efficiency must be calculated in terms of winning or losing the war. The seriousness of the problem may also be gauged by the amounts spent by the American public on pharmaceutical products and beverages advertised as possessing antifatigue properties.

Fatigue may be defined as the progressive diminution in output resulting from the repeated performance of a given action. Such a definition is

limited, and not in accord with all pertinent data. It is limited in being conceived as a direct and proportional result of work. It fails to recognize the compensatory mechanisms that may operate to maintain output despite fatigue. Most important, however, is its failure to define the subjective aspects of fatigue, which according to some authors¹ constitute the essential feature of the condition.

The site of fatigue has been the subject of much interest, and for a number of reasons workers have been in a large measure preoccupied with the muscles.² From muscle physiology of an earlier period come two concepts that have until recently had a prepotent influence on views concerning fatigue. The first is that the various physiologic systems operate by virtue of stores of energy that are dissipated by effort and must be restored by rest. Thus, the authors of an account of chronic exhaustion in test pilots³ speak of stores of "nervous" energy that become depleted by mental strain. The second legacy from muscle physiology of a past era is the concept of fatigue products or metabolites arising from activity, which accumulate and reduce performance. There is of course no doubt that muscles are subject to fatigue, although in the presence of an adequate blood supply and at a reasonable rate of stimulation—for example, a

*The articles in the medical progress series of 1941 have been published in a book form (*Medical Progress Annual*, Volume III 678 pp. Springfield Illinois Charles C Thomas 1942 \$5.00).

†From the Department of Physiology McGill University, Montreal
Head of Department of Physiology McGill University

maximal twitch every two or three seconds—the vigor of contractions is maintained at a relatively high level for a considerable time. With newer knowledge of the chemistry of muscular contraction, it becomes increasingly difficult to account for fatigue on the basis of accumulation of lactic acid or disappearance of muscle glycogen.⁴⁻⁶

The myoneural junction is perhaps more susceptible to fatigue than is the muscle itself, and failure of transmission at this point may account for diminution in muscular response in normal persons, as it does in victims of myasthenia gravis. The reflex centers in the spinal cord may also become subject to fatigue, especially when reflexes are elicited in too rapid succession. On the other hand, some reflexes are surprisingly little influenced by fatigue, and I have observed a single neurone discharging in the crossed-extension reflex for more than an hour without any signs of fatigue. There is considerable evidence that rhythmically discharging neurones do not become fatigued and fall out, to be replaced by other units (rotation).

When voluntary muscular effort is suspended because of fatigue, it is known that the motor apparatus is still capable of reaction, and in fact most ergograph records of a rhythmic series of muscular contractions carried to the point of fatigue show a characteristic increase in the vigor of contraction as a final effort before contractions cease.⁷ In this case the limiting factor is the central nervous system, presumably the cortex, acting under the influence of stimuli arising in the exercising muscle, which give the sensation of fatigue, exhaustion or pain. Anoxia and excessive or prolonged contraction per se are possible factors responsible for the sensory stimulation.⁸

Just what part this type of fatigue plays in the various daily occupations is not precisely known. There may be types of work in which limited groups of muscles are thus fatigued and subsequently rested many times a day; this undoubtedly occurs in persons handling tools to which they are unaccustomed. It must be less frequent in workmen who have become adapted to their tasks. On the whole, in the group of occupations calling for moderate exercise at a rate of no more than three times the basal metabolic rate, there is no evidence of this type of muscular fatigue.⁹

When the amount of muscular work is pushed to higher levels,—for example, eight or more times the basal metabolic rate,—muscular fatigue may well limit the duration of exertion. The breaking point may be determined by the muscles themselves, but frequently a limit is set by the inability of the cardiovascular-respiratory system to furnish an adequate supply of oxygen to the exercising muscles, as shown by increasing dyspnea and a

rapid rise in the pulse rate. Hypoglycemia may also determine the breaking point, through its influence on the brain rather than on the muscles, which are relatively insensitive to lack of blood sugar.

Finally there remains what is perhaps, in civilian life, the largest category, characterized by the clear absence of excessive muscular effort. Here are found the afternoon fatigue of the worker doing moderate work, the chronic fatigue of the housewife and the exhaustion of the test pilot.³ Intercurrent infections, anemias and subclinical vitamin deficiencies may well play a part in such cases, but psychologic factors most often predominate. Here, according to Bartley,¹ conflict and frustration constitute the basis of fatigue.

Treatment must be directed by an analysis of the type of fatigue in each case. Rest is the basic treatment in all types, but the duration and frequency vary. A pleasant environment, adequate diet and interesting social activities, often combined with physical activity, are essential parts of the rest period. As more is learned of the psychologic aspects of fatigue, it is being recognized that such factors as rest periods, the taking of food during working hours and a variety of other changes in working conditions operate in a substantial measure through psychologic rather than direct physiologic mechanisms. This is strikingly illustrated in a table published by Dill⁶ showing the output of a group of skilled persons working under carefully controlled conditions. It is noteworthy that practically every alteration led to an increased output; even returning to earlier conditions resulted in increases. The conclusion seems valid that optimal working conditions may be determined by factors other than purely physiologic ones, such as work and rest periods, food, lighting and heating. It can probably be assumed, however, that in the study mentioned above these factors were adequate from the start, and there is evidence that even with great motivation, output cannot be maintained if the working hours are excessively long.

A number of measures have been proposed to reduce fatigue or hasten recovery, and because of the war they are now receiving added attention. Three of these are dietary factors: carbohydrate, gelatin and vitamins.¹⁰

Hypoglycemia is not usually considered to be a factor in fatigue except as a terminal sign of exhaustion after severe and protracted exercise. When carbohydrate is available for fuel, exertion at a maximum level may be continued longer than when carbohydrate is not available, and workers have reported that ingestion of dextrose increases the ability to perform muscular work after exhaustion.¹¹ Carbohydrate feeding during rest periods has been observed to increase mechanical

efficiency in workers not subject to such extreme demands. This improvement has been attributed to psychic factors on the ground that the energy output of these workers is not sufficient to cause any significant fall in blood sugar. Hellebrandt¹⁰ concludes "that extra carbohydrate is clearly advantageous to the machine only when the work done approaches peak capacity, and that the use of sugar as a recuperative is physiologically rational only when the activity is sufficiently prolonged and vigorous to produce a hypoglycemic state." Actually, sugar is advantageous to the human machine, and is rational whenever blood sugar falls to hypoglycemic levels, whatever the type of activity or emotional state that produced the fall. The observation by Michael¹² that the blood sugar may reach low levels during a game of golf indicates that one cannot be too dogmatic about the degree of activity required to induce hypoglycemia.

Portis¹³ suggests that hypoglycemia may be a factor in the genesis of fatigue noted in neuropsychiatric patients, and believes that hyperinsulinism resulting from overactivity of the vagus nerve supply to the pancreas is responsible. He claims that there is often substantial clinical improvement on a dietary regime in which carbohydrate is not taken in the form of simple sugars and is accompanied by appropriate doses of thiamine and atropine.

An antifatigue action has recently been claimed for gelatin (60 gm. a day by mouth), but the more recent reviews on this subject indicate that evidence to this effect is not yet entirely convincing.^{11 14}

In reports of subclinical deficiencies of the vitamin B group, fatigue is one of the most pronounced symptoms, and improvement on administration of the vitamins has been noted. Just how widespread borderline vitamin deficiencies may be among workers, and how effective vitamin therapy on a wide scale would prove to be, are purely conjectural matters. Undoubtedly extensive experimentation with vitamin preparations in industrial groups is now proceeding, and definite information on this topic will some day be available. Experimental studies by Egaña et al.¹⁵ on sedentary workers taking a diet grossly deficient in thiamine indicated that deficiencies could be established within four weeks. They state that symptoms "were mild and vague, the most constant being easy fatigue, loss of ambition and loss of efficiency in daily work. There was moderate deterioration in the subjects' physical fitness for exhausting exercise, and, particularly, poor recuperation between bouts of exhausting exercise." It is hard to evaluate the subjective factors in this experiment, controls with addition of adequate amounts of vitamins to the diet unknown to the subjects and with placebo therapy not being reported. Well-controlled

studies by the same group¹⁶ on manual laborers exposed to a diet deficient in the vitamin B complex showed that the subjects began to suffer within five days a serious impairment of their fitness for sustained hard work.

Among the inorganic salts reported as of assistance in delaying the onset of fatigue are both alkalis and acidifying agents. Sodium chloride is of course invaluable in circumstances where there is salt depletion, to prevent muscular cramps. Although the success of salt therapy is most apparent in industries where work is done at high temperatures, even taking part in strenuous athletic contests may well lead to salt depletion to a harmful degree, and the danger must also be present in many military operations. Potassium salts have an antifatigue action on muscle and on neuromuscular transmission.¹⁷ They have been used in the treatment of familial periodic paralysis and myasthenia gravis, but not of fatigue.

Hellebrandt and Karpovich¹⁰ have reviewed the pharmaceutical substances advocated at one time or another to increase work or lessen fatigue. Oxygen administration prior to a strenuous but short-acting effort, such as swimming one hundred yards, seems to be helpful, mainly by increasing breath-holding ability, which permits the development of more powerful arm or leg action.

The observation that the cardiovascular system is often a limiting factor in maximum exertion has led to the use of digitalis, Coramine and Metrazol to improve maximum performance. Reports favoring the use of Metrazol are extensive.

There is general acceptance of the ability of caffeine, amphetamine (Benzedrine) and allied compounds to ward off fatigue. Apparently amphetamine is more potent than caffeine, and both operate through the central nervous system rather than directly on the muscular system.¹⁸⁻²²

The asthenia and fatigue so characteristic of Addison's disease have prompted the use of extracts of the adrenal cortex to prevent fatigue or promote recovery. Statements both claiming and denying effectiveness of cortical extracts have been made as a result of studies in normal animals and in man.¹⁰ Much better established is the influence of adrenalin or stimulation of the sympathetic nervous system to postpone fatigue or hasten recovery. Their action may be directly on the muscle, on the cardiovascular system or on the level of blood sugar.

Training is undoubtedly a key to the prevention of fatigue. Its effect is exerted both on the maximum rate of work output and on the quantity of work done.²³ The curve of maximum rate naturally tends to flatten out, and rigorous training is required to increase it thereafter. On the other

hand, the quantity of work done may increase enormously. Six to twelve weeks of daily training resulted in increases of as much as 4000 per cent in work output when the work was done at the rate of one fifth horsepower, and training increased total output 50 to 400 per cent when work was done at one half horsepower.²⁴ Other authors report comparable increases. Despite a voluminous literature, the physiology of the process remains uncertain. The muscles participate in the process, but so also does the cardiovascular system. Just what changes the heart itself undergoes remains questionable. The fact that a trained person responds to exercise with less increase in the heart rate than does an untrained person may be ascribed to changes in the heart itself or to alterations in the nervous system. Whatever the cause, this response, with the rate of deceleration of the pulse after exercise, constitutes one of the mainstays of tests of physical fitness.²⁵⁻²⁸

EFFORT SYNDROME

Discussion of fatigue and the response of the heart to exercise in trained and untrained persons naturally leads to a consideration of the so-called "effort syndrome," in which fatigue is again an outstanding complaint, and in which the heart re-

sponds to effort with an exaggerated increase in rate. If to these two signs are added breathlessness and left inframammary pain, the outstanding features of the condition have been mentioned. Wood²⁹ has listed the salient signs and symptoms of the syndrome as shown in Table 1. It has occurred to numerous observers that such a list of symptoms and signs might well be produced as the result of a widespread disturbance in the nervous system, including overaction of certain parts of both the sympathetic and the parasympathetic nervous system, muscular spasm in the muscles of the left pectoral region and alteration in respiratory movements. Secondary effects from over-ventilation are thought to account for many of the signs and symptoms, including dizziness, tendency to syncope, paresthesia, sweating and shortness of breath.^{30, 31} Although it is evident that hyper-ventilation may play a major role in producing symptoms in some persons, it may not be present at all in others; in fact, hypoventilation may occur.³²

There is a growing tendency to consider the effort syndrome as a psychoneurotic manifestation. Miller and McLean,³³ discussing the status of the emotions in palpitations and extrasystoles, say:

Palpitation is a biological manifestation of fear in the face of danger. The increased pulse rate and intensified heart action make the individual subjectively aware of the increased activity of the heart. Situations which produce palpitation involve an immediate urge to activity and at the same time a fear of it. Common examples are: palpitation experienced upon receiving a rebuke from one's superior, taking an examination, going to a forbidden amatory rendezvous and the like. In all of these situations the individual is driven by his active, ambitious attitude into an apparent danger at the same time he feels an urge to avoid. His flight is blocked.

Writing on the psychologic treatment of cases with cardiac pain, Bourne and Wittkower³⁴ take much the same position:

The data obtained confirm the view put forward previously that in cases of functional cardiac pain the pain is nearly always due to transformed anxiety arising from a conflict, unusual in intensity and abnormal in type, between menace to vital feelings and existence on the one side and self-preservation and self-assertion on the other.

It has repeatedly been remarked that the victim is often more than normally conscientious, which perhaps is of some significance from the psychologic viewpoint. The frequent and remarkable distaste for alcohol and the low incidence of venereal disease observed in victims of effort syndrome may be associated phenomena. On the other hand, it must be recognized that infection and general constitutional insufficiency are also frequent etiologic factors. Studies of the work output in the effort syndrome indicate that the reaction of patients with "true effort syndrome" is like that of convalescents from toxic-infective conditions and of constitutionally weak persons, and differs significantly from the response in those with hysteria and in the so-called "anxiety group."⁷ In a certain sense the effort syndrome may be considered to be an extreme response of "untrainedness," and the gen-

TABLE 1. Symptoms and Signs of Effort Syndrome.

SYSTEM	SYMPTOM	SIGN
General	Fatigue	Typical facies
	Nervousness	Nervous manner
Vasomotor	Palpitations	Overactive heart
	Vascular throbbing	Tachycardia
	Dizziness	Blood pressure above 150/90
	Headache	High deceleration time after exercise
	Syncope	Cold, blue hands
	Paresthesia	Visible flushes
	Flushes	Hyperpnea and tachypnea
Respiratory	Breathlessness	Frequent sighs
	Sighing	Breath-holding for less than 30 seconds
Sudomotor	Undue sweating	Palmar and axillary sweating
Muscular	Cramps	Tremor and shakiness
	Trembling and shakiness	Poor development
	Left thoracic pain	Hyperalgesia over area of pain
Gastrointestinal	Dry mouth	
	Anorexia	
	Vomiting or diarrhea	
Others	Insomnia	
	Frequency of micturition	

erally, the quantity of work done may increase enormously. Six to twelve weeks of daily training resulted in increases of as much as 4000 per cent in work output when the work was done at the rate of one fifth horsepower, and training increased total output 50 to 400 per cent when work was done at one half horsepower.²⁴ Other authors report comparable increases. Despite a voluminous literature, the physiology of the process remains uncertain. The muscles participate in the process, but so also does the cardiovascular system. Just what changes the heart itself undergoes remains questionable. The fact that a trained person responds to exercise with less increase in the heart rate than does an untrained person may be ascribed to changes in the heart itself or to alterations in the nervous system. Whatever the cause, this response, with the rate of deceleration of the pulse after exercise, constitutes one of the mainstays of tests of physical fitness.²⁵⁻²⁸

erally favorable response to careful training bears out this view.

PHYSIOLOGIC AND CLINICAL TESTS OF AUTONOMIC FUNCTION AND BALANCE

However satisfying it may be to be able to ascribe the majority of cases of effort syndrome to a noncardiac etiology, the physiologist is as yet unable to give an account of the manner in which each part of the intricate symptom-complex is developed. It is apparent that the autonomic nervous system is implicated, and that a cortical representation of that system exists through which the various peripheral effects may be mediated. Beyond this there lies a broad field for detailed study. The recent review by Darrow³³ entitled the "Physiological and Clinical Tests of Autonomic Function and Autonomic Balance" should prove to be a useful guide.

The problem is complicated by the following facts. In the first place, regulation in the sphere of the autonomic system occurs through the activity of two antagonistic divisions, sympathetic and parasympathetic. Although most tissues receive a double innervation, this is not universally so. Further complication is added by important exceptions to the rule that the sympathetic division is adrenergic and the parasympathetic cholinergic. Secondly, although in general there is reciprocal control of the two divisions in the central nervous system, this is not invariable, and increased activity of one division cannot be assumed to be accompanied by an equivalent reduction in the activity of the other. This is particularly so in states that impose severe strains on the organism.^{36, 37} And, thirdly, the existence of buffer or moderator mechanisms, such as the carotid sinus, adds further complications, in that these mechanisms respond to changes in autonomic activity in certain spheres by setting up vigorous reactions in an opposite direction.

These difficulties are surmounted in part by techniques that, so far as possible, isolate a single system for study. Some structures, such as the nictitating membrane of the cat, have but a single innervation. Sweat glands have only a sympathetic innervation, although their secretory fibers are cholinergic. The adrenal glands themselves are innervated by preganglionic fibers of the sympathetic nervous system, justifying the use of circulating adrenaline as an index of sympathetic activity. Other tests aim at the same effect by utilizing preparations in which one of the nerves supplying an organ is sectioned or in which the activity of one division is suppressed, as by atropine or ergotoxine. Other indices of autonomic activity employ a diametrically opposite maneuver, in which an end organ is sensitized to one or another division of the autonomic system. Drugs such as eserine or cocaine

may be employed. A particularly ingenious method is that of Beattie, Brow and Long,³⁸ who have sensitized the heart to sympathin by the administration of low concentrations of chloroform vapor. The sensitization of skeletal muscle to acetylcholine has been employed in the monkey by Bender³⁹ to reveal the liberation of that substance during emotional activity. The assay of circulating acetylcholine and adrenaline is a technic frequently employed, whereas a fruitful modification, developed particularly by Nachmansohn,⁴⁰ is the assay of acetylcholine esterase.

Darrow's suggestion that exercise-tolerance tests may be included in the category of tests of autonomic balance is worthy of consideration. In the Schneider test, for instance, low reclining and standing pulse rates are important factors in obtaining high scores. These factors, as well as the pulse-rate increment with exercise and decrement after it, are potent indications of autonomic activity, and indicate the intimate connection of physical fitness and autonomic activity.

EXPOSURE TO COLD

Warfare in cold climates and on the ocean at low temperatures has emphasized the need for physiologic studies of the influence of hypothermia, either of the body as a whole or of the extremities. Fortunately, the work of Fay⁴¹ had already contributed much to the renewed interest in the problem.

One of the most interesting phases of this development has been the reinvestigation of the response of the normal unanesthetized body to cold. The work of Cannon, Querido, Britton and Bright⁴² emphasized the dual nature of the response to cold. On exposure to cold, or when a heat deficit was produced by the ingestion of ice water, an increase in metabolism occurred, through which the deficit was made up. This increase in metabolism consisted of a moderate (13 or 14 per cent) increase in metabolism, which was regarded as due to the liberation of adrenaline, and a secondary and greater elevation induced by shivering. Objections to this evidence for a chemical factor in the augmented metabolism resulting from exposure to cold were based mainly on the difficulty of judging the moment when shivering begins.

Recent experiments, in which the onset of shivering is judged by electrical records, indicate that chemical augmentation of metabolism may not invariably be present.⁴³ The careful work of Hemingway and Hathaway⁴⁴ on trained, unanesthetized dogs places a limit of about 7 per cent on the augmentation of metabolism that occurs without shivering. An extremely interesting report is that of Odum,⁴⁵ who developed an ingenious

device to record motion in nestlings and in unhatched bird eggs. He demonstrated that homeothermic behavior does not begin until the young bird is able to shiver in response to cold. It appears that some birds are precocious in their ability to maintain the body temperature when hatched. These birds gain the ability to shiver some time before hatching. The chick appears to possess the ability to shiver at or shortly after birth, but this mechanism is not able to maintain the body temperature with efficiency until several days after hatching, presumably with the development of feathers, increased metabolism and body temperature and a more stable thermoregulator center.⁴⁶

Pinson and Adolf⁴⁷ have shown clearly that after moderate heat loss, induced by the ingestion of ice water, a nude man exposed to a room temperature of 30°C. makes up the heat deficit, solely by diminution in heat loss without increase in metabolism. On closer inspection these findings seem to accord with the experience of Cannon and his co-workers,⁴² who noted that with high environmental temperatures minimal increases in heat production occurred. Evidently heat deficits at lower environmental temperatures are required to evoke chemical augmentation of metabolism. Sex differences have also been noted: women evidently show a marked decrease in metabolism as the environmental temperature is raised, whereas men do not.⁴⁸ Apparently heat loss by sweating is less important in women than in men. The possible mechanism of the chemical regulation to be inferred from this observation has not been discussed.

In the procedure of artificial induction of hypothermia for therapeutic purposes, rectal temperatures are lowered to from 28° to 33°C. At these temperatures shivering, voluntary muscular activity and a muscular rigidity of undetermined nature are still present. Probably for this reason the metabolic rate remains above normal.⁴⁹ Blood tends toward acidity and becomes less fully saturated with oxygen. Below 30°C., possibly because of anoxia, and possibly because of reduction in blood sugar,⁵⁰ shivering begins to fail. With disappearance of shivering, production of heat diminishes and it is reasonable to assume that a further fall in body temperature will proceed with greater rapidity.

The anoxia at low body temperatures has been noted also in animals artificially cooled, and attention has been called to the possibility that many of the mental changes in hypothermia are due to anoxia.⁵¹ Walther's⁵² observation in 1862 that artificial respiration applied to rabbits cooled to 18°C. permitted their recovery even if they were left in a cool environment (10 to 12°C.) suggests that anoxia might have been responsible for the failure to

survive of animals not so treated. Randall⁴⁶ has recently observed that chicks normally cease breathing when cooled to 15°C., the heart continuing to beat at temperatures as low as 8.5°C. He states, "Administration of 100 per cent oxygen into the trachea and out by way of a punctured abdominal air sac maintained a respiratory rhythm (6 per minute) at a temperature of 10°C., indicating that hypothermic death is primarily caused by anoxic paralysis of the respiratory mechanism." There is a strong suggestion from this work that measures of revival after exposure to cold should include oxygen therapy and possibly the intravenous administration of glucose.

The renewed interest in the anesthesia and the peripheral vasoconstriction associated with hypothermia, probably first noted by Walther,⁵² has led to the introduction of local cooling, sometimes in conjunction with tourniquets, in the treatment of injuries of the extremities. Reduction of pain, prevention of bleeding, limitation of exudation, postponement of tissue necrosis by reduction of local metabolic requirements and, above all, prevention of shock are the advantages sought in this treatment. Reports^{53, 54} on the subject to date are promising, but indicate that the procedure cannot be used conveniently except on the limbs, and that cooling is not a particularly successful treatment for shock following trauma to a limb, although it appears to lengthen the survival period.⁵⁵

The cutaneous vascular responses to cold have been studied with improved technics by Hertzman and Roth.⁵⁶⁻⁵⁸ The initial response to cold is vasoconstriction. There is a reflex component, restricted to the small vessels, and found in both cooled and noncooled regions. This response is reinforced by further, delayed constriction in the same vessels in the cooled areas only, and by constriction of the large arteries in the cooled parts, apparently as a direct result of the cold. After five to sixteen minutes of vasoconstriction, a period of vasodilation supervenes. It appears after sympathectomy and after section of sensory fibers, but not after their degeneration. It has been attributed to the liberation of a histamine-like substance that excites an axon reflex. This suggestion is supported by the observation that in certain cases of excessive vasodilator response to cold, desensitization with histamine or treatment with histaminase affords a measure of relief.^{59, 60}

REGENERATION OF NERVOUS TISSUE

The ability of nerve cells to regenerate severed axons is another subject of physiologic interest receiving renewed attention as a result of the war. A recent review by Young⁶¹ provides a general account that includes most of the newer work on the subject. Evidently, the essential factor making

regeneration of function possible after severance of a peripheral nerve is the survival, in the peripheral segment of the nerve, of Schwann cells, which maintain their integrity and form small tubes down which the regenerating fibers may grow. The Schwann cells also play a leading role in bridging the gap between the cut ends of the nerve, thus providing a scaffold down which the new nerve fibers are led. Young discusses the various attempts to bridge large defects by nerve grafts to provide such tubular channels. Among the most successful of these attempts is that of De Rezende,⁶² who finds that homografts are not necessary and that formalin-fixed and stored nerves serve equally well.

The relation between rate of growth and restoration of function in regenerating nerve has been studied but little. Recently Berry, Grundfest and Hinsey⁷³ have measured the rate of conduction in regenerating fibers and have found that the fine newly regenerated fiber conducts at the slow rate of a few meters a second, and that as it grows in diameter it becomes capable of more rapid conduction. The relation between rate of conduction and fiber size discovered in adult nerves is thus found to hold for regenerating fibers.

The favorable influence of acetyl- β -methylcholine and Prostigmine on the rate of recovery of function after alcohol blocking and section of the sciatic nerve in cats⁶⁴ may indicate that the rate of growth of the regenerating fiber is increased by acetylcholine and allied compounds. It may, on the other hand, indicate a prompter recovery of function in the motor neurone supplying the cut axon. This latter supposition is strengthened by the observation of Ward and Kennard⁶⁵ that recovery of function after ablation of Areas 4 and 6 in the monkey is hastened by a similar treatment. Recovery of function in this event can hardly be expected to depend on regeneration of nerve fibers.

NEW HAMPSHIRE MEDICAL SOCIETY

PROCEEDINGS OF THE ONE HUNDRED AND FIFTY-SECOND ANNIVERSARY

House of Delegates, May 10 and 11, 1943 (Concluded)

THE report of the Committee on Medical Education and Hospitals was then presented.

Report of the Committee on Medical Education and Hospitals

The preoccupation of all our members, with the added demands on our time and energies, and the similar conditions prevailing throughout the country have reduced the scope of this report to perfunctory dimensions.

We have no data on past postgraduate medical education or plans for the immediate future beyond the hope that if anyone can foresee the opportunity he will consider the Commonwealth Fund fellowships.

As this is written, there is still some uncertainty whether there will be fellowships available this year for physicians in New Hampshire. The amount appropriated for Commonwealth Fund fellowships this year was considerably reduced over that available in previous years, and this amount was made available with the understanding that preference would be given to applicants from the states in the South in which the Fund is carrying on its public-health program. If the number of applicants from these states is insufficient to exhaust the funds available, applicants from New Hampshire may be considered.

Because of the war situation, the number of courses available at Harvard has been somewhat reduced, but application may still be made for a month's work in obstetrics to be taken during any month in the year; for internal medicine during the month of October; and for pediatrics during the month of November or a short intensive course of two weeks' duration during August. The usual stipend of \$250 for the month's course, plus reimbursement of tuition and necessary travel expenses to and from Boston, will be offered. For the short intensive course in pediatrics, the stipend will be at the rate of \$10 a day.

It is our recommendation, however, that anyone who can anticipate finding the necessary time should make application as usual in the hope that a fellowship may become available.

JOHN P. BOWLER, *Chairman*
JAMES W. JAMESON
HERBERT L. TAYLOR

Dr. Peters, of the Committee on Officers' Reports, moved the adoption of this report; it was so voted.

Dr. Peters then read a letter from Dr. Dolloff, of the Committee on Mental Hygiene, stating that the committee had no report to make, because of pressure of other matters and a paucity of ideas among the members of the committee. The Committee on Officers' Reports moved the acceptance of this report. The motion was carried.

The next report was that of the Committee on Public Health.

Report of the Committee on Public Health

This is the second year that the Committee on Public Health has functioned. Having started to grow up, the members are becoming conscious of the many duties that beset our particular group. War has already devastated many sections of the world, and in most living-rooms are the empty seats of sons or daughters who are already serving with our fighting forces. These facts tend to bring home the thought that we have a tremendous job ahead of us in supplying, in ever-increasing amounts, the many products necessary to carry on this titanic struggle. Of itself this obligation seems large, but add to it the needs and necessities of our allies and the proportions become so great as to be staggering; yet these are our commitments and we will carry through. This means of course a proportionate drain on man power, particularly in the industrial fields, which have constantly been depleted of their youth by the need of these men in the fighting forces. Older men and women have had to take their places in the workshops of the nation.

Loss of time means loss of ships, ammunition and other supplies vitally needed for the successful progress of the war. The industrial-health program is one of the prophylactics by which we hope to meet our responsibilities and to keep our war effort constantly on the increase.

In New Hampshire there are few companies capable of having a full-time medical department; however, many can and do have the part-time service of a doctor, with

possibly the full time services of a nurse. There are many other suggestions, such as the combined or joint services of a doctor among several different plants or units and so forth, all of which will have to be worked out in accordance with the particular set up under consideration.

The promotion of better health among our workers through education regarding sanitary and safety methods in plants, together with improvement in hygienic conditions in the workers' homes, should be part of our contribution toward victory. This can be organized along the many lines set forth by the Committee on Industrial Health of the American Medical Association, with modifications to suit our particular needs.

Your committee recommends that although our industrial efforts in New Hampshire are small as compared with those of many other states, we should keep informed on national industrial activities as they pertain to the medical man. In part this can best be accomplished by representation at the Annual Congress of Industrial Health, and the dissemination of the information gained through this meeting to our members in New Hampshire.

Using this as a basis we can spread out in our activities as our needs and circumstances permit.

HARRIS E. POWERS

Dr Metcalf then presented the report of Dr Powers as the delegate of the Society to the Fifth Congress on Industrial Health. He added that copies of the report were available to members of the Society who wished them.

Dr Peters for the Committee on Officers' Reports, recommended that the House of Delegates extend their appreciation to Dr Powers for his excellent and comprehensive report. He said that it reflects the diligence and interest applied to the papers of the meeting, and emphasized the increasing importance and value of this committee to the Society.

This motion was carried.

Dr Peters said that it was further recommended by the Committee on Officers' Reports that the House of Delegates approve continued representation at the Annual Congress of Industrial Health, and that the expenses of such delegate again be defrayed by the Society. He moved the adoption of this portion of the report.

Dr Metcalf questioned how much value the report had, adding that it had cost the Society over \$100. Dr Sycamore asked Dr Metcalf whether the cost of the report included all expenses. Secretary Metcalf replied that the total cost was \$125 including about \$25 for printing and \$100 for traveling and hotel expenses.

The motion was put to a hand vote and was lost. Speaker Parsons in answer to the question whether the enabling act could be carried out without a meeting of the House of Delegates, by sending the proposition to each delegate, stated that he could find nothing in the constitution or by-laws that covered the matter but that Chapter XV of the by-laws read

For the purpose of transacting any important business which the by-laws do not permit, the by-laws may be suspended by a unanimous vote of those present and in executive session either in the House of Delegates or in a General Session.

It would be necessary, he said, to suspend the by-laws temporarily and vote unanimously to take a vote on the proposition for the medical service corporation in that way. The by-laws did not permit the action of the House of Delegates except when in active session.

Dr Johnston moved that the by-laws be temporarily suspended for the purpose of taking a nonassembled vote on this question when the committee was prepared to present it.

Dr Parker said that the matter was of enough importance to be disposed of quickly, so that it might be possible to get a quorum at a special meeting called by the President when the time was ripe.

Dr Johnston suggested getting the consensus of the members present as to how they would react to coming to a special meeting, and some idea of how many would attend it, before entertaining any motion. The majority of those present indicated by a hand showing that they would attend. In view of this, Dr Johnston then withdrew his motion, and its second agreed.

There was no report of the Committee on Public Relations or of the Committee on Scientific Work. The next report was that of the Committee on Tuberculosis.

Report of the Committee on Tuberculosis

The phenomenal progress which has been won during the past period of twenty years in the reduction of mortality and morbidity from tuberculosis in New Hampshire and throughout the Nation is now seriously menaced. There is real danger that this fight against a devastating foe of mankind which has met with such dramatic and encouraging success in its new meet with reverse.

The more hopeful workers in the campaign among whom is the chairman of your committee, are of the opinion that we cannot be certain of continued substantial reduction in mortality and morbidity within the next few years. However, it is our belief that the gains already won can be held and perhaps even further slight declines achieved. Other workers and observers have expressed the belief that the annual reductions are at an end and that definite increases are inevitable.

The reason for these forebodings is, of course, the effects of total war on the physical and mental stamina of the people with resultant lowering of resistance and consequent tendency to development of tuberculosis.

Alarming increases in the diseases are known to be occurring in all the countries at war in Europe. One of our leading public health authorities who has studied the European situation states that tuberculosis will become a plague affecting approximately 10,000,000 persons in Europe after the war.

A three per cent program by which the United States

could help check this anticipated plague has been outlined as follows:

- (1) Governmental and private agencies dealing with tuberculosis in this country can appraise the problem and develop the control program, for which public or private funds or both could be used.
- (2) Many American physicians and x-ray technicians who are gaining tuberculosis experience and training with the armed forces during the war could be used for postwar service abroad.
- (3) Some of the vast amount of equipment acquired by the armed forces for the chest x-raying of men entering the services could be assigned or contributed to foreign service after the war.

Wartime increases in tuberculosis are reported in England, Wales and Scotland. Particularly significant is the fact that, whereas the increases in tuberculosis deaths in adults is only 15 per cent, the increase in children approximates 45 per cent. A large part of this increase is due to tuberculosis meningitis in children. This increase indicates that English and Welsh children have been coming more and more in contact with open cases of the disease at a time when their resistance was lowered by change in diet, unaccustomed environment, poor milk, lack of sleep and frequent retreats to air-raid shelters, where the spread of tuberculosis is so easily facilitated.

In Canada the tuberculosis death rate increased in 1941.

In the United States the tuberculosis death rate in 1941 was 44.4 per 100,000 population. This figure represents a decline from the rate of 45.9 in 1940. Preliminary data for 1942 imply that the slight decline in the death rate may continue throughout our first year at war. A far different result may be the case, however, if the war should last several years and if the American people should be subjected to conditions that approximate those now prevailing in England.

During the past year a committee appointed by Governor Blood made a study of the tuberculosis situation in New Hampshire. The committee was assisted by Dr. Herman E. Hilleboe, surgeon-in-charge of Tuberculosis Control, States Relations Division, United States Public Health Service, who made a survey at the sanatoriums at Glenciff and Pembroke, the New Hampshire State Hospital, the Laconia State School, the Mary Hitchcock Hospital, the New Hampshire Tuberculosis Association and several other organizations.

As a result, many recommendations were made for the further development of the tuberculosis-control program in New Hampshire. These include the following: an addition to the State Sanatorium at Glenciff to take care of all patients requiring hospitalization and treatment, including chest surgery; the mass examination of all industrial workers in the State in co-operation with management and labor; the co-ordination of the activities of the several interested institutions, organizations and state departments through a representative advisory council; and the placing of the control over admittance to and continuance of hospitalization in the institutions in the hands of the State Department of Health.

The committee's report urged that tuberculosis-control efforts should be concentrated among "males 35 to 65 years of age—the persons who provide the backbone of our man power during the present emergency and the principal source of infection today."

Governor Blood in this message concurred, telling the Legislature that the greatest incidence of tuberculosis now is found in this age group, surveys in other states having

detected the disease in 1 per cent of those examined. Experience also has found that 60 per cent of those cases found were in the minimal stage, when treatment is most effective. Also pointed out was the net result that the effect of such a program would be to decrease tuberculosis in the State to the vanishing point within a few years, though showing a temporary increase at the start, which would tax the facilities available for treatment until the reduction could make itself felt.

The Industrial Hygiene Division of the State Department of Health and the New Hampshire Tuberculosis Association are now engaged in developing this program. Management and workers in a number of industries have been enlisted in several parts of the State. In the beginning, 14-by-17-inch film will be used, but plans are to secure a semiportable 35-mm. x-ray unit or a 4-by-5-inch mobile unit, which will enable the entire program to be more rapidly developed. The State Department of Health and the New Hampshire Tuberculosis Association appeal to the members of the New Hampshire Medical Society for their active support in the development of this important phase of the tuberculosis-control program.

The slogan of the sixteenth annual early-diagnosis educational campaign of the National Tuberculosis Association and its affiliated organizations is, "Follow the Example of the Armed Forces—Get a Chest X-Ray." The slogan draws attention to the fact that every man examined for the armed forces has an x-ray examination of his chest. The objective of the 1943 campaign is to emphasize that chest x-ray examination among the civilian population is just as important, and that the successful carrying out of this program can hasten the eradication of the disease.

Your committee urges more frequent use of the chest x-ray films by the physicians in New Hampshire, particularly for all patients presenting any symptoms that might suggest tuberculosis, for all who have lived or worked with a person who "took sick" with tuberculosis and for pregnant mothers. The New Hampshire Tuberculosis Association is ready to provide this service through its chest diagnostic clinics for patients referred by physicians. Also the association will provide chest x-ray films through co-operating hospitals for patients and "contacts" when the physicians so request. It should be and is the urgent desire that no person in New Hampshire needing an x-ray examination of the chest shall be deprived of the same because of lack of funds.

ROBERT B. KERR, *Chairman*
CLARENCE O. COBURN
M. DAWSON TYSON

Dr. Peters, for the Committee on Officers' Reports, moved the acceptance of this report. The motion was carried.

The next report was that of the Committee on Medical Preparedness, by Dr. D. G. Smith.

Report of the Committee on Medical Preparedness

The Committee on Medical Preparedness has continued its co-operation with the Selective Service System and has approved all appointments of physicians as examining physicians and members of the medical advisory boards.

The committee is closely affiliated with the State Committee of the Procurement and Assignment Service, which is endeavoring to secure physicians for the armed forces and at the same time retain sufficient doctors at home to take care of the civilian population. This work is becoming more and more difficult as nearly all of those under

forty five years of age and physically fit who still remain at home are either essential to the Dartmouth Medical School, are needed in their specialties or are the only physicians in their respective towns. Theoretically, replacements should be found for these men, releasing them for service in the Army and Navy, but practically there are almost no physicians suitable for replacement.

The young men have done their part in applying for commissions, but it is regretted that some of the older men have failed to realize that they must work harder than ever before to provide adequate medical service for all.

It is hoped that the House of Delegates appreciates the time and effort that the members of the county committees have given to the preparedness and procurement programs.

DEFRING G. SMITH, *Chairman*

LZRA A. JONES

CARLETON R. METCALF

The Committee on Officers Reports recommended that the Committee on Medical Preparedness remain unchanged. The motion was carried.

Dr. Peters said that the Committee on Officers Reports further recommended—and this was concurred in by two members of the committee—that the House of Delegates express their appreciation to Dr. D. G. Smith for his devotion to his duties on the Committee on Medical Preparedness, multiple as they were, and undoubtedly at a personal sacrifice in the performance of this work. He moved the adoption of this portion of the report. The motion was carried.

It was voted that the reading of the Necrology Report be suspended with, since it would appear in the Transactions.

The next business was the selection of the place of the next meeting. Dr. Dye moved that the Society express its gratitude to the Manchester group and that the next year's meeting be held at Manchester. The motion was carried.

Dr. Berudon moved that Dr. T. C. Pulsifer be made an affiliate member. The motion was carried.

The next report was that of the Committee on Maternity and Infancy, by Dr. B. P. Burpee.

Report of the Committee on Maternity and Infancy

This year marks the ninth in the study of maternal and infant deaths in New Hampshire by the Committee on Maternity and Infancy. This year again the maternal death rate is lower than that of 1941, as are the infant death and stillbirth rates. The committee has endeavored, as in the past, to study and analyze all available data on the maternal deaths of 1942, and to appraise these data so far as possible, having the advantage of knowing the result of a procedure and not having to decide the actual course to be taken. The committee realizes that it is much easier to decide what should have been done in a certain case retrospectively than it is to be confronted with the actual problem and have to decide what course to pursue. It is with this thought in mind that we wish physicians to read these recommendations and suggestions made. It is the committee's thought that such comments

as are made may be of value to all physicians who may at any time have similar cases. It is realized too that there are situations where two avenues of approach are present, or seemingly present, and it is up to the attending physician to choose the one that seems to him the best, if the approach used by him fails, he can only wager that the other approach would have given a better result.

The information for this study was gathered from physicians and hospital records. It has been a little more difficult in obtaining the necessary data this year, owing to the fact that some of these physicians are in military service and their hospital records, in some cases, are incomplete. In 1 case only were there insufficient data for the committee to classify it in one of three groups.

It is gratifying to all to see a reduction in the maternal death rate, the highest over a period of ten years being 3 per 1000 live births in 1933.

The greater portion of deaths were classified as unavoidable, which is encouraging, but we must point out that 3 of these had been treated by out-of-state physicians and had been sent over the border in such a physical condition that these deaths were unavoidable to the extent that the New Hampshire physician was involved. In all 3 cases, from information gathered as to care given by the out-of-state physician, it would seem that the care was inadequate. This situation may work in reverse; that is, patients go into other states for final treatment, living received inadequate care in New Hampshire so perhaps we are not justified in trying to make our maternal death rate appear lower.

As yet, not much has been done in the study of infant deaths in this state, mostly for the reason that it would be too much of a task for this committee to gather data complete enough on each case to make feasible recommendations. The deaths have merely been tabulated according to causes, these causes having been taken from the death certificates.

Stillbirths have also been tabulated according to causes. The definition of a stillborn child now in general use in the United States, and the one accepted by the Children's Bureau, the American Public Health Association and the Bureau of the Census, has been adopted by New Hampshire and will be found in the section on stillbirths. The problem of stillbirths is a real one, not only for New Hampshire, whose stillbirth rate compares favorably with many other states, but for the United States as a whole. Even though the Bureau of the Census issues statistics, the whole story cannot be told by figures, as there is no single definition of a stillbirth in universal use. The period of gestation, which must be reached before registration as a stillbirth is required, differs in each state.

MATERNAL DEATHS

There were 15 maternal deaths in 1942, which is 2 less than in 1941, and the lowest number recorded since this study began. In 1942 there were 9599 live births thereby giving a maternal mortality of 1.6 per 1000 live births. It is to be noted that there were 914 more live births in 1942 than in 1941. This was expected, owing to the influx of people into New Hampshire to the defense area, and in the increased number of marriages on the part of those men leaving for military service.

These 15 maternal deaths have been classified according to the International List of Causes of Death (fifth revision). This classification was made on the basis of what the attending physician placed on the death certificate as the cause of death.

CLASSIFICATION No.	No. OF DEATHS
147 (b) Puerperal sepsis	3
148 (b) Puerperal nephritis	1
149 (b) Difficult delivery with hemorrhage	1
147 (c) Puerperal thrombophlebitis	2
140 (b) Abortion with infection	1
141 (a) Abortion without infection—hemorrhage.....	1
144 (b) Toxemia—nephritic (death before delivery)...	2
142 (a) Ectopic gestation	1
150 (c) Other and unspecified conditions of childbirth— asphyxiation due to inhalation of foreign matter	1
146 (c) Postpartum hemorrhage	2
Total	15

The committee has reclassified these deaths for the purpose of this report on the basis of data presented in the following way:

CAUSE OF DEATH	No. OF DEATHS
Accidents of pregnancy	5
Puerperal embolism	2
Ectopic gestation ruptured	1
Asphyxiation—inhilation	1
Acute pulmonary edema	1
Post-partum hemorrhage	4
Following spontaneous abortion	1
Retained placenta	1
Cause undetermined	2
Toxemias (all types)	3
Puerperal sepsis	2
Abortion (self-induced with resulting bacterial endocarditis)	1
Total	15

There were two cesarean sections done in the 1942 series. One was considered as justifiable and the data on the other were insufficient for the committee to make any comments. Of these 15 deaths, 4 autopsies were obtained, 3 of which confirmed the diagnosis made by the clinician. In 1 autopsy the cause of death could not be determined, but a complete autopsy was not done since permission to examine the head was not given. The committee from the data obtained classified this as an accident of pregnancy, probably acute pulmonary edema.

It has been the usual procedure of this committee to classify these deaths further, just by way of making the problem more concrete and to try to point out to what extent clinicians can be held responsible in helping to lower maternal deaths. Group I includes the cases in which the patient was at fault because of refusal for prenatal care, neglect, self-induced abortion and so forth; Group II, those in which the obstetric treatment was inadequate; Group III, those which were apparently unavoidable; and Group IV, those where data were insufficient and, therefore, undetermined.

CLASSIFICATION	No. OF DEATHS
Group I	3
Group II	4
Group III	7
Group IV	1
Total	15

The causes of death in Group I, where the patient was at fault, were as follows:

CAUSE OF DEATH	No. OF CASES
Toxemia of pregnancy (neglect of treatment)	2
Induced abortion	1
Total	3

The causes of death in Group II, where it was considered that inadequate care was given, were as follows:

CAUSE OF DEATH	No. OF CASES
Post-partum hemorrhage	2
Puerperal thrombophlebitis with pulmonary embolism	1
Difficult delivery with puerperal sepsis	1
Total	4

The causes of death in Group III, in which the death were considered unavoidable, were as follows:

Asphyxiation due to inhalation	1
Phlebitis with embolism	1
Post-partum hemorrhage	2
Ruptured ectopic gestation	1
Puerperal sepsis	1
Toxemia	1
Total	7

The toxemia listed in this group was one of those that had been treated out of state and was first seen by a New Hampshire doctor when the patient was having sustained convulsions and died within a few minutes. An immediate cesarean was performed and a live baby delivered. The case of puerperal sepsis was one of those seen by a New Hampshire doctor in the terminal stage. In both these cases, the committee considered them unavoidable since this particular study is to comment on the grade of obstetrics being done in the State, as is evidenced by the analysis of these particular cases.

Only one case must be put in Group IV because of insufficient data. The cause of death given was puerperal sepsis following cesarean section.

In the numerical analysis, the group of unavoidable deaths is the greatest, and the order of causes of death are accidents of pregnancy, post-partum hemorrhage, toxemia, puerperal sepsis and induced abortion with resulting endocarditis.

In the 1942 series all cases were delivered in a hospital. The deaths by county in urban and rural areas were as follows:

COUNTY	URBAN CASES	RURAL CASES	TOTAL
Belknap	1	0	1
Carroll	0	0	0
Cheshire	0	0	0
Coos	0	2	2
Grant	3	1	4
Grafton	2	0	2
Hillsborough	0	0	0
Merrimack	3	1	4
Rockingham	0	0	0
Strafford	0	2	2
Sullivan	0	2	2
Totals	9	6	15

The maternal mortality rates per 1000 live births by year, from 1933 to 1942, inclusive, are as follows:

YEAR	No. OF DEATHS	RATE PER 1000 LIVE BIRTHS
1933	63	5.4
1934	46	6.1
1935	37	4.8
1936	34	4.3
1937	24	3.8
1938	25	3.1
1939	24	3.1*
1940	17	1.9*
1941	15	1.6
1942		

*Corrected rates.

The most recent figures available for maternal death rates are those of 1940. At that time the maternal death rate for the United States as a whole was 3.8 per 1000 live births. North Dakota had the lowest maternal death

rate, 17, and South Carolina the highest, 68. New Hampshire for 1940 was in nineteenth place with a rate of 31. We have no comparable figures for 1941 and 1942.

Comments and Recommendations

The committee, having reviewed all the available data reports that in no case was there evidence of really bad obstetrics. In most cases, it was a matter of not giving enough treatment, rather than the wrong kind. This appeared to be true in the 2 cases of postpartum hemorrhage, and at this time the committee would like to make certain comments on the treatment of such cases.

The committee would like to emphasize once again the necessity of proper diagnosis and immediate treatment of those women who suffer hemorrhage or who show signs of shock immediately or soon after delivery, whether the delivery has been spontaneous or operative. One must remember that uterine atony is not the only cause of postpartum hemorrhage, and more especially of shock without evidence of external bleeding.

Other pathologic conditions may be a partially separated placenta, retained cotyledons of a removed placenta, cervical tear, tear of the lower segment or body of the uterus and, less frequently, inverted uterus, fibromas and ruptured vaginal varicosity. These may all cause profuse bleeding.

The conditions that may cause profound shock without external bleeding are tear of the lower uterine segment, rupture of the uterine body and inverted uterus.

Each of these conditions is serious enough to justify immediate sterile vaginal examination, both manual and visual, to establish correct diagnosis, the specific treatment to follow depending on that diagnosis. Partially separated placenta and retained cotyledons should be removed manually. Cervical lacerations should be repaired under direct vision. A ruptured uterus requires abdominal surgery, either to repair the rent, if possible or to do a hysterectomy. Fibromas with persistent bleeding may also necessitate hysterectomy. An inverted uterus requires replacement either manually from below or by abdominal surgery. Ruptured vaginal varicosities may be controlled by packing tightly. In addition to these briefly outlined specific treatments, the committee would like to reiterate the immense value of intravenous fluids, especially transfusions of whole blood or plasma.

It is thought worth while to stress the importance of keeping confined to bed a patient who shows clinical evidence of a phlebitis, particularly in the presence of a septic temperature, regardless of how low grade until the temperature becomes normal and remains normal and the signs and symptoms clear. There is a great tendency on the part of physicians to disregard these warnings and to get these patients out of bed, only to have them die in a few minutes.

One death was due to inhalation of vomitus while being delivered. Although this was considered unavoidable it does nevertheless remind us that we can be more careful in explaining to patients the importance of not eating heavily, or not at all, if there are signs and symptoms of going into labor.

The 2 cases of death due to toxemia were classed in Group I that is the patient being at fault. In both cases, the patients were being seen regularly and being given good prenatal care. Both patients were more or less toxic throughout, and both neglected to report back to the physician when told to do so. Both were severely toxic

when finally seen. The committee wishes to point out that the fault does actually lie with the patient, but can a physician who is giving good prenatal care forget about a toxic patient? In most cases, it would be easy to contact this patient either by telephone or letter or by sending out the district nurse or public health nurse and asking her to check on these patients or to see that they come in to their doctor. These nurses are placed in the field to help physicians as well as patients. It is up to the physician to educate his toxic patient as to the value of frequent prenatal visits.

The committee must continue to comment on the value of hospital records and the necessity of keeping these up to date. For the most part, hospital records, when resorted to for information this year, were most in complete. To be sure most of these incomplete records were those of physicians who had gone into the armed services and were undoubtedly too busy at the last to think of hospital records. There are also incomplete records of physicians who are not in service. The one case classed in Group IV is an example of the latter. From the hospital record it can be gathered that the infant was delivered by cesarean section and that the mother died two days post partum. No reasons for performing a section were given. It seems necessary to keep stressing the subject of records. Keeping poor records helps to lower the standard of the hospital. It is as much the hospitals' responsibility to see that their records are kept up to date as it is the physicians'. Good records are a safeguard for both physicians and hospitals.

MATERNITY CARE PROGRAM FOR SERVICEMEN'S WIVES

The committee served this year, as before, as an advisory committee to the State Board of Health regarding programs involving the care of mothers and infants. The purpose of this procedure has been to afford proper representation of the Society regarding such programs.

With the induction of thousands of young men from New Hampshire into the armed forces it became apparent that provisions had to be made for the care of pregnant wives of these men. The committee was confronted with the problem of aiding the State Board of Health in meeting this emergency. The following facts are presented for the information of the Society.

The First Deficiency Appropriation Act of Congress in 1943 provided for a sum of money to be allotted to any state setting up a program for maternity care of wives of servicemen. New Hampshire has such a program now in operation, administered by the State Board of Health through the Division of Maternal and Child Health. As to eligibility for care under this plan, Any woman in the State irrespective of legal residence, whose husband is an enlisted man [this includes men deceased or missing in action] in the armed forces of the United States of the fourth fifth sixth and seventh grades [Army, Navy, Marine Corps and Coast Guard], and who makes application for such care will be eligible for the medical and hospital maternity services provided under the plan, without cost to the family, when similar services are not otherwise available from the medical or hospital facilities of the Army or Navy or from facilities provided by or through official state or local health agencies.

Application forms for this service have been distributed to physicians, hospitals, the Red Cross and other social agencies throughout the State and more may be obtained from the State Board of Health.

The service gives prenatal, delivery and post-partum care, and hospitalization on ward service at a flat rate at present of \$45 for a ten-day period. Physicians are paid on the basis of \$15 for prenatal care and \$20 for delivery. This fee was recommended by the Committee on Maternity and Infancy of the Society.

Applications must be returned to the Division of Maternal and Child Health, 17 School Street, Concord, and on receiving the application, authorization for this care will be sent to the physician and hospital involved. The plan is not retroactive; all care must be authorized before financial responsibility for the case can be assumed by the Division of Maternal and Child Health. In case of an emergency delivery, this department must be notified within forty-eight hours.

Hospitals to be used under the plan are those which are duly licensed by the State Board of Health to admit and care for maternity patients. Home deliveries are to be done at the discretion of the attending physicians. Only those physicians who are graduates of a recognized medical school, have an M.D. degree and are licensed to practice medicine in New Hampshire may be authorized to give medical care under this plan.

Any further information regarding this plan may be obtained from the State Board of Health.

INFANT MORTALITY

Included in this group are those infants who died under one year of age. There were 322 infant deaths in 1942, giving an infant death rate of 33.5 per 1000 live births. In 1941 there were 319 deaths, a rate of 33 per 1000 live births. These deaths are tabulated as to causes and time of death after birth.

CAUSE OF DEATH	No. OF DEATHS
Deaths occurring during the first day:	
Prematurity	87
Congenital deformity	29
Atelectasis	12
Intracranial hemorrhage	7
Birth injury	4
Toxemia	2
Prolapse of cord	1
Hemorrhagic disease of newborn	1
Total	143
Deaths occurring during the first month exclusive of the first day:	
Prematurity	20
Congenital deformity	16
Pneumonia	7
Atelectasis	5
Asphyxia	2
Hemorrhagic disease of newborn	2
Intracranial hemorrhage	5
Enteritis	2
Septicemia	1
Hydrothorax and edema	1
Meningitis	1
Syphilis	1
Unknown	1
Total	69
Deaths occurring from the second to the twelfth month, inclusive:	
Pneumonia	33
Malnutrition	10
Congenital anomaly	10
Gastroenteritis	9
Suffocation (accidental)	8
Influenza	2
Intussusception	2
Pyelonephritis	1
Septicemia	1
Tubercular meningitis	2
Pyloric stenosis	2
Osteomyelitis	1
Unknown	4
Total	85
Unclassified owing to late reporting	25

There has been a steady decline in infant mortality in the United States as a whole since 1915, when data on this subject were first collected. The rate then for the country as a whole was 100 per 1000 live births, and in 1938 it was just half, 50 per 1000 live births. The better control of communicable diseases and a better understanding of infant feeding, thereby decreasing gastrointestinal disturbances, have probably contributed greatly to this decrease. It is interesting to note, that, so far as figures can be obtained, New Zealand has consistently reported a lower infant death rate than any other country, whereas the Netherlands, Australia, Norway, Sweden and Switzerland have reported rates that have been lower than those of the United States, according to the last obtainable figures (1936).

For the year 1936, in the United States the causes of deaths of infants under one year of age, as compiled from the death certificates, showed that 52 per cent died of prenatal and natal conditions. These conditions included prematurity, injury at birth, malformation and debility. From 1915 to 1936, where figures are available, deaths under one year have been cut in half, deaths during the first month have been reduced one fourth, and deaths occurring on the first day have shown no decrease.

Our own series of infant deaths bear out some of these facts, namely, that the death rate for those during the first day of life remains high. In the United States as a whole the rate in 1915 and 1936 was 15 per 1000 live births, and New Hampshire also shows 15 per 1000 live births in 1942. The New Hampshire series also shows that over 50 per cent are attributable to prenatal and natal conditions. Adair and Potter point out in their book *Fetal and Neonatal Death* that the classification used by the Bureau of Census, which is an international one, classifies all conditions under one of five headings, namely, congenital malformation, congenital debility, premature birth, injury at birth and other diseases peculiar to early infancy. Congenital debility usually indicates that the physician was uncertain as to the cause of death. Prematurity usually takes precedence over contributing causes of death on a certificate, thereby possibly masking the real cause of death. On the basis of this classification, they believe that the figures from the Department of Vital Statistics are inaccurate for actual frequency of the various causes of death in early infancy.

The infant mortality rates per 1000 live births by years are as follows:

YEAR	RATE
1935	54
1936	47
1937	48
1938	48
1939	45
1940	32
1941	33
1942	33.5

STILLBIRTHS

Of the 244 stillbirths recorded in the State for 1942, the following causes were given:

CAUSE	No. OF CASES
Unknown	67
Prematurity	44
Toxemia	36
Hemorrhage, maternal	31
Congenital deformity	30
Attributed to cord	19
Difficult delivery	8
Syphilis	3

Hemorrhage fetal	2
Atelectasis	1
Therapeutic abortion	1
Erythroblastosis	1
Diabetes	1
Total	244

Stillbirths vary from year to year, and no evidence for this variation is apparent. For the last five years the figures are as follows:

YEAR	NO. OF CASES
1933	242
1939	211
1940	187
1941	203
1942	244

Previously, New Hampshire has used the definition of a stillbirth recommended by the League of Nations and the International Institute of Statistics—namely, A dead birth (stillbirth) is the birth of a (viable) foetus, after at least twenty-eight weeks pregnancy in which pulmonary respiration does not occur, such a foetus may die either (a) before, (b) during or (c) after birth, but before it has breathed. The statistical definition adopted for use in the United States, and the one accepted by the Children's Bureau, the American Public Health Association and the Bureau of the Census and the one now in use in New Hampshire, is as follows: A fetus showing no evidence of life after complete birth (no action of heart, breathing or movement of voluntary muscle), if the twentieth week of gestation has been reached, should be registered as a stillbirth.

The differences between these two definitions relate to the period of gestation required and to the criterion for determining life. Since the point of differentiation between liveborn and stillborn is highly controversial, the final decision as to the definition of stillbirth really rests with the obstetrician who is to make the decision in actual practice. If these physicians would voice their opinion on the controversial points involved, it would aid the State Board of Health and Vital Statistics Office in becoming aware of the desires of the medical profession in regard to this subject. Meanwhile in order to make uniformity in reporting for the purposes of comparison, it seems essential that physicians follow the United States definition.

As has been said, there is no single definition of still birth in use in the states, the period of gestation differing widely in different states. In Maryland, Missouri and New York City the delivery of any product of conception must be registered, in Delaware there is no definite ruling, in Connecticut registration is not necessary unless the period of gestation is seven months or more. In the majority of states, a fetus that has advanced to the fifth month must be registered.

It is, therefore, evident that there is a lack of comparable bases for analysis. The stillbirth rate for New Hampshire for 1942 is 25.4 per 1000 live births. We have no available figures for the United States except for 1939, which showed 32 stillbirths per 1000 live births. The highest rate was in Mississippi, 51.1, and the lowest was in Washington, 17.5.

In 1936, the Children's Bureau conducted a study of the maternal and fetal conditions associated with still births for the purposes of determining and classifying the causes of death. The study was made on 6750 still births, and certain interesting figures were obtained. It showed, among other things, that 58 per cent of

the fetuses die before the onset of labor and 42 per cent during labor, that in the early months of pregnancy deaths before the onset of labor were proportionately higher than deaths during labor, that the greater per cent of fetuses died before labor began in those cases where toxemia, hemorrhage and syphilis were maternal complications, and where deformities were found in the fetus. In this series it was found that the following conditions were associated with stillbirths in the order of frequency, toxemia, intra partum and intra partum hemorrhage, cord complication or anomaly, congenital malformation, syphilis and birth injury.

For the most part the causes of fetal death as given on death certificates are maternal conditions with the exception of fetal deformities. Here again the classification of causes of stillbirths varies. The International Commission for Revision of the International List of Causes of Death in 1938 adopted the following classification: Group I, stillbirth caused by disease in, or accident to, the mother; Group II, anomalies of the fetus, placenta or cord; Group III, death of the fetus by injury or other causes; and Group IV, stillbirth due to other causes.

The purpose of the committee in going somewhat into detail on stillbirths is to try to stimulate the interest of physicians in this problem. Any comments as to the definition of a stillbirth or as to the causes of stillbirth will be gratefully received by the committee.

The committee wishes to thank the physicians and hospitals for their continued co-operation in furnishing the data necessary for making this report. Any recommendations that the physicians throughout the State may have to make regarding these annual reports will be greatly appreciated.

The committee wishes to acknowledge with appreciation the co-operation of the Division of Maternal and Child Health of the State Board of Health in furnishing data and personnel in the preparation of this report.

ROBERT O. BLOOD, *Chairman*
BENJAMIN P. BURPEE
MARION FAIRFIELD

Dr Burpee then read a letter from Dr Mildred A. Chamberlin, acting director of the State Board of Health, which requested an interpretation of a paragraph in the regulations governing the maternity care program for servicemen's wives. This paragraph read as follows:

Authorization for medical or hospital care is to be made by the State Board of Health under agreement with the attending physician or the hospital that no payments will be accepted from the patient or family.

The Board of Health believed that the patient should be allowed to contribute, if she so desired, and asked if this was prohibited by the rule in question. After a lengthy discussion, Dr Peters reported that the Committee on Officers' Reports thought that they did not have enough information to bring in any definite recommendation regarding this matter, other than to recommend that the House of Delegates consider the Government plan for the payment of hospital and medical care of servicemen's wives at the time of deliv-

ery. He moved the adoption of that portion of the report; this motion was carried.

Dr. Burpee said that the State Board of Health would also like advice on the matter of stillbirths. There was still a great deal of argument going on as to what should constitute the definition of a stillbirth. Previously, New Hampshire had used the definition recommended by the League of Nations and the International Institute of Statistics: "A dead birth or stillbirth is a birth of a fetus after at least twenty-eight weeks of pregnancy, in which pulmonary respiration does not occur. Such fetus may die either before, during or after birth, before it has breathed." The statistical definition adopted in the United States and the one accepted by the Children's Bureau, the American Public Health Association and the Bureau of the Census, and the one now in use in New Hampshire, was as follows: "A fetus showing no evidence of life after complete birth, no action of heart, breathing or movement of the voluntary muscles, if the twentieth week of gestation has been reached, it should be registered as a stillbirth." He said that the State Board of Health would like an expression of opinion from the doctors of the State as to what definition of a stillbirth should be used.

Dr. Wilkins asked whether the definition now being used was not satisfactory. Dr. Burpee replied that it was satisfactory to some people but not to others. Any fetus, he said, that was born after the twentieth week was considered a stillbirth. Speaker Parsons asked Dr. Peters whether he had a report on this matter.

Dr. Peters moved that the Committee on Maternity and Infancy take the matter up with the Public Health Department for further clarification. This motion was carried.

Dr. Peters for the Committee on Officers' Reports, further moved that the report of the Committee on Maternity and Infancy be accepted. The motion was carried.

Speaker Parsons said that Dr. Burpee had asked for an opinion from the delegates on the question of medical fees in obstetric work, assisted by government grant, and asked whether there was any further discussion on the matter.

Dr. McGregor said he thought the fee was too low.

Another member asked whether the \$15 and the \$20 fees were standard ones. Dr. Smith said that the chief objection of the Nashua doctors was that the State Board of Health, the Government and the Children's Bureau were dictating fees, and they did not see why they could not charge more and have the patient pay the difference between the charge that they might make and what the Government would give under this appropriation. If that didn't occur, they would

rather not accept any money from the Government or the State Department of Health and take their chances of collecting the regular fee from the patient's family or the patient. For that reason, they were crossing out that agreement at the bottom of the application.

Dr. Smith said further that his authority for the investigation of these cases by the Red Cross was given by the field secretary of the Red Cross in New Hampshire, and also that Dr. Chamberlin in a letter in February asked that the Red Cross investigate. One of the doctors also stated that three women came to him with the blanks for him to sign, applying for aid, who, so far as he knew were perfectly able to pay for the maternity care. He said he did not see why a doctor could not get \$50 or more for taking care of the patient, and not have to accept \$35 from the Government. For these reasons, Dr. Smith said, the Nashua Medical Society, not an official body, so far as the New Hampshire Medical Society was concerned, voted to disapprove the plan.

The meeting then adjourned at 10:30 p.m. until 8:30 a.m., May 11.

The House of Delegates convened at the Hotel Carpenter, Manchester, on May 11, 1943, at 8:30 a.m., with Speaker Charles H. Parsons, of Concord, presiding.

The following members answered the roll call:

The President, *ex-officio*
 The Vice-President, *ex-officio*
 The Secretary-Treasurer, *ex-officio*
 W. J. Paul Dye, Wolfeboro
 Francis J. C. Dube, Center Ossipee
 Walter F. Taylor, Keene
 A. C. Johnston, Keene (alternate for Norris H. Robertson)
 Leander P. Beaudoin, Berlin
 Arthur B. Sharples, Groveton
 Arthur W. Burnham, Lebanon
 Leslie K. Sycamore, Hanover
 Deering G. Smith, Nashua
 Edward V. Putnam, Warner
 Clarence E. Butterfield, Concord
 Frederick S. Gray, Portsmouth
 Anthony E. Peters, Portsmouth
 Edwin D. Lee, Exeter
 Roland J. Bennett, Dover
 George G. McGregor, Durham
 B. Read Lewin, Claremont
 Emery M. Fitch, Claremont (alternate for Henry C. Sanders, Jr.)

Dr. Putnam presented a report, held over from the day before, on the National Conference for Medical Service. He explained that in conference with some of the other delegates, it had been decided that the basic point seemed to be a question of some sort of liaison officer or commission to be established in Washington for the purpose of mak-

ing contact between the medical groups in any legislative work that might be done. He recommended that the House of Delegates be put on record as favoring the basic principle of having a liaison representative in Washington. This should be done through existing committees, or as it might be deemed best by the American Medical Association. He moved the adoption of this recommendation. The motion was carried.

The report of the delegate to the American Medical Association was then presented by Dr D. G. Smith.

Report of the Delegate to the House of Delegates of the American Medical Association

The role of the medical profession in the war was the chief subject discussed by the House of Delegates at the ninety-third annual session of the American Medical Association held at Atlantic City on June 8-12, 1942. The meetings were well attended and interesting as usual. Your delegate served as chairman of the Reference Committee on Reports of Officers.

President Frank H. Lahey stated that the public and the medical profession were not aware of the seriousness of the war, and warned that "optimism is one of the things which can lead to our downfall."

President-elect Rankin, most fittingly a colonel in the Army, and since the meeting made a brigadier general, emphasized that this is a young man's war but the older men left at home will have to do work of equal importance.

Paul V. McNutt, director of the Office of Defense Health and Welfare, stressed the urgency of securing 70,000 physicians to serve with the armed forces. This tremendous feat has now been accomplished and New Hampshire has done her part. Mr. McNutt stated that the medical profession does not realize the magnitude and seriousness of the war, but it seems as if we have begun to do so.

The importance of industrial health studies and programs was emphasized, for aside from actual war medicine there is no factor that will contribute so much to the war effort as industrial health.

The Council on Medical Education and Hospitals was instructed to develop a program of refresher courses for physicians returning to civilian practice after the war. It was recommended that the Board of Trustees confer with the proper governmental authorities regarding the granting of furloughs with full pay to officers taking these courses.

The Committee on Medical Preparedness was discharged, and a War Participation Committee was established. Your delegate recommends that no change be made in the State Medical Preparedness Committee, but that its duties include those pertaining to participation in the war.

The activities of the National Physicians Committee for the Extension of Medical Service was approved and it was declared the policy of the House of Delegates to encourage this effort and similar efforts with identical purposes.

James F. Paullin of Atlanta, Georgia, was chosen president-elect and New York was selected as the site of the 1945 session. The 1943 general session has been

canceled except for a meeting of the House of Delegates in Chicago next month.

DEERING G. SMITH

Dr Dye reported for the Committee on Nominations as follows:

OFFICERS

President James W. Jameson

Vice President Fred Fernald

Secretary-Treasurer Carleton R. Metcalf

Councillors (five year term) Clifton S. Abbott, Belknap County, and Arthur W. Burnham, Grafton County

Trustee (three year term) Howard N. Kingsford

House of Delegates speaker, George F. Dwinell, vice speaker, Ralph W. Tuttle

Delegate (American Medical Association) Deering G. Smith

Alternate Delegate (American Medical Association) Emery M. Fitch

Necrologist Henry H. Amsden

STANDING COMMITTEES

Advisory Committee on Jurisprudence Clifton S. Abbott, W. J. Paul Dye, John J. Brosnahan, Richard F. Wilder, John F. Gile, David W. Parker, Robert J. Graves, Samuel T. Ladd, Jeremiah J. Morin, Henry C. Sindors, Jr., Carleton R. Metcalf, *Chairman*

Amendments to Constitution and Bylaws James B. Woodman, W. J. Paul Dye, Frederick S. Gray

Child Health Colin C. Stewart, Jr., B. Read Lewin, Franklin N. Rogers

Control of Cancer George C. Wilkins, Ralph E. Miller, George F. Dwinell

Maternity and Infancy Benjamin P. Burpee, Marion Fairfield, John J. Boardman

Medical Economics Leslie K. Sycamore, Richard W. Robinson, Francis J. C. Dube

Medical Education and Hospitals John P. Bowler, James W. Jameson, Herbert L. Taylor

Medical Preparedness Deering G. Smith, Ezra A. Jones, Carleton R. Metcalf

Mental Hygiene Benjamin W. Baker, John B. McKenna, Simon Stone

Public Health Harris E. Powers, Anthony E. Peters, Clinton R. Mullins

Public Relations The President, The Vice President, The Secretary-Treasurer, Robert J. Graves, Joseph N. Fritborg

Publication Carleton R. Metcalf, John I. Gile, Emery M. Fitch

Scientific Work Carleton R. Metcalf, Frederic P. Scribner, Sven Gundersen

Literatures Robert B. Kerr, Clarence O. Coburn, Richard C. Batt

The report was accepted. Dr. James W. Jamieson, of Concord, was elected president, and Dr. Fred Fernald, of Nottingham, was elected vice-president. The Secretary was instructed to cast one ballot for the remainder of officers and committee members, as nominated; this was done, and all were declared duly elected.

Dr. Metcalf moved a vote of gratitude to the members in Manchester who had arranged the details of the meeting; it was so voted.

Under unfinished business Dr. McGregor opened discussion about maternity fees for soldiers' wives, in order to see if there was some way in which the fee schedule could be increased, and to ascertain what fees were being paid in other states. There seemed to be considerable misunderstanding as to whether the agency concerned was a Government or a Red Cross agency. Some doctors were not satisfied with the present fee schedules. The amount did not seem to meet the minimum for the hospital in Exeter.

Dr. Sycamore thought that this question called for more investigation by the Committee on Maternity and Infancy, and added the matter could be left in their hands to make alterations, if possible.

Dr. D. G. Smith spoke as follows:

I believed that Dr. Burpee would tell more about the plan than he did. It was brought to my attention first about ten days ago. I got the feeling that the thing was rushed through, perhaps slipped through rather rapidly, because there was a copy of a letter sent to the Red Cross in Nashua that was to be sent to every doctor in the State. I, for one, did not receive the letter. I have talked to a number of others who received no letter explaining the plan. The fee list was apparently established by Dr. Burpee — because Dr. Fairfield was on the same committee with Dr. Burpee and said they were consulted — and was rather hurriedly adopted. That was probably why the medical society was not consulted.

A number of men in Nashua think this is an entering wedge for state medicine; that the Government is appropriating this money to the State Board of Health and the Children's Bureau, dictating our fees. They say if the Government is starting now to take care of the soldiers' wives and children, it will be only a short time after the war when they are taking care of the soldiers. The doctors in Nashua are opposed to it. Also, they did not think that the fee schedule is high enough.

Speaking unofficially, in talking with the Superintendent of the Memorial Hospital in Nashua, I discovered that \$45 for ten days would not cover the cost of hospital care. It would not take care of a number of things, such as charges for x-ray films, delivery room, medicines, anesthesia, supplies and what not, including care of the baby, and it was said last night

that the doctors there are very much opposed to the general idea. Probably we can do little or nothing about it, but the men are especially upset about the dictation as to the fees. It is bad enough on welfare cases, but why should they be dictated to us on other cases? Many of these people have sufficient funds to pay these bills.

The original appropriation, according to Dr. Chamberlain and the head of the Red Cross in New Hampshire, was for the care of soldiers' wives who had no available funds, and this new appropriation is to take care of all soldiers' wives in the four lowest pay groups, regardless of their income.

Dr. Gray said he thought that a discussion of the fee schedules should be carried on by the committee, as previously suggested, and that the House of Delegates should go on record as recommending that an elastic fee schedule be adopted, or at least recommended, whereby in abnormal cases, a higher fee could be charged, and that the top limit be not set as it is in the recommendation.

Dr. Smith said that an alternative proposal was made by Dr. Fairfield, namely, that a grant of \$35 toward the doctor's bill and \$45 toward the hospital bill be given to the soldiers' wives, if they needed it, and that the balance be taken care of by the individual. He moved that the delegates go on record as being opposed to the present fee schedule for the maternity care of soldiers' wives as inadequate, and as suggesting to the committee that either these rates be raised, or else the \$35 to be given to the doctor be considered as a part payment in some cases, and that the doctor be allowed to charge a reasonable balance. The motion was carried.

Dr. Dye, referring to the motion made the previous evening for expediting the medical insurance plan, asked for clarification of how the matter now stood. It was voted then that the Committee on Medical Economics and the officers be a committee to formulate a plan and to present such a plan at the earliest possible moment to the House of Delegates. Was there, he asked, a further provision that this plan be sent to each member of the House prior to said meeting, so that the members could look it over and discuss the question intelligently?

Speaker Parsons replied that no definite motion was made that that plan be specifically referred to each member, but it was understood that it would be; otherwise, it would be impossible to consider the matter intelligently.

The second and final meeting of the House of Delegates was adjourned at 9:15 a.m.

CASE RECORDS OF THE
MASSACHUSETTS GENERAL HOSPITAL

Weekly Clinicopathological Exercises

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor**BENJAMIN CASTLEMAN, M.D., *Acting Editor*EDITH E. PARRIS, *Assistant Editor*

CASE 29391

PRESENTATION OF CASE

A twenty-seven-year-old medical student was admitted to the hospital because of massive bloody stools.

The patient was in good health until two days prior to entry when he developed coryza, photophobia and slight sore throat. There was no muscle pain or stiffness. His bowels, which had moved normally the day before, had not moved on that day. The following day, while on a train, he noted that he was sweating more than usual and felt chilly. He had marked tenesmus with two unsuccessful attempts to pass a stool. The third time there was a pinkish spotting of the toilet. He felt weak and faint. About midnight that evening, two hours before entry, he had a great desire to defecate, broke out in a cold sweat and had a massive liquid, tarry and bloody, foul-smelling stool, with a volume of about "1½ to 2 pints." He felt weak and nauseated and vomited a yellow mucoid material in which no coffee grounds or blood was seen. He had had no pain, chills, fever, jaundice or other gastrointestinal or genitourinary symptoms. The upper respiratory infection was still present.

His appetite had always been good, and his weight steady. He had a "softening of the spine" at eighteen, for which he wore a brace for three months. Following a maxillary sinus operation, two and a half years before entry, he had had a tarry stool, but he had experienced no other episodes of melena until his present illness. There was no history of cough, night sweats, chest pain, hemoptysis, dyspnea, orthopnea or heartburn.

Physical examination showed a well-developed, well-nourished man in no distress. The chest was somewhat barrel shaped and hyperresonant. The abdomen was scaphoid, entirely soft and nontender. Peristalsis was normal. The liver edge could be felt and percussed two fingerbreadths below the costal margin in the anterior axillary line. Rectal examination showed some tarry material on the examining finger.

*on leave of absence

The blood pressure was 90 systolic, 70 diastolic. The temperature was 99°F., the pulse 96, and the respirations 20.

Examination of the blood revealed a red-cell count of 4,150,000 and a white-cell count of 11,700. The blood protein was 5.4 gm. per 100 cc., the chloride 92.6 milliequiv. per liter. The prothrombin time was 22 seconds (normal, 20 seconds), and the hematocrit was 31 per cent. The urine was normal. The stools gave a +++ test for guaiac. The aspirated gastric content had free hydrochloric acid and was guaiac negative.

During the physical examination, shortly after admission, he had two large, loose, foul stools of tarry material admixed with red blood. He became pale and felt faint. He was given 1000 cc. of whole blood intravenously. The bleeding subsided, with elevation of the blood pressure.

The following day, the bleeding having ceased, a gastrointestinal series was done. This showed a normal esophagus, and there was no evidence of a hiatus hernia; the stomach and duodenal bulb were normal.

The third day, when plans were being made for further study, the patient had another massive, grossly bloody stool and showed "early evidence of shock." An abdominal exploration was performed immediately.

DIFFERENTIAL DIAGNOSIS

DR. ROBERT R. LINTON: We have a history of a twenty-seven-year-old, apparently healthy young man who suddenly developed massive bleeding in the rectum. The bleeding consisted not entirely of old blood, characterized by tarry material, but also of some fresh blood. The first thing one thinks of, of course, is a bleeding duodenal ulcer. There usually is no fresh blood in the stools following bleeding from a duodenal ulcer, but on the other hand it may occur. It is true that he had no history of previous ulcer symptoms, and there is nothing to suggest that he had a duodenal ulcer; nevertheless, duodenal ulcers may suddenly bleed or perforate without any preliminary symptoms suggestive of the disease.

The physicians looking after this patient seem to me to have been courageous in giving a gastrointestinal series the morning following so much bleeding. This may have been all right, but it is not the way we have been taught to handle massive hemorrhage supposedly from duodenal ulcer. They may have thought of some other diagnosis and felt free to go ahead. At any rate, their judgment was correct, since there was obviously no lesion involving the stomach or duodenum. At the same time they ruled out esophageal varices, which one would have to consider as a possible diagnosis.

The likelihood that there were esophageal varices is very small because of the fact that there was no vomiting of blood, which practically always occurs if there is bleeding from this source. It seems to me that one has to accept the x-ray report that there was nothing wrong with the stomach and duodenum, so that the bleeding did not come from high in the gastrointestinal tract.

What other conditions can produce massive bleeding? I suppose that a tumor of the jejunum is a possibility. Tumors of the jejunum are rare. I have never happened to see one that bled so much as this one did, and usually intestinal obstruction is associated with it, which this man did not have. So I do not see how we can incriminate

of bloody material. So I do not believe that he had an intussusception or carcinoma of the colon, with bleeding from either of these conditions. Lymphoma is another cause one must consider. Because the stool contained old and fresh blood I should expect such a lesion to be in the terminal ileum or the right colon. Other conditions that I have read about but have not seen, such as congenital hemangioma involving some part of the gastrointestinal tract, may cause bleeding. If that is what it is, the diagnosis would be purely a guess on my part, and for that reason I am going to rule it out in the differential diagnosis.

In reviewing this case it seems to me that, since the gastrointestinal series was negative and since

FIGURE 1.

the jejunum. Then we come down farther to the ileum, where one must consider two conditions seriously—intussusception and a Meckel's diverticulum. Intussusception is unusual in a man of twenty-seven. It usually occurs in infants and in children under five; there was also too much bleeding for intussusception. Bleeding from an ulcer in a Meckel's diverticulum again is unusual in a patient of twenty-seven. Such lesions do occur, however, at that age but are much commoner under the age of ten. The other conditions that we should consider are carcinomas involving the large bowel. The cecum, for instance, is a common site for bleeding from the rectum; but again, massive hemorrhage from tumors in the cecum usually does not occur: it is usually a continued, small amount of bleeding. The same is true of carcinoma of the colon, in which one observes less bleeding than in carcinoma of the cecum. The history is of interest in that it states that the patient had marked tenesmus with two unsuccessful attempts to pass a stool, which suggests that he had some degree of intestinal obstruction. Apparently this did not amount to much because within a few hours he did defecate a large amount

the patient passed large amounts of blood that was both old and fresh, indicating that the hemorrhage arose somewhere in the middle of the intestinal tract rather than at either end of it, and since the lesion was asymptomatic in that he had had no preliminary gastrointestinal symptoms previous to this episode except for the one time after the sinus operation when he passed some blood by rectum, I am going to make a diagnosis of an ulcer in a Meckel's diverticulum. A Meckel's diverticulum is usually asymptomatic unless it produces signs of intestinal obstruction, becomes acutely inflamed or develops an ulcer, which erodes a blood vessel and produces bleeding similar to that of a duodenal ulcer. The ulcer that forms is secondary to the fact that some of them contain gastric mucosa, which secretes hydrochloric acid. Since the mucosa of the ileum has no neutralizing secretion against this acid, it is apt to produce an ulceration similar to that of peptic ulcer, either at the base of the diverticulum or in the adjacent ileum.

DR. JOSEPH C. AUB: Would Dr. Linton consider the possibility of "walking" typhoid fever? He was a medical student and had been miserable for two days.

DR. LINTON: It was my impression that cases of typhoid fever do not bleed. They perforate, but do not bleed.

DR. AUB: They sometimes bleed.

DR. J. H. MEANS: I should like to mention one patient who had a massive gastrointestinal hemorrhage, the source of which was not found until operation. He had gastric varices without esophageal varices. They did not show in the x-ray; in fact they were not seen at gastroscopy.

DR. BENJAMIN CASTLEMAN: Is it not true that the patient had appreciable symptoms before the bleeding?

DR. MEANS: Yes. Such a diagnosis is most unlikely, but if you are considering all the possible explanations that might be mentioned.

DR. LINTON: I may be making a mistake by passing over the diagnosis of duodenal ulcer, but on the other hand this seems to be a very unusual case and is more likely to have been due to something lower in the gastrointestinal tract.

DR. FRANCIS D. MOORE: How about polyposis of the colon?

DR. LINTON: That is a possibility. However, I should not expect the bleeding to be so massive.

DR. MOORE: On the service we followed much the same reasoning that Dr. Linton has. We knew that this man might start to bleed massively again, which would necessitate operation. If we did operate, we wanted to locate the lesion, if possible. That is why we asked for the gastrointestinal series, although we realized that it carried some hazards. When he started to bleed again, we operated through a lower abdominal midline incision and immediately saw blood in the small bowel. This confirmed our suspicion that the blood was coming from above the ileocecal valve, and we shortly found that it was emanating from a tumor in the ileum in the region where one expects to find a Meckel's diverticulum. The tumor was about the size of a lemon, and we thought that it was associated with a Meckel's diverticulum. The tumor was resected, and the patient has done extremely well.

CLINICAL DIAGNOSIS

Meckel's diverticulum, with ulcer.

DR. LINTON'S DIAGNOSIS

Meckel's diverticulum, with bleeding ulcer.

ANATOMICAL DIAGNOSIS

Neurofibroma of ileum.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: This is a photograph of the specimen (Fig. 1), showing the tumor through the

serosa. It was a lobulated, soft, somewhat gelatinous intramural tumor about 5 cm. in diameter. There was no Meckel's diverticulum. The usual benign intramural tumors of the gastrointestinal tract are the leiomyomas and neurofibromas; the malignant ones are the leiomyosarcomas, neurogenic fibrosarcomas and lymphomas. This one proved to be a neurofibroma. These tumors usually ulcerate in the center and often produce massive bleeding.

DR. LINTON: Did you find the bleeding point?

DR. CASTLEMAN: We did not find the bleeding point. The specimen was already sectioned when received in the laboratory.

DR. MOORE: After taking a picture of the specimen we opened it and found the bleeding point to be a dilated vein about twice the size of the lead of a pencil. Where the tumor was close to the mucosa the vein had ruptured into the lumen of the bowel.

CASE 29392

PRESENTATION OF CASE

A forty-five-year-old housewife was admitted to the hospital about midnight because of severe abdominal pain. The patient was too sick to give a complete history.

About thirteen hours before admission, soon after lunch, the patient developed severe pain in the upper abdomen and back, associated with nausea and vomiting. That evening, while visiting her husband, who was in a hospital, she collapsed. She was seen by a physician who sent her to this hospital.

For the past twenty-five years she apparently had had recurrent attacks of pain in the upper abdomen, associated with nausea and vomiting, which had been interpreted as being due to gallstone colic.

Physical examination showed a lethargic, ill-appearing, moderately obese woman, complaining of pain in the upper abdomen. The skin was moist. There was questionable jaundice of the skin and scleras. There was an apical systolic murmur, but the heart was otherwise normal. The lungs were clear. There were spasm, resistance and a sense of a mass in the right upper quadrant, with tenderness in the right lower quadrant, the left upper quadrant and the left costovertebral angle. Peristaltic activity was somewhat reduced but essentially normal. There was a suprapubic abdominal mass that was more prominent on the right than on the left and still present after catheterization. On vaginal examination this mass was believed to be a fibroid uterus.

The blood pressure was not obtained. The temperature was 99°F., and the pulse 100; the respirations were normal.

Examination of the blood revealed a hemoglobin of 18.7 gm., and a white-cell count of 9200. The urine was dark amber, cloudy and acid, with a specific gravity of 1.019 and a +++ test for albumin and bile. The sediment contained many granular, hyaline and cellular casts, and occasional red cells, 10 white cells and 20 epithelial cells per high-power field. A urine culture was negative.

An x-ray film of the abdomen showed both kidneys to be normal in size, shape and position. There were several areas of calcification having the appearance of calcified lymph nodes near the right transverse processes of the third lumbar vertebra. No shadows suggesting renal or ureteral stones were seen. There were no dilated loops of small bowel. Films taken in the upright position showed no air under the diaphragm.

Ten hours after admission an exploratory laparotomy was performed.

DIFFERENTIAL DIAGNOSIS

DR. RICHARD H. SWEET: In this patient, the onset was acute, the story short and the illness severe, the outstanding symptoms being abdominal pain going through to the back, and nausea with vomiting, the collapse following later. In the past history we learn that for twenty-five years she had had recurrent attacks of upper abdominal pain associated with nausea and vomiting, which had been interpreted as being due to gallstone colic, but I am sure you are all acquainted with the fact that nausea, or at least vomiting, is not an outstanding symptom of the ordinary uncomplicated gallstone attack. Very frequently we see gallstone colic without any vomiting. This patient, however, had vomiting with all the attacks.

In a physical examination made at about 1:00 a.m., I think that most of us would find it difficult to decide whether the patient was jaundiced; so I do not attach much significance to that finding until later when we discover that she had a large amount of bile in the urine.

It is interesting that this patient had widespread tenderness; in fact the only place she did not have any was in the left lower quadrant. Thirteen or more hours after the sudden onset of the abdominal pain and the pain in the back, there were marked physical findings related entirely to the abdomen. In fact the tenderness was so widespread that it suggests peritonitis. The maximal tenderness and spasm were in the right upper quadrant.

The blood pressure is not recorded. It might have been of some help.

The white-cell count was low for a person as ill as this, provided she had an inflammatory process. The hemoglobin indicates that she had not been suffering from blood loss. Since the urine gave a +++ test for bile, its presence cannot be doubted. I presume that the specimen was voided; hence the few red cells, the 10 white cells and 20 epithelial cells have little or no significance.

Whoever saw this patient thought of a perforated ulcer and had an abdominal film taken in the upright position, which did not show any gas under the diaphragm. Although, of course, there are plenty of cases in which this does not occur, the presumption is that we are not dealing with a case of perforated ulcer. Furthermore, the attacks of upper abdominal pain that the patient had had for twenty-five years do not sound like those due to ulcer. The physician in charge of the patient also thought of small-bowel obstruction, but there were no dilated loops.

I presume that renal or ureteral disease was considered as well. All abdominal surgeons have at times seen people with renal or ureteral disease, caused by stone or infection, in whom the spasm and tenderness and the superficial behavior were such that a diagnosis of peritonitis was made. I remember being called one night to see a patient at the Deaconess Hospital. The medical man said, "This girl has peritonitis and something should be done about it." The abdomen was so spastic that it was boardlike, and yet there were perfectly normal peristaltic sounds. She had an acute renal shutoff, with secondary infection and fever. I presume, however, that this is not a case of renal or ureteral disease. There was no x-ray suggestion of a stone, although, of course, it might not have been visible. A report on a catheter specimen of urine would be helpful.

May we see the x-ray films?

DR. MILFORD D. SCHULZ: These films show no evidence of gas in the peritoneal cavity. There are calcified mesenteric lymph nodes. I see no evidence of biliary or renal calculi. The preperitoneal fat line seems to be preserved. If she had a localized peritonitis it could not have been of long standing.

DR. SWEET: This patient did not behave the way patients with perforated ulcer usually do. She had pain but was still well enough early that evening to visit her husband, who was in a hospital. If it was a perforated ulcer, there must have been a tiny leak that became temporarily sealed off, so that she was able to walk about for five or six hours, and then underwent a massive rupture, which produced collapse. This is a possibility, but a rather unusual one, I should say.

Was this an ordinary attack of gallstone colic? I do not believe so. Of course some people react

to pain much more severely than others, and I presume that the collapse occurred because the patient was suffering a terrific amount of pain. We do not know what the blood pressure was. I am sure from the description, however, that she really was in collapse. Because of the fact that nausea and vomiting were outstanding symptoms, I shall exclude gallstones as the immediate cause of the difficulty. I shall also exclude acute cholecystitis because she had an essentially normal temperature and a normal white cell count after thirteen hours. Acute cholecystitis, as you all realize, is one of the few conditions that will cause excessively high white cell counts, sometimes quite early in the course of the disease.

Could she have something related to the intestinal tract other than perforation of an ulcer? We cannot exclude small bowel obstruction, even in the absence of dilated loops by x-ray, but it would be most unusual for this condition to produce pain of this severity and lead to sudden collapse of the patient. I shall exclude it.

How about mesenteric thrombosis? The patient was rather young. Furthermore, most of the cases usually have a very high white cell count, and the pain is not quite typical.

There is one acute abdominal emergency that I have not touched on which fits the whole picture and even ties in with the history of gallstone attacks—namely, acute pancreatitis. A prodromal attack of pain is characteristic. The pain in pancreatitis is always upper abdominal, and it frequently goes to the back. A great many patients complaining more of pain in the back than anything else. Most of the patients with pancreatitis whom I have seen would not be described as lethargic early in the course of the disease; they are apt to be writhing in bed, complaining of pain in the back and upper abdomen. The white cell count is not inconsistent; patients with acute pancreatitis often have relatively low counts, and early in the disease they often have low temperatures. The physical examination is consistent with acute pancreatitis—namely, tenderness in the left upper quadrant, right upper quadrant and right lower quadrant.

I have not considered acute appendicitis because the onset was severer than one would expect in that condition. Furthermore, the distribution of the tenderness, as well as the maximal tenderness in the upper rather than in the lower abdomen, seems to exclude it.

For reasons mentioned before, I have excluded intra-abdominal hemorrhage from such conditions as ruptured ectopic pregnancy and accident connected with an abdominal pelvic tumor, such as rupture of a cyst. So with the history as given

and with the physical signs as stated, I shall incline toward a diagnosis of acute pancreatitis to explain the present illness. On the basis of the past history we must also conclude that she had cholelithiasis.

CLINICAL DIAGNOSIS

Acute pancreatitis

Cholelithiasis

Choledocholithiasis

PATHOLOGICAL DISCUSSION

DR BENJAMIN CASTLEMAN: At operation the surgeon found a distended gall bladder, to which the omentum was adherent. He inserted a trocar into the gall bladder, and some light colored bile came out. He was able to scoop out several stones from the cystic duct, following which the bile became normal in color. The peritoneal cavity contained slightly blood tinged fluid and several small areas of fat necrosis. He believed that the patient was too sick to do anything more. A drainage tube was placed in the gall bladder. The patient died a few hours later.

At autopsy we found an extensive hemorrhagic pancreatitis. The whole pancreas was involved, and there were areas of fat necrosis throughout the omentum and peritoneum. The cystic duct was markedly thickened and dilated and contained numerous stones, which apparently the surgeon was unable to remove. The common duct was also thickened and markedly dilated and was filled with faceted stones along its entire course. Stones were also present in the intrahepatic ducts.

In this case I am sure that the cause of the pancreatitis was a blockage of the exit of bile, with bile entering the pancreatic duct. It is satisfying to have a case of acute pancreatitis in which we are able to determine the exact cause, in many cases we find no stones or other cause for the pancreatitis. There was no squamous cell metaplasia of the epithelium of the pancreatic ducts.

DR EDWARD B. BENEDICT: Do you mean that pancreatitis without any gall bladder disease occurs in a great many cases?

DR SWEET: The late Dr. Daniel F. Jones* looked that up some years ago and found that 40 per cent of the cases occurred in the absence of stones.

BY THEIR FRUITS—

THE time has come when the Victory Gardener, at long last, can count his chips and see if the game he has been playing this departed summer has gone for him, or against him. Discounting the element of luck, present in all our enterprises in inverse proportion to the amount of time spent in planning and in executing our plans, he should be able to mark up a good score against his opponents in the game—poor soil, pests and plant disease, weeds, drought and indolence. Of these the last, perhaps, is the most important. Many an inspired spring planter has found his enthusiasm wilting under a July sun and the

necessity for regular cultivating, weeding, spraying, dusting and watering.

The number of seeds that have gone into the ground this planting season must certainly have been astronomical; Nature herself rings the bell on too gross overproduction, else we might be reminded of the geometric computation concerning the fly's eggs: If every egg hatched and produced a fly and these flies' eggs hatched and produced flies, and so on through the creatures' generations, how large would the resulting fly mass be in a specified time? Instead we are reminded of the parable of the sower, or perhaps, facetiously, of Jack Benny's description of his potato crop—some were the size of marbles, some were as big as peas, and there were quite a number of small ones

Be their productive ratio as it may, the number of war gardens that have burst into being in the backyards and waste spaces of America, when properly cultivated and harvested, must add an appreciable increment to our precarious food supply. They have done more than that; they have drawn many thousands of indoor workers into the most healthful recreation known, but none, and have added greatly to hundreds of thousands of individuals' previously meager knowledge of the methods of production and relative values of the various vegetable foods.

Fortunately for us, information on gardening and on the storing of crops has been freely available. It is essential, however, that the latter should be properly carried out. Short cuts and slipshod methods in the preserving of vegetables and fruits, particularly in home canning, may lead to serious dangers, as has been indicated in Dr. Gettung's* excellent and timely articles in recent issues of the *Journal*. Although botulism is relatively uncommon in the East, it is by no means unknown and is usually the result of the underprocessing of nonacid foods. Foods put up at home by the cold-pack method should be reboiled for ten to fifteen minutes after opening and before eating

*Gettung, V. A. Epidemiologic aspects of food borne disease. *J. Med.* 2:8 754 762 788 796 and 823 830 1945

or tasting. The much commoner staphylococcal enterotoxin is heat stable, but is much likelier to be found in canned foods that have spoiled after opening than to have survived ordinary processing.

SEVENTY-FIVE YEARS OF ACHIEVEMENT

The Metropolitan Life Insurance Company celebrated its seventy-fifth anniversary last spring. Founded in March, 1868, it has witnessed the greatest period of progress in public health that the world has ever seen and has, particularly in the latter half of the period, been a factor in carrying on and in helping to initiate many of these advances. In the *Statistical Bulletin* for March, 1943,—an anniversary number,—the company has reviewed these seventy-five years of progress.

In 1868 the death rate for New York City was 28 per 1000 persons, reaching 40 in some wards, and even higher figures in individual blocks. As a result of this high mortality, particularly among children, the average length of life was correspondingly low—about forty years, as against sixty-four years today. In the underprivileged classes of society worse than the average conditions prevailed.

Public-health organizations, however, soon began to put into effect the knowledge gained from the discoveries of Pasteur and the experiments of Lister, and although gains were at first slow, medical progress really began to hit its stride with the turn of the century. In 1909 the company launched an organized welfare program, and from that time on its health program, combining nursing and educational activities among policyholders with co-operation and support of existing health organizations, has been identified with most of the health advances made in this country and Canada.

The statistical experience among industrial policyholders of the company exemplifies the progress that has been made. In 1911 the standardized death rate from all causes among these policyholders between the ages of one to seventy-four was 13.5 per 1000, whereas in 1942 it was 6.1. During the same period the average length of life in the group has increased from less than forty-seven years to about sixty-four years. The infant death rate has dropped to about one fifth of its 1920 figure; the mortality in the age group from one to fourteen has improved four fifths since 1911; tuberculosis, with a death rate of more than 220 per 100,000 in 1911, has now a rate of scarcely more than 40; and between the years 1937 and 1941, the mortality from pneumonia has been reduced by 54 per cent. The current death rate from appendicitis is the lowest in history; and the mortality from all accidents, even including those due to automobiles, has been reduced. In fact, if war could be banished, one might say that the people of this country alone were facing a millennium.

The activities of the welfare program deserve a brief review. Most vital has been a nursing service to policyholders, now reaching nearly eight thousand communities. In the field of health education, about one and a quarter billion pamphlets have been distributed, and the company's motion pictures have been viewed by more than one hundred and twenty-five million persons. The well-known demonstration at Framingham, Mass., showed how a community could solve its tuberculosis problem; the demonstration at Theford Mines, Quebec, reduced infant mortality by two thirds in three years; and important advances in the treatment of pneumonia have been aided by the Influenza-Pneumonia Commission, organized in 1919.

Its seventy-five years of achievement have certainly justified the high respect in which this organization is universally held.

MEDICAL EPONYM

GILBERT'S DISEASE

This was first described by Professor A. Gilbert (1858-1927) at a meeting of the Société médicale des hôpitaux de Paris on July 27, 1900, in a paper entitled "De l'ictère familial: contribution a l'étude de la diathese biliaire [Familial Jaundice: A contribution to the study of the biliary diathesis]," in collaboration with Drs. J. Castaigne and P. Lereboullet, in which a number of cases of jaundice of diverse origin are described. Their paper appeared in *Bulletins et mémoires de la Société médicale des hôpitaux de Paris* (17:948-959, 1900). A portion of the translation follows:

Whatever else the nature of this hereditary predisposition to infection of the biliary passages may be, it seems to us to be proved by the facts that we have reported. Not only lithogenic angiocholecystitis, then, is hereditary; simple or cirrhotogenous angiocholitis may equally be so, and by reason of this predisposition, one may meet in a single family with the various clinical types, the principal characteristics of which we have described.

In subsequent papers he further describes simple, nonhemolytic familial jaundice—for example in an article entitled "La cholémie simple familiale [Simple Familial Cholemia]," in the *Gazette hebdomadaire de médecine et de chirurgie* (7:889-897, 1902) he states: "Familial cholemia is extremely common. . . . It is a familial, hereditary disease."

Whooping cough	286	673	533

*Pfeiffer-bacillus meningitis only other form reportable previous to 1941.

COMMENT

The poliomyelitis situation in Massachusetts is of special interest at the present moment owing to the relatively large number of cases occurring in certain other states. The incidence in August was about two and a half times the seven-year median, and subsequent weeks will probably show a still further increase. Nevertheless, the season during which poliomyelitis usually occurs is now so far advanced that the chances are against the occurrence of a real epidemic this year.

Meningococcal meningitis has shown the seasonal decline that was expected, although the level is higher than in the average year. The August figures are less than half those of June. Salmonella infections, on the other hand, show an increase over those of the last three months. These were distributed through eleven towns and do not represent any major outbreak.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anterior poliomyelitis was reported from: Arlington, 1; Attleboro, 3; Beverly, 1; Boston, 1; Braintree, 1; Brockton, 1; Cambridge, 1; Chelsea, 1; East Longmeadow, 1; Everett, 1; Fall River, 1; Lynn, 1; Marblehead, 1; Medford, 1; New Bedford, 2; New Marlboro, 1; Norton, 1; Palmer, 1; Quincy, 2; Waltham, 1; total, 24.

Anthrax was reported from: Woburn, 1; total, 1.

Diphtheria was reported from: Amesbury, 1; Athol, 2; Dighton, 1; Somerville, 2; Westport, 1; total, 7.

Dysentery, bacillary, was reported from: Boston, 1; Chelsea, 3; Holyoke, 9; Worcester, 1; total, 14.

Encephalitis, infectious, was reported from: Everett, 1; total, 1.

Malaria was reported from: Boston, 1; Chicopee, 1; Concord, 1; Fort Banks, 4; Fort Devens, 5; Milford, 1; Springfield, 1; total, 14.

Meningitis, meningococcal, was reported from: Athol, 1; Attleboro, 1; Barnstable, 1; Boston, 6; Brookline, 1; Bridgewater, 2; Camp Edwards, 4; Chelmsford, 1; Chelsea, 1; Everett, 1; Fitchburg, 1; Fort Devens, 2; Gloucester, 1; Holbrook, 1; Holyoke, 2; Lawrence, 2; Longmeadow, 1; Lowell, 2; Lynn, 2; Malden, 1; Medford, 1; Middleboro, 1; Montague, 1; Southbridge, 1; Swampscott, 1; Taunton, 2; Weymouth, 1; total, 42.

Meningitis, other forms, was reported from: Foxboro, 1; Malden, 1; Pittsfield, 1; Springfield, 2; total, 5.

Meningitis, undetermined, was reported from: Boston, 1; Springfield, 1; Worcester, 2; total, 4.

Salmonella infections were reported from: Adams, 1; Beverly, 2; Everett, 1; Haverhill, 4; Marblehead, 3; Melrose, 1; Northfield, 5; Salem, 2; Somerville, 1; Winchester, 1; Worcester, 1; total, 22.

Septic sore throat was reported from: Boston, 5; Pittsfield, 1; total, 6.

Tetanus was reported from: Boxboro, 1; Falmouth, 1; Somerville, 1; total, 3.

Typhoid fever was reported from: Ludlow, 1; Shirley, 1; North Adams, 1; total, 3.

Undulant fever was reported from: Adams, 1; Brookline, 1; Hopkinton, 1; Lowell, 1; Whitman, 1; total, 5.

BOOK REVIEWS

Clinical Laboratory Diagnosis By Samuel A Levinson
M.D. and Robert P MacFate, Ch E., M.S. Ph.D. Second
Edition 8", cloth, 980 pp, with 156 illustrations 92 ta-
bles and 15 plates Philadelphia Lea and Febiger, 1943
\$10.00

The second edition of this book lives up to the ex-
pressed purpose of the first edition, namely, to present to
the student, intern, practicing physician and technician a
concise review of clinical laboratory diagnosis to meet
general needs.

The subject matter has been brought up to date, new
text has been added and the special appendix on the
course in clinical pathology at the University of Illinois
College of Medicine has been deleted to provide space
for new items have been added relating to water metabolism
and acid base balance. Recent blood clinical methods for
the determination of ascorbic acid, the sulfonamides
phosphatase, alkaline and acid phosphatase, amylase and
other substances are described. The chapter on hemato-
logy has been enlarged to make room for a discussion of
bone marrow findings, Rh factor, blood volume and other
items. The inclusion of chapters on water and milk
analysis and toxicology and legal medicine as well as
histological technique, skin tests and other biologic exam-
inations adds value in that in a single volume one has
at hand a ready reference book on virtually any type of
examination with which clinical laboratory diagnosis may
be concerned in its broadest scope. A brief and concise
review of pertinent anatomical physiologic and biochem-
ical considerations is of great value in illuminating the
background of the accumulation of knowledge that is to
be interpreted by means of findings obtained by specialized
technical procedures.

A separate section on laboratory methods in pediatric
procedure is cited as an example of the well planned ar-
rangement of subject matter, which offers ready access
to the source of the specific information one may be
seeking.

Methods described in blood clinical analysis make use
of procedures which, so far as possible can be adapted
for either colorimetric or photometric determinations.
This simplification and adaptation of methods is particu-
larly of advantage in these times when new apparatus is
scarce if not impossible, to obtain.

The chapter on bacteriology is arranged in an orderly
fashion. Bergey's nomenclature and classification are fol-
lowed. The description of appropriate methods to be
used in the bacteriologic examination of specific materials
is particularly valuable to the inexperienced technician.
The charts of the characteristics and classification of the
commoner bacteria are a useful feature.

It is interesting to note the complete exposition cover-
ing the function and examination of saliva and pathologic
conditions of the mouth. In this section, as well as those
on the stomach and intestines, are old and tried methods
of examination, which, although little used nowadays,
have their value.

In the chapter on immunology and serology, serologic
tests for syphilis include the Kolmer complement fixation
test the Kahn precipitation test and the Kline micro-
scopic slide precipitation test. The reviewer believes that
the Hinton test deserves at least mention as an acceptable
serologic test for syphilis.

This comprehensive treatise is concise and clear in
structure and in detail. The charts, illustrations and
tables are well chosen for their purpose, and add much
to the general usefulness of the book. It is highly re-
commended to those for whom it was written—the stu-
dent, the intern, the practicing physician and the tech-
nician. In addition, it should be in the working library
of every clinical laboratory.

Surgical Practice of the Lahey Clinic Boston Massachusetts
8", cloth, 897 pp with 376 illustrations Philadelphia
and London W B Saunders Company, 1941
\$10.00

In this volume are collected seventy-eight papers by the
staff of the Lahey Clinic, Boston previously published in
American journals in the years 1937-1941. Nearly half
are from *Surgical Clinics of North America*. According
to the preface by Dr. Lahey, it is a cross section of the
methods in use in his clinic, representing an attempt at
standardization, which he believes is largely responsible
for improved end results. Written by twenty-two con-
tributors, the papers are necessarily of uneven merit.

Nine papers by Dr. Lahey and collaborators on the thy-
roid gland are authoritative and one on esophageal diver-
ticula is based on his almost unique experience with
such lesions. Articles on laryngoscopy, empyema, pul-
monary lobectomy, branchial cysts and carcinoma of the
breast are routine descriptions of technique. Twenty-one
contributions by Lahey, Cattel and their associates on the
stomach, duodenum, colon and rectum describe methods
that they have proved to be effective. It may be noted
that no mention is made of the Miller-Abbott tube, whose
inventor bids fair to supplant some of the methods de-
scribed. Four papers on the bile duct are of routine na-
ture and four gynecologic topics, three on the kidney and
prostate and six on orthopedic subjects necessarily cover
but little of those fields. Two important and useful
groups are those by Horrax and Poppen on neurosurgery,
and ten papers by Sise and his collaborators on anesthesia
—two fields of comparatively recent development in which
the work of the Lahey Clinic has been conspicuous.

The illustrations are numerous, many of them excel-
lent but some of the line drawings are quite inadequate
and a few are positively misleading. It is regrettable to be
obliged to say that the literary quality of some of these
papers leaves much to be desired, and that proper editorial
supervision has not been exercised. There are in
stances of clumsy phrasing in some of which, apparently,
a meaning is expressed precisely the opposite to that in-
tended. Did space permit it would be informative to in-
experienced writers to list these solecisms. A few are as
follows: the malignancy is now given to the pathol-
ogist (p. 460) the removal of a large portion
of malignancy (p. 481), and the entire bone-
flap may be safely elevated if the staphylococci [sic]

been proved, and I doubt that they have had any foundation in fact.

At the board meetings, hearings are conducted to settle the guilt or innocence of registered physicians against whom complaints have been made, or who have been found guilty in the courts. The complaints are usually concerned with negligence or deceit. The doctors who have been found guilty in the courts are those who, in most cases, have violated the federal narcotic law or have performed criminal abortions.

If the doctor is found guilty, his license is suspended or revoked, according to the seriousness of the case. Most of the complaints are handled by the secretary, who decides, after a conference, either that the matter can be settled without a hearing before the full board or that the complaint is not worthy of a hearing.

Complaints against unregistered practitioners of medicine are many and varied; these are turned over to the State Police for investigation. The latter frequently make arrests; the culprits are tried and if found guilty are fined. All that we have to do is to testify that the accused is not registered to practice medicine in the Commonwealth.

One of the duties of the board is to introduce legislation considered essential to the elevation of the standards of the profession, and for the protection of the interests of the people of the Commonwealth. I believe that it is also the duty of the board to oppose legislation that it knows is detrimental to the advance of medicine and the maintenance of its standards.

I have found out during the past year that it is very important at public hearings before a legislative committee to have one's facts well in hand, to be able to present arguments concisely, and not to antagonize the members of the committee. It is of the greatest help to be able to talk to the members of the legislature who may be influential in passing or defeating the legislation. An eagle eye must be kept on the calendar so that important bills may not slip by without the knowledge of the medical profession. One antivivisection bill reached the governor's desk this year without any opposition's having been presented by the profession. Fortunately, in this case, the omission was discovered in time to organize protests that finally brought about the withdrawal of the bill. By hard work and long hours spent on the problems, and with complete co-operation with the Massachusetts Medical Society, the board has been able to defeat two dangerous nursing bills and two antivivisection bills, and now has a bill in committee to continue the control of approved medical schools in this state forever.

Since the process of introducing legislation or defeating unfavorable legislation is a matter that concerns the law, and since physicians are very busy at their daily tasks of caring for the sick, and since physicians generally abhor anything that has to do with politicians and their ways, I believe that it would be for the best interests of this society to employ a legislative counsel to assist the members of the Committee on Legislation and of the Board of Registration in Medicine with such problems. A well-known and astute lawyer who "knows his way around" would be of great help, and I am sure that he would meet with the approval of those legislators who are looking after the interests of the medical profession.

Once a doctor has been registered to practice medicine in this state, he may do so throughout his life unless he is found guilty of gross misconduct. It has been extremely humiliating for our office not to be able to furnish information to the Army, the Navy, the F.B.I., the Committee of Ethics and Discipline of the Massachusetts Medical Society, hospitals, civic groups and individuals concerning doctors whom we have registered. For a small fee and a few minutes' time on the part of the doctors we could make it possible to know the pertinent facts concerning every registered physician in the Commonwealth; every member of this society could have the list in his bookcase; he could be immediately aware of the presence of the unregistered practitioner in his community; and the office of the board could give fairly accurate information to the right people concerning physicians registered in Massachusetts. I have no doubt that this information would have been of considerable help to the various district committees of the Procurement and Assignment Service during the past two years. I am sure that if every registered doctor had to reregister every year on his birthday, the profession as a whole would be benefited. Such legislation has been of great value to the nurses and the dentists.

The secretary of the Board of Registration in Medicine is the chairman of the Approving Authority for Medical Schools; the other two members of that board are the commissioner of education and the commissioner of health. It is the task of the authority under the present law to inspect medical schools at the request of their trustees. As you very likely know, the present law requires that any young man entering medical school after January 1, 1941, must graduate from an approved school in order to be allowed to take the examination for registration in this state. Therefore, after January 1, 1945, the problem of the unapproved medical school in the Common-

wealth will disappear, and Massachusetts will rise to an even rank with the other states. This most excellent piece of legislation was made possible by the combined efforts of the members of this society, the Board of Registration in Medicine and interested legislators.

The failure of the Massachusetts General Court to enact this important legislation earlier produced many difficulties for this society, the medical profession generally and the Board of Registration in Medicine in particular. Although it will take many years to eliminate all the bad results of inferior medical education in Massachusetts, at least we have the pleasure of knowing that the situation is improving constantly and that hereafter we need not be ashamed of our state in this important matter.

The secretary of the Board of Registration in Medicine is also the secretary of the Board of Registration in Nursing, which comprises six physicians and nurses who are leaders in their respective fields, who must shape the destiny of nursing education in the Commonwealth. It is the duty of this board to examine candidates for registration in nursing who are the graduates of any one of the sixty-three approved schools in Massachusetts, and to register those from other states by reciprocity if they meet the educational requirements of our law. These women must be at least twenty-one years of age and must have attended a school of nursing for one thousand and ninety-five days. Here again, each member of the board writes, proctors and corrects his own examination, and the candidates are known only by numbers. Since one does not have to be a registered nurse to work at her profession in Massachusetts there is no monetary value attached to the certificate, and the difficulties met with in the medical profession are not encountered.

The Board of Registration in Nursing also examines those who wish to become licensed attendants. These women must be twenty years of age or over and must have attended a school for the training of practical nurses. After October, 1944, they must be graduated from an approved school for attendants before they can take the examination for a license. Last year we licensed by waiver and examination about 2000 of these valuable women.

The secretary of the Board of Registration in Medicine is also the secretary of the Approving Authority for Nursing Schools. This board is made up of men and women who are on the ad-

ministrative, executive or teaching staffs of hospitals or nursing schools. They are appointed by the Governor. It is the work of this board to determine the educational qualifications of the prospective nurse, the courses to be taught in the nursing schools and the qualifications of the teachers in the nursing schools. It must determine the quality of the schools in every respect. To inspect the sixty-three approved schools in this state, to help them with their various problems, to try to improve them and to make sure that the quality of our nurses is maintained at a high level are the duties of two supervising nurses employed by our office. These nurses are at the top of their profession, and the success or failure of the work of the approving authority rests, to a great extent, on their shoulders. During this emergency, when there is a shortage of nurses, the approving authority has attempted in every way possible within the law to increase the number of nurses and at the same time to maintain high standards. Their latest act has been to present legislation to the Governor for emergency action whereby nurses may become registered at the age of twenty instead of twenty-one and attendants at the age of nineteen instead of twenty. If this is done, more young women will go into nursing schools as soon as they finish high school, since they will not have to await their eighteenth birthday.

* * *

I have presented an outline of the work of the Board of Registration in Medicine, the Board of Registration in Nursing and their respective approving authorities. All these units are functioning under new laws that promise to work to the advantage of medicine and nursing in the Commonwealth and eventually to bring it into line with the states that have the highest standards. There is no doubt that all this will be to the best interests of the public when they need medical and nursing care. Personally, I have but one aim in all this work: to improve the conditions in private practice and in hospitals that affect the care of patients. Better schools of medicine and nursing mean better physicians and nurses, and that means better care of the sick. The Board of Registration in Medicine is representative of the Massachusetts Medical Society. The board wants to do what you would like to have it do. We are trying at all times to interpret your desires to make the practice of medicine in Massachusetts the very best. We hope for, and expect to get, your co-operation in this vital work.

CARCINOMA OF THE LARYNX*

LEROY A. SCHALL, M.D.†

BOSTON

IT HAS been estimated that the larynx is involved in from 2 to 5 per cent of all cases of carcinoma. This incidence varies with different authors, since most of the data have been obtained from actuaries and are based on different opinions concerning the primary source of the tumor. Even acceptance of the lowest rate of incidence signifies that the disease is not uncommon. It has likewise been pointed out that the life expectancy in untreated cancer of the larynx is one year in 50 per cent of patients and that 95 per cent die within two years.

In no other internal organ of the body does cancer cause symptoms so early as it does when it occurs within the larynx. In the great majority of cases, laryngeal cancer begins as a lesion of the vocal cord. Here even a minute growth interferes with the normal function of the cord, and this interference is expressed as an alteration in the voice, progressing with time to a persistent hoarseness. Such hoarseness is so suggestive of something more serious than a simple laryngitis that the axiom, "In persistent hoarseness of two weeks' duration think of cancer, tuberculosis and syphilis," should never be forgotten.

Just as no other internal organ of the body produces a symptom so early as does cancer of the larynx, no other internal organ of the body can be so easily examined. In spite of these facts, it is not unusual to see not only patients with a history of hoarseness of months' and even years' duration who have received no medical advice, but also, and in too many cases, those who have been treated by gargles or sprays without the benefit of a laryngeal examination. Yet an examination of the larynx does not require unusual skill. A reflected light and a laryngeal mirror comprise the necessary equipment—and a few minutes of time.

In early laryngeal cancer the examination often reveals a proliferating new growth of the vocal cord and, in the vast majority of cases, it is the anterior half of the cord that is involved. Such a lesion is relatively benign; the lymphatics are few and scattered, so that the growth may persist for months and still be local. As the cancer slowly infiltrates along the long axis of the cord, it finally reaches the posterior half of the cord, where the lymphatics are more numerous, and from then on its progress is rapid. Fixation of the cord signifies

that the cancer has infiltrated through the mucous membrane into the muscle of the cord or into the cricoarytenoidal joint. It is no longer a lesion of the mucous membrane. From the posterior portion of the cord the cancer spreads to the subglottic space, into the ventricle, into the false cord, to the arytenoid and aryepiglottic fold, and frequently to the esophagus and to the cervical lymph nodes.

Laryngeal cancer that is untreated or that fails to respond to treatment terminates with extreme suffering and a lingering death. Laryngeal obstruction means a fight for air, relieved only by tracheotomy. Extension to the mouth of the esophagus blocks the lumen so that the patient drools, since he cannot swallow his own saliva. Gastrostomy for feeding is frequently necessary. Involvement of the superior laryngeal nerve means severe pain, frequently referred to the temporomandibular joint or to the ear.

Just as no other internal organ of the body produces so early a symptom as does the larynx in cancer, and just as no other internal organ is so easily examined, so in no other internal organ of the body does cancer present a larger series of cures than it does in the larynx.

The limits of time do not permit a detailed discussion of the treatment of laryngeal cancer. The selection of the treatment is a highly individual one, and no hard and fast rule can cover every case. The location of the growth, the extent of the lesion, the degree of malignancy and the degree of cord fixation, as well as the physical condition of the patient, should determine the plan of treatment.

The ideal treatment is one that not only eradicates the disease but also leaves a normal physiologic state. External irradiation answers these requirements. Laryngeal cancer that responds to irradiation leaves the patient with a normal, or nearly normal, useful voice.

Cancer of the larynx may be classified as follows: Group I—small localized lesions of the vocal cord; Group II—extensive cordal or subglottic intrinsic growths; and Group III—intrinsic involvement with extrinsic extension.

In Group I, the small localized cordal growths, irradiation is to be preferred if the cancer is of Grade III or IV according to Broder's classification, and surgery if it is of Grade I or II. Surgery has in its favor that it can be performed under

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 26, 1943.

†Professor of laryngology, Harvard Medical School; chief, Department of Otolaryngology, Massachusetts Eye and Ear Infirmary.

local anesthesia; that the operative mortality is less than 1 per cent; that the period of hospitalization averages ten days to two weeks; and that unless the vocal process is removed there is frequently a regeneration of the vocal cord. When the case has been properly selected as suitable for laryngeal surgery by laryngofissure, a three-year to five-year cure can be obtained in approximately 75 to 82 per cent of cases, depending on the knowledge and skill of the operator.

In Group II, where there is cord involvement with subglottic extension, most radiologists agree that the carcinoma is not radiosensitive and that irradiation should not be used. Surgery offers only a total laryngectomy as a hope of cure.

In Group III, the extensive intrinsic and extrinsic carcinomas, particularly those of Grade III or IV, irradiation is the treatment of choice, although it may be only palliative.

The history of total laryngectomy is interesting. It is a little more than fifty years since Dr. J. Solis-Cohen,¹ assisted by Dr. W. W. Keen, operated on Daniel Hickey, performing the first successful total laryngectomy in the United States. Improvement in anesthesia as well as in surgical technique has robbed this operation of its high mortality. Among 53 patients, I have lost 2 from conditions attributable to the operation. One died from pneumonia on the sixth postoperative day, and the second from cardiac failure on the eighteenth postoperative day, on the eve of her discharge from the hospital.

From the earliest writings concerning cancer of the larynx to the most recent ones, total laryngectomy has often been described as a mutilating procedure leaving its victim in a pitiable condition—one that is worse than death. The psychic reaction to the loss of the power of speech, it is said, frequently leads to suicide or to insanity.

The medical profession and the public are familiar with the blind, the deaf and the crippled. Neither the public nor the vast majority of physicians are familiar with the patient who has lost his larynx and consequently the power of normal speech. It is a human failing to avoid the unknown. There is need of educating the medical profession as well as the laity to an understanding that the laryngectomized patient is not a pitiable creature who has given up all that life holds dear. It is hard properly to evaluate human suffering. The blind say that they would rather be blind than deaf; the deaf, that they would rather be deaf than blind; but the patient without a voice considers himself fortunate that he is neither blind nor deaf.

In advising the total removal of the larynx, one must appreciate the readjustments the patient must make and must evaluate his ability to make them.

His mental outlook should be given serious consideration. The patient who lives wholly within himself—the self-centered, brooding person who faces any crisis with the greatest difficulty—is poor material to make the mental readjustment necessary after total laryngectomy.

Although the larynx is described as the organ of speech, it is not necessary for speech. Useful audible speech may be obtained after removal of the larynx by use of the so-called "artificial larynx," as developed by the laboratories of the Bell Telephone Company, or by re-education and development of the so-called "esophageal voice."

The artificial larynx consists essentially of a flexible, noncorrosive metal reed that is placed in juxtaposition to a rubber membrane inside a brass sound box, a mouthpiece that fits into a metal stem at the top of the sound box and a flexible connection to the tracheal stoma. When this apparatus is being used for speaking, the air is inhaled through the hole in the side of the sound box and passes through the metal tube in its bottom, down through the rubber connecting tube and through the tracheal connection into the lungs. The air when exhaled tends to pass out by the way it entered, but if the hole in the side of the sound box is closed by the finger or thumb, the air is forced out around the reed. This causes the reed to vibrate and to produce sound, which passes out through the stem in the top of the sound box and to the rubber mouthpiece into the mouth, to be converted into speech. The artificial larynx is supplied to the patient early after the operation so as to offer a positive substitution for the lost power of speech.

The esophageal voice depends on the esophagus acting as an air chamber. The patient inflates his esophagus by swallowing air, creating a positive pressure that is thrown into air currents at the side of the tongue when its base is closed against the posterior pharyngeal wall. With exercise and training this action becomes automatic. (Dr. Schall then demonstrated 2 cases as examples of the successful use of these devices. In one, the patient had received a total laryngectomy, and by means of an artificial larynx was able to carry on successfully his work as a plumber. In the other, the patient was treated by external irradiation for an extensive carcinoma of both vocal cords. For three years he was free from disease. With recurrence and with the skin unable to stand further radiation, a total laryngectomy was performed. The patient developed an esophageal voice that permits him to continue his work as a fireman.)

CONCLUSIONS

In carcinoma of the larynx, as with cancer elsewhere, early diagnosis is of prime importance.

External irradiation is the ideal treatment, and it leaves a useful voice.

Laryngofissure, when indicated, gives a 75 to 82 per cent five-year cure.

Total laryngectomy, when necessary, does not always wreck the life of the patient, for this

result can be avoided by the use of an artificial larynx or of an esophageal voice.

ERYTHROBLASTOSIS FOETALIS*

Report of a Case

GERHARD J. NEWERLA, M.D.†

ALBANY, NEW YORK

EVER since Diamond, Blackfan and Baty¹ in 1932 first designated as erythroblastosis foetalis, a syndrome characterized by the triad of hydrops, icterus gravis and anemia of the newborn, this interesting disease has been studied intensely. Darrow² in 1938 first suggested isoimmunization by the mother against fetal red cells as the basic etiology, but had no means of proving this theory. Levine and Stetson³ in 1939 were the first to point out that isoimmunization of the mother through the fetus can occur. Landsteiner and Wiener⁴ in 1940 discovered the occurrence of the Rh factor in 86 per cent of human beings as a dominant mendelian gene, and Levine with his co-workers^{5, 6} since 1941 have accumulated many data to prove that the Rh factor is at least one of the major etiologic causes of erythroblastosis foetalis. Javert^{7, 8} accepted the Rh factor as one of the causes, but suggested other necessary factors as further underlying conditions.

Most of the evidence, however, points to serologic phenomena, and erythroblastosis foetalis is most probably the outcome of an isoimmunization resulting from fetal antigens and subsequent hemolysis of the fetal red cells by maternal antibodies produced by these antigens, and transmitted from one circulation to the other in a process of diaporesis and dialysis.

Recently, a case of erythroblastosis foetalis of atypical form was observed in an infant who displayed icterus gravis as well as neonatal anemia, but no hydrops congenitum. A prompt diagnosis led to transfusions and resulted in cure and survival.

CASE REPORT

C. W., a 14-day-old boy, was admitted on October 14, 1942, with known intense jaundice of 5 days' duration. He was the second child of young, healthy parents, and was born at home without instrumentation. At birth he appeared normal and the attending obstetrician ob-

served no untoward symptoms or signs. The birth weight was not recorded, but the child appeared well developed. On the 9th postnatal day, a deep icterus became apparent and reached its maximal intensity 24 hours later. On admission the weight was 7 pounds, 2 ounces.

Both parents gave negative Wassermann and Kahn reactions. The mother was 19 years old and had a daughter of 21 months, born at term, who had at no time shown any degree of jaundice. She denied any miscarriages or stillbirths. The father was 24 years old and was jaundiced in infancy. Otherwise the family history was negative.

Physical examination was negative except for an intense icterus of the entire body. Enlargement of abdominal organs, and especially of the spleen and liver, could not be demonstrated by several examiners nor by a consultant, and roentgenograms of the long bones taken on October 16 gave no evidence of any pathologic lesions. The fragility test was negative, since hemolysis occurred in sodium chloride solutions ranging from 0.44 to 0.32 per cent, whereas in a normal control it occurred in solutions ranging from 0.40 to 0.30 per cent. A tentative diagnosis of erythroblastosis foetalis was made, substantiated by subsequent consultation and serologic studies by Dr. Philip Levine, of Newark, New Jersey. A total of three transfusions was given at intervals of about once a week. The essential features of the hemograms will be discussed in detail.

Serologically the father was Type A and the mother was Type O. The patient was also Type O, as was a sister of the mother. Agglutination of the patient's red cells by the mother's serum was positive, although both were Type O. This indicated the presence of some substances in the mother's serum that agglutinated the red cells of the infant. These substances were later proved to be anti-Rh agglutinins.

The initial hemogram of the patient gave a count of 1,520,000 erythrocytes. The white-cell count was 42,000, with 39 per cent mature and 6 per cent immature polymorphonuclear leukocytes and 5 per cent myelocytes, as well as 4 per cent nucleated red cells. The hemoglobin was 32 per cent (Sahli), and the color index 1.06. Marked anisocytosis and polychromasia were present in this as well as in all subsequent stained smears except the last. During the next 2 days the red-cell count fell to 1,500,000, and the white-cell count to 34,000, with 30 per cent polymorphonuclear leukocytes and 18 per cent myelocytes; the nucleated erythrocytes increased to 7 per cent.

*From the Pediatric Division of the Leonard Hospital, Troy, New York.

†Formerly, intern, Leonard Hospital, Troy, New York.

On October 17, a transfusion of 50 cc. of whole blood from a professional donor of Type O was given without regard to the Rh factor. The red-cell count reached a maximum of 2,290,000; the white-cell count decreased to 12,300, with a minimum of 19 per cent polymorphonuclear leukocytes, and an additional 8 per cent immature and 8 per cent myelocytic granulocytes. The hemoglobin rose to 46 per cent, with a color index of 1.04. Simultaneously with the first transfusion, 1 mg. of vitamin K and 0.3 cc. of liver extract were given daily, and the patient showed a normal weight-increase curve.

On October 23 the red-cell count had fallen to 2,090,000. The white-cell count was 18,500, with 24 per cent mature and 5 per cent immature polymorphonuclear leukocytes and 9 per cent myelocytic granulocytes, and 6 per cent nucleated red cells. The hemoglobin was 39 per cent, with a color index of 0.89. A second transfusion of 50 cc. of whole blood was therefore given from the original donor, after routine cross matching at room temperature. This transfusion was followed by fever and facial twitchings of the recipient. The red cell count reached 3,000,000 the day after the transfusion. The white-cell count fell to 11,600 after a slight increase during the period of reaction. The polymorphonuclear leukocytes increased to 33 per cent, the immature granulocytes remained stable at 5 per cent, and the myelocytes decreased to 5 per cent. The nucleated erythrocytes reached a maximum, 16 per cent, on the day following the transfusion, decreasing to zero 5 days later. The hemoglobin increased to 62 per cent, whereas the color index remained stable at 1.03. Physical examination revealed that the icterus had greatly decreased and that the weight had increased in a regular curve.

On November 2, a third transfusion of 50 cc. of whole blood was deemed necessary to hasten complete recovery. A new donor was found in the mother's sister, whose cells were compatible by Levine's⁹ modified cross-matching technic.* Following this transfusion the red-cell count rose rapidly to 3,000,000, at which level it stabilized, with complete disappearance of the nucleated erythrocytes. The white-cell count rose from 13,900 to 28,000 owing to a minor skin infection, but decreased in a few days to 17,000. The polymorphonuclear leukocytes increased steadily from 30 to 55 per cent, the immature as well as the myelocytic granulocytes disappeared, and the hemoglobin reached 60 per cent, with an average color index of 1.0. The icterus disappeared completely, and by November 21, when the patient was discharged, the weight had reached 8 pounds, 8 ounces. The anisocytosis and polychromasia had disappeared.

Blood samples of the mother were submitted to Dr. Levine, who gave the following report:

The mother's blood is in Group O; it is Rh-negative with each of the three varieties of anti-Rh serums, and positive with anti-Hr serum. The serum contains anti-Rh agglutinins with a titer of about 1:50 and its specificity corresponds to that of an anti-Rh₁; that is, it gives 85 per cent reactions.

Subsequent physical examination and hemograms of the patient were negative. He was last seen on January 26, 1943, or 2 months after discharge, at the age of 4 months. He appeared physically well and displayed no signs of jaundice or other residual, and was considered cured. The red-cell count was 4,290,000 and the white-

cell count was 13,000, with 34 per cent polymorphonuclear leukocytes plus 2 per cent immature granulocytes. The hemoglobin had risen to 78 per cent, with a color index of 0.90. Neither anisocytosis nor polychromasia was evident. It should be pointed out that the severe icterus and the facial twitchings during the course of the disease may very well have been associated with kernicterus, and that, therefore, cerebral palsies and retardation in physical and intellectual development must be watched for during the next 6 months to be certain that this damage did not occur.

DISCUSSION

The importance and role of the Rh factor in the pathogenesis of erythroblastosis foetalis and its logical therapy were well pointed out by Levine and his co-workers^{5,6} in 1941-1942. The existence of qualitative differences in the Rh agglutinogens in human Rh+ blood was first demonstrated by Wiener¹⁰ in 1941. Levine⁹ in 1941 claimed that about 90 per cent of intragroup transfusion reactions are due to isoimmunization, either because of repeated transfusions or because of diapedesis of fetal blood in Rh- women, although anti-Rh agglutinins cannot always be demonstrated. He assumed that the anti-Rh antibody is fixed to the tissue cells of the reticuloendothelial system. To prevent such accidents all Rh- recipients should be transfused with Rh- blood only. In cross matching, the patient's serum and donor's cells should be incubated at 37°C. for the fifteen to thirty minutes before the result is reported, since anti-Rh agglutinins frequently behave like warm agglutinins, as in the present case. However, even this modified cross-matching technic is reliable in less than half of the cases, and should not take the place of typing for the Rh factor in well-organized hospitals and medical centers. Levine's⁹ article should be consulted for details of the modified cross-matching technic.

The clinical triad of erythroblastosis foetalis consists of fetal hydrops, icterus gravis neonatorum and neonatal anemia. This patient presented a deep icterus as well as neonatal anemia with excessive normoblasts and progressive decrease of the peripheral red-cell count. However, the fact that hemolysis became grossly evident as late as nine days after birth does not argue against the isoimmunization theory of erythroblastosis foetalis, since several authors have made such reports. The suggestion has been advanced that the delayed reaction—that is, hemolysis—may be produced in breast-fed infants by the ingestion of colostrum. This, however, does not pertain to our observation, since the patient was bottle fed. Another theory holds that the agglutinins of the mother can be stored in the fetal tissues or remain in combination with other red cells, to be released

*The tubes are incubated at 37°C. for thirty minutes, then centrifuged at 500 r.p.m. for one minute; they are then inspected for agglutination, both grossly and under the microscope.

later, although it is not as yet clear what mechanism brings about this release. Yet this last theory may be applied to the present case, in which after transfusion with nonagglutinating blood jaundice apparently became clearly visible nine days after delivery, and in which isoagglutinins were demonstrated in the mother's blood. Furthermore, (third transfusion) higher hemoglobin levels and red-cell counts were maintained.

The theory of Levine and his co-workers is in essence that 87 per cent of all human beings are Rh+ and 13 per cent are Rh-. Levine et al.^{5,6} also found that 90 per cent of mothers whose infants developed erythroblastosis foetalis were Rh-, and all these women were married to Rh+ husbands. If an Rh- woman bears a child by an Rh+ man, all offspring will be Rh+ if the husband is homozygous, but only half if he is heterozygous (mendelian dominant), and only these may develop erythroblastosis. This occurs oftener in the second Rh+ child (as in our case) and in subsequent children, since isoimmunization is said to be initiated by the first pregnancy. During this period of isoimmunization the Rh+ red cells from the fetus apparently pass through the placental membranes into the Rh- maternal circulation, where they stimulate the production of antibodies. These antibodies then pass back into the fetal circulation, and if they there attain a suitable concentration produce agglutination and, secondarily, hemolysis of the fetal red corpuscles, the equivalent of the agglutination effect in vitro.

At birth the fetal and maternal circulations are permanently severed and the exchange of Rh+ cells between fetus and mother and of anti-Rh antibodies between mother and fetus ceases. Yet fetal hemolysis will continue until all anti-Rh antibodies are neutralized—that is, used up. This occurs normally in eight to fourteen days post natus unless the hemolysis is so severe as to bring about fetal death. At autopsy, even the brain nuclei may show deep jaundice (kernicterus), a characteristic peculiar to 25 per cent of cases in which death is due to erythroblastosis foetalis. To combat this hemolysis in the infant, frequent transfusions of Rh- cells are required, since these cells cannot be hemolyzed by the anti-Rh antibodies, and thus sufficient erythrocytes are left to maintain vital functions. The infant will, however, counteract this hemolysis also by increased red-cell production. The result of this increased hemopoiesis is the appearance of many nucleated erythrocytes in the peripheral blood stream, another characteristic of this neonatal anemia.

Javert⁸ gave the incidence of erythroblastosis foetalis of all types as 0.23 per cent, and its cause of fetal death as 3.2 per cent. The nearer to term

the disease develops the better is the prognosis. It occurs more frequently in multiparas than in primiparas since preceding pregnancies predispose to it. Javert concurs to a large extent with the theory of Levine, but finds sufficient exceptions to maintain that the Rh factor cannot be the sole cause of erythroblastosis foetalis, since other agglutinogens may also produce isoimmunization of the mother.

SUMMARY AND CONCLUSIONS

A case of erythroblastosis foetalis with icterus gravis and neonatal anemia in a nine-day-old infant is reported, and the recent pertinent literature and theories are briefly reviewed.

Serologic studies substantiated the fact that the Rh factor was at least one of the major etiologic causes in the pathogenesis. However, it seems that other fetal antigens may also stimulate the production of maternal antibodies that bring about fetal hemolysis as late as nine days post partum. The true mechanism of development is still obscure, but it seems that the antibodies can be stored, or may at least remain latent, in the fetal red blood cells or tissues even after separation of the two circulations, and can be liberated by still unknown processes. Ingestion of colostrum did not produce their liberation in the present case.

Therapeutically, repeated transfusions of properly selected and cross-matched blood, preferably by anti-Rh serum, or by Levine's modified technic, are the only successful methods. It should be stressed that Rh- blood is important for the infant with erythroblastosis foetalis for at least the first week after birth. This need becomes less and less important as evidence of hemolysis diminishes in the second and third weeks of life.

HISTAMINE BY MOUTH IN THE TREATMENT OF VASOMOTOR RHINITIS*

JULIAN C. GANT, M.D.,† RAYMOND J. SAVIGNAC, M.D.,‡ AND ADOLPH HOCHWALD, M.D.§

BOSTON

SINCE the work of Dale and Laidlaw¹ on the role of histamine in anaphylaxis and allergy was published in 1919, many papers on this subject have been written. Ramirez and St. George² in 1924 first attempted the use of histamine as a therapeutic agent, but with inconclusive results. Stahl and Masson³ applied histamine to skin scarifications and had encouraging success, although the technic of dosage was crude. Dzsinich⁴ emphasized the importance of extremely small doses and worked out an effective scheme of treatment. Alexander and Elliott⁵ had excellent results in urticaria with intravenous injections of large doses. Attention should also be paid to the papers by Farmer,⁶⁻⁸ who reports a great number of cases treated with Dzsinich's technic and gives a complete review of the work done in this field.

Although most of the investigators have tried to imitate the technic used in specific desensitization, and to build up a so-called "specific non-specific" resistance to histamine by giving frequent and steadily increasing doses, a few—mostly accidental—observations have shown that histamine has an immediate beneficial effect in the allergic manifestation. Thus far only Stahl and Masson have tried to use this effect in therapy. They applied histamine by skin scarifications during an attack of asthma and observed a beneficial effect.

Since the effect of histamine is almost immediate and is transient, it is evident that the drug should be given at frequent intervals. For the average patient, injection, whether given by the intradermal, subcutaneous or intravenous route, is impractical, and we have been led to investigate further the effectiveness of giving histamine by mouth.

Although it is generally considered that histamine is largely destroyed by the gastric juices, there are a few reports in the earlier literature indicating that small amounts may be absorbed through the intestinal wall (Meakins and Harington,⁹ Ivy and McIlvain¹⁰ and Koessler and Hanke¹¹).

That histamine given by mouth is absorbed promptly and has a definite action is shown by the variety of toxic effects. For example, one of

our patients developed a characteristic flushing of the face within ten minutes after taking 13 drops of a 1:1000 dilution of histamine, and all treatment with histamine had to be discontinued because of severe menstrual pain. In another case, severe headaches occurred regularly within ten minutes after each dose of histamine, but they subsided in another ten minutes. Three patients developed abdominal cramps and pain following the taking of histamine. One of them had taken the drops shortly after a highball, and it is likely that the permeability of the stomach wall was altered by the alcohol. One of us (R. J. S.) has had abdominal cramps repeatedly following experimental doses of histamine.

Even more suggestive are specific reactions in which the original symptoms are duplicated. Thus, when histamine is given in doses larger than the empirically established optimum, patients with vasomotor rhinitis may have increased nasal obstruction or rhinorrhea, and those with asthma develop a wheeze.

It is apparent that histamine is absorbed from the gastrointestinal tract and that the same physiologic reactions are obtained as with parenteral injection.

The technic for its administration by mouth requires close attention to details. The therapeutically effective dose varies greatly among patients, but for each it remains quite constant over a long period of time. Our method is to start with a 1:1000 dilution and a dose of 1 drop in a glass of water. The patient is asked to observe the reaction closely. He finds that too large a dose aggravates his symptoms and too small a dose causes no change, but that the correct dose relieves him within fifteen or twenty minutes. If there are no bad effects, he is advised to increase the dose by adding 1 drop each day until toxic effects appear. Thereafter he is maintained on the dose that is just below the toxic level, and this dose is repeated as often as is necessary to control the symptoms.

The dose may vary from 1 drop of a 1:1000 dilution to 25 drops of a 1:100 dilution, but the average dose is 5 to 7 drops of the 1:1000 dilution. The necessity for perseverance and for intelligent cooperation by the patient is obvious. In most of our patients, oral histamine therapy was given only

*Case of hay fever; all others, vasomotor rhinitis.

after treatment with other methods had been followed, often for years, without success.

Two of us (J. C. G. and R. J. S.) have made routine use of histamine in treating a large group of private patients suffering from vasomotor rhinitis during the last four years. We are convinced of its value as an agent for symptomatic relief. Unfortunately, however, the private cases cannot be included in a statistical report because other therapeutic procedures—vaccines, thyroid and diets—were used at the same time with the histamine.

To test the value of histamine alone, a small group of clinic patients was selected, and, as a rule, no changes in their routine way of life were made except to prescribe histamine in doses as described above. Forty cases of perennial vasomotor rhinitis and 6 of seasonal hay fever were chosen. Of this group 13 were lost and the end results are unknown. The balance (33 cases) are listed in Table 1. In 3 cases, treatment had to be discontinued because of the lack of co-operation by the patient. Of the remaining 30 cases, 1 (Case 24) showed no effect up to a dose of 15 drops of 1:100 dilution, and in another (Case 33) there was temporary relief from 5 drops of 1:1000 dilution, but the patient later became refractory and doses up to 16 drops of 1:100 dilution were ineffective. In the other 28 cases, histamine produced repeatedly or regularly an immediate beneficial effect on the nasal symptoms, and most of these patients have been followed over a period of several months. This series is being rapidly extended, and histamine is being tried in other conditions with results that will be reported later.

The most striking therapeutic effects so far observed have been seen in the cases of vasomotor rhinitis. In such cases, within ten to twenty minutes after a dose of histamine by mouth the symptoms cleared and nasal obstruction, sneezing and watery discharge ceased. The benefit is more marked than that derived from ordinary nasal sprays or drops, and it usually lasts for several hours. In rare cases the symptoms return in less than an hour, but in others the relief from a single dose lasts for a full day or more. When the symptoms recur, another dose is taken, with the same effects. This immediate symptomatic relief is the main objective of our technic, and it should be noted that the effect of single doses is prolonged as time goes on—that is, histamine is needed less and less frequently. Patients who in the beginning needed six or eight doses of histamine daily, after a few weeks of treatment needed only two or three doses daily, and later on only occasional doses once every few days.

The following case reports illustrate the method and the results:

CASE REPORTS

CASE 17. This 45-year-old, married woman had had a stuffy nose persistently since the age of 35. She had also had migraine. Skin tests were positive for a large number of allergens, among them ragweed. Ragweed injections were given weekly or biweekly from July 31 to September 8, 1942, without improvement. During October, the patient's condition became somewhat better, but nasal obstruction persisted. On October 19, histamine treatment was started. On November 9, the patient reported on her 3 weeks' experience: doses up to 3 drops of 1:1000 dilution had been ineffective, but 4 drops brought complete relief within 20 minutes. In November, she was taking 4 drops once a day before bedtime and was sleeping the whole night.

CASE 25. This 24-year-old, married woman had had perennial vasomotor rhinitis and headaches since the age of 19. She had had attacks of urticaria for years, and had suffered from cold hands and feet as long as she could remember. Her father had had hay fever. Her nose had been packed with ephedrine but without any permanent effect. On September 28, 1942, the nasal mucous membranes were pale and boggy. Skin tests were negative. Therapy with histamine in 1:1000 dilution by mouth was begun on October 5. On October 13, 3 to 4 drops of this dilution relieved the headaches and the nasal obstruction within 15 to 20 minutes. On November 2, the headaches and nasal obstruction had developed only once during the last 3 weeks and were promptly relieved by 4 drops of histamine. On November 6, examination of the nose showed normal mucous membranes. Meantime, however, the urticaria remained unimproved and the patient had daily eruptions. A new oral course of histamine was started.

CASE 9. This 21-year-old woman had had perennial vasomotor rhinitis since the age of 16. Intradermal tests had been positive for goose feathers, but elimination of feathers and dust as well as treatment with vaccines had been of no benefit. On August 4, 1942, oral doses of histamine in 1:1000 dilution and of thyroxin were begun. On August 18, the patient was still sneezing but 6 drops of histamine always brought relief. The dose caused stomach cramps, however, and the treatment had to be discontinued. Through the fall histamine was tried off and on, but always with the same effect. A dose of 6 drops brought relief from nasal symptoms, but they caused stomach cramps. When the drops were taken before meals instead of after them, 4 drops was ineffective, but 5 drops gave complete relief and the stomach pain was much less severe.

CASE 4. This 64-year-old baker had had chronic vasomotor rhinitis since the age of 22, becoming worse recently. Nasal discharge and sneezing made it difficult for him to work. During a vacation in Florida in the winter of 1941-1942 he was entirely free from symptoms, but on the first day of work on his return, sneezing and nasal discharge began again in full strength. From May 25 to October 2, 1942, injections of wheat extract were given each week, but with hardly any improvement. On October 2, a vaccine injection was given and oral histamine therapy, combined with thyroxin in doses of 30 mg. twice a day, was begun. On October 23, doses of histamine up to 14 drops of 1:1000 dilution had been ineffective, but 15 drops gave regularly almost complete relief. If this dose was taken every morning before going

to work the nose cleared within 15 to 20 minutes and remained clear during the time at work. Only this single dose was needed each day. On November 20, the patient was still well.

CASE 28. This 79-year-old, married woman had had a stuffy nose since the age of 74. Treatment with vaccines had been of no benefit. On October 1, 1942, she was miserable with continuous nasal discharge and sneezing and was unable to sleep. Histamine by mouth was begun. On October 22, she took up to 6 drops of 1:1000 dilution. Relief came from 1 or 2 drops, but she misunderstood the directions and increased the quantities. As a result, her nose ran more than ever. As soon as the dose was reduced to 2 drops, however, relief was obtained. On November 23, the patient was taking this small dose four or five times a day and felt better than she had for 4 years.

SUMMARY AND CONCLUSIONS

The occurrence of good results in all except 2 of 30 cases is more than a coincidence. That histamine is absorbed from the gastrointestinal tract is demonstrated by Farmer's results in guinea pigs and by the occurrence of toxic reaction as reported above. The object has not been to build up a general resistance to histamine but rather to control the symptoms by repeated small doses. The wide variation in patients' susceptibility to histamine is very interesting and constitutes the chief difficulty, if not the actual danger, in treatment of this sort. In the present series, once the proper dose was determined, other doses of this same size repeated their physiologic effect from time to time indefinitely. It has also been observed that the good effect of single doses seems to last longer as the treatment is continued for weeks or months.

This observation somewhat contradicts the current attempts to explain the effect of histamine in allergic diseases on the basis of mithridatization of a desensitization against histamine.

Histamine is sometimes less effective during menstruation or a few days before it. This is understandable in view of the fact that allergic manifes-

tations are frequently more severe at this time. The effectiveness of histamine and therefore the size of the dose depend also on the functional state of the stomach. The amount of histamine that passes undestroyed through the wall of an empty stomach is quite different from that which is absorbed at the height of gastric activity. Because the dosage of histamine is so delicate and the variations in absorption so great, it is imperative to maintain basic conditions rigorously. It seems advisable to take histamine only before meals, when the stomach is empty.

Sometimes unpleasant by-effects cannot be avoided. If severe stomach cramps appear at the level that gives therapeutic results, or if menstruation is strongly affected, it may become necessary to discontinue the treatment as was the case in 3 of this series.

Oral histamine therapy is not a panacea. Much work remains to be done on the problem, but so far it can at least be said that it brings results that are definitely superior to those obtained by the other methods of treatment of vasomotor rhinitis, which are so cumbersome and unsatisfactory.

MEDICAL PROGRESS

THE DIAGNOSIS OF GOUT*

WALTER BAUER, M.D.†

BOSTON

THE diagnosis of gout is frequently not made because the patient does not exhibit the classic features of chronic gout. This common diagnostic error and the ensuing therapeutic mistakes will continue to occur unless physicians become increasingly alert to the various manifestations of the disease. It is hoped that this treatise, dealing solely with those features pertaining to diagnosis, will help serve the above purpose.

Gout is a hereditary constitutional disease, preeminently of males, occurring at any age and in most cases characterized by recurring attacks of acute arthritis. The clinical picture may, however, vary from an asymptomatic hyperuricemia to a severe, crippling joint disease even in the same patient. The articular inflammation of both acute and chronic gouty arthritis is caused by deposits of sodium urate (tophi), which may also be found in many other tissues. Although the exact etiology of the disease remains unknown, it is rightly classed as one of inborn metabolism, the fundamental metabolic defect, the inability of the organism to dispose of uric acid, being evidenced by a hyperuricemia. The latter may be present long before the ailment assumes its striking articular form. Space does not permit a discussion of the various theories advanced to explain the altered excretion of urates, the hyperuricemia and the formation of urate deposits in the tissues. It is sufficient to state that these phenomena remain three of the enigmas of the disease.

PATHOLOGY

Only those pathological features of the disease that pertain to a better diagnostic understanding will be discussed. The changes observed are dependent on the deposition of sodium urate in the various tissues and the inflammatory and degenerative changes resulting therefrom. The urate deposits surrounded by tissue exhibiting inflammatory and foreign-body reactions constitute the one

pathognomonic lesion of the disease, and are readily demonstrated provided the tissues to be examined are properly fixed and stained.¹ Many of the anatomic alterations observed in the late stages of gout are the result of the ill-understood arterial and arteriolar sclerosis that frequently manifests itself as the disease advances.

Deposits of urate in articular structures are the cause of the most frequent disability resulting from gout. No joint is exempt, although certain ones are more frequently involved than others,²⁻⁴ for example, the joints of the lower extremities as compared to those of the arms. The metatarsophalangeal joints of the great toes are most regularly affected and may be the only site. The small joints affected in order of frequency are those of the feet, the ankles and the wrists. The knees, elbows, shoulders and hips are less commonly involved. The sacroiliac and sternoclavicular joints and the articulations of the spine, jaw and larynx most rarely contain foci of urate deposition.

The term "tophus" has through general usage come to denote a urate deposit in tissues other than joints. These abarticular tophi are most commonly seen in the helix or antihelix of the ear, the olecranon and prepatellar bursae and the tendons of the fingers and wrists, toes, ankles and heels. Less frequently they are met with in the skin of the palms and soles, the tarsal plates of the eyes, the nasal cartilages, the fingertips, the tendinous expansion of the muscles and the cornea and sclerotic coat of the eye.⁵ The kidneys may also be the seat of urate precipitates. Very rarely they have been found in the corpus cavernosum, the prepuce of the penis, the aorta, the myocardium and aortic valves, the tongue,⁶ epiglottis and vocal cords, and the arytenoid cartilages. Occasionally the crystals have been recovered from the sputum of gouty subjects.⁷ The isolated reports of urates in the central nervous system and its coverings have never been verified. Such abarticular deposits are followed by the foreign-body inflammatory reaction previously referred to, and vary in extent and degree with the vascularity of the affected tissue.

The renal lesions observed in gout have been called *gouty nephritis*, *gouty form of Bright's disease*, *interstitial* or *arteriosclerotic nephritis* and *renal impairment of gout*. This varied terminology indicates that no unanimity of opinion has

The articles in the medical progress series of 1941 have been published in book form (*Medical Progress Annual*, Volume III, 68 pp., Springfield, Illinois: Charles C. Thomas, 1942, \$5.00).

The arthritis studies in this clinic were made possible by a grant from the Commonwealth Fund, New York City.

Physician, Massachusetts General Hospital, associate professor in medicine, Harvard Medical School (on leave of absence).

existed concerning the nature of these changes, but all writers are agreed that the incidence of kidney disease is higher in gout than in other chronic disorders, such as rheumatoid arthritis, diabetes mellitus and pernicious anemia. Few if any, however, argue that anatomic alterations of the kidney can be demonstrated as the primary cause of gout.

The incidence of arteriosclerosis and hypertension is higher in gouty subjects than in a control group of comparable age.⁸⁻¹¹ The latter is usually a late manifestation. The triad of arteriosclerosis, nephrosclerosis and increased arterial tension frequently leads to hypertrophy of the left ventricle. Marked arteriosclerotic degeneration of the aorta is not uncommon. Extensive coronary and cerebral vascular disease may be the immediate cause of death. Other pathologic changes associated with the disease are similar in nature and extent to those found in any corresponding age group.

GENERAL CONSIDERATIONS

Incidence

The incidence of gout is unknown. Undoubtedly, many more cases are seen in private practice than in hospitals because acute gouty arthritis is, as a rule, self limited and of short duration. Hench¹² estimates that 5 per cent of all patients with joint disease seen at the Mayo Clinic have gout. This is a much higher incidence than has been found in most other clinics. The evidence derived from pathological studies reveals an incidence varying from 1 to 5 per cent.^{13, 14} Despite such marked discrepancies, gout does not appear to be a rare or declining disease. As stated previously, the diagnosis frequently is not made because the patient fails to exhibit the classic features of chronic gout.

Heredity

The earliest medical writers have stressed the hereditary nature of gout. A familial incidence as high as 75 per cent has been observed.^{2, 15, 16} The propensity of the disease to pass over one generation is a hindrance to the investigator gathering genealogic data. It is commonly stated that women, although infrequent victims of gout, are likely to transmit it to their children.⁷ Thus, a patient may inherit his maternal grandfather's gout although his mother never experienced any clinical manifestations of the disease.

Sex

Slightly over 95 per cent of all patients affected with the disease are males. The explanation for this striking difference in the incidence of gout in the two sexes is unknown.

Age

Gout is an inherited disease. Its potentialities are assumed to be present at birth. The finding of hyperuricemia in apparently normal young relatives of gouty patients and its presence with or without tophi in adults for years prior to the onset of articular complaints indicate that the disease antedates the appearance of symptoms. It rarely manifests itself in infancy or adolescence. Acute arthritis occurs with increasing frequency in the second to the sixth decade, being commonest in the forties. The first evidence of the disease, however, may not appear until late in life. Cases are on record demonstrating the initiation of symptoms in the sixties, seventies and eighties. In such cases the attacks as well as the subsequent course tend to be mild. The converse is likewise true: onset at an early age frequently portends severe seizures, often polyarticular in distribution, and may lead to extensive crippling and severe vascular nephritis before middle life.

Race and Climate

There is at present no accurate information concerning the relevance to gout of either race or climate.

Habits and Occupation

Those who believe that gout is the nemesis of high living cite a higher incidence among people whose occupations are conducive to overindulgence in food and drink. Until more conclusive statistical information concerning the occupational incidence of the disease is available, it is impossible to evaluate past statements or to make further comment.

Clinical Manifestations and Course

The symptomatic or articular manifestations of gout are designated by various terms. The acute attacks, which are followed by complete remissions, have been called "acute gout" and "regular" or "acute recurrent gouty arthritis," in distinction from chronic gout, signifying chronic gouty arthritis with or without tophi. Because the disease runs an extremely diversified and irregular clinical course, the simple yet satisfactory classification of acute and chronic gouty arthritis has been generally adopted.

The onset of the first attack of acute gouty arthritis is as a rule dramatic. The patient, usually a healthy-appearing middle-aged man, is suddenly seized with severe, sometimes excruciating, pain, often in one of the metatarsophalangeal joints. Although such attacks frequently begin at night, they may occur at any time. Within a few hours of the onset, the afflicted joint becomes swollen, red, hot and exquisitely tender. The swelling may

appear so rapidly that within a few hours the patient is unable to remove his shoe without cutting it. The inflammatory edema is much more marked than in other acute arthritides and often extends some distance beyond the joint margins. Effusion into the large joints is not uncommon. At the peak of the attack the intense swelling of the foot, accompanied by redness and extreme heat, resembles septic inflammation or an extensive cellulitis. There may be an associated lymphangitis. The skin is red, tense and shiny. The superficial veins are distended. The pain, often described as crushing and usually worst at night, generally confines the patient to his bed or room because weight bearing is intolerable.

As tenderness and redness subside, pitting edema is demonstrable. With the disappearance of the swelling, the overlying skin become loose and thin and desquamation of the cutis and itching may follow. The combination of these findings is rarely encountered in other types of acute arthritis, and is therefore of singular diagnostic significance. The attack subsides spontaneously within ten days to a few weeks, with complete restoration of normal joint function.

Approximately 50 per cent of the initial attacks are confined to the first metatarsophalangeal joint, but not infrequently other joints are affected at the same time. The neighboring metatarsal and tarsal joints or those of the opposite foot may be involved simultaneously or in rapid succession. A bursa, more commonly over the olecranon or patella, may be the site of an attack. The younger the patient, the more likely is the attack to be polyarticular and migratory in nature. Fever, again more prominent in young patients, is usually mild, rarely lasts more than a few days, and may be absent. The severity of the initial attack varies greatly. In some cases the acute illness is extremely mild and lasts only a few days. Occasionally one sees abortive attacks.

Physical examination at the time of the initial attack of gouty arthritis is usually negative except for the articular findings. Maximal joint tenderness is usually present on the medial aspects of the involved joint. A tophus, unknown to the patient, may be found in the helix of the ear, indicating that the disease has been present for some time. The clinical course subsequent to the initial attack, although usually conforming to a distinct pattern, may vary considerably. Very rarely the patient remains symptom free altogether, or for an interval of many years, as exemplified by a case in which the initial seizure at twenty-seven years of age was succeeded by a second one sixty-two years later. In the benign form two to six distinct attacks may be scattered over a period of

thirty to fifty years or concentrated in one of the middle decades of life.

The recurrent attacks of acute arthritis are commonly followed by remissions during which the patient experiences no articular symptoms whatever. These latent periods tend to become progressively shorter until acute episodes occur once or twice yearly, often with a certain regularity. Some patients, for unexplained reasons, are taken ill each spring and fall. At this stage of the disease, the patient is less likely to experience complete remissions and his illness is approaching or has entered on the phase of chronic gouty arthritis or chronic gout. In a few cases, most of which belong to the juvenile form, the disease is chronic from the outset. More frequently, a period of five to forty years separates the initial attack from the chronic phase.

In the advanced stages of the disease, an increasing number of joints are affected, particularly those of the feet, ankles and wrists and the knees and elbows. Subcutaneous tophi, representing infiltrations of urates into periarticular and bursal tissues, are frequently found and are responsible for the knobby deformities of the knuckles and interphalangeal joints. They may also be seen about the knee and elbow and along the tendons of the fingers, toes, ankles and wrists. Tophaceous deposits occur in nonarticular cartilage; indeed, their commonest site in chronic gout is the helix of the ear. They vary in size from a barely palpable nodule to deposits measuring as much as 5 cm. in diameter. Their presence in cartilage may be unattended by any symptoms, but in subcutaneous tissue visible inflammatory reaction usually results. There the deposits appear first as slightly red elevations that gradually develop into white, cream-colored or yellow nodules of varying size. The skin overlying a tophus may ulcerate and discharge a white, chalky material that on microscopic examination shows the characteristic acicular crystals of sodium urate. Such ulcerating lesions may occur anywhere on the body surface but are commonest on the hands and feet. They rarely become infected.

Tophi are found in about 50 per cent of all cases of gout. In some cases they antedate the acute joint disease, whereas in others they are not found until ten to thirty years after the initial attack. They should not be confused with the subcutaneous nodules of rheumatic fever and rheumatoid arthritis. Because they constitute the one pathognomonic lesion of gout, they should always be searched for. Regardless of whether or not a nodule has the characteristic clinical appearance of a tophus, it is unwise to accept it as such until it has been needled and the monosodium urate crys-

tals have been demonstrated or a positive murexide reaction has been obtained.

The term "irregular gout," still used by some writers, originally designated a group of nondescript symptoms that in the past has also been referred to as lithemia or as a uric acid, lithic acid, or gouty diathesis. The clinical markings of irregular gout were most varied and apparently incorporated all the inexplicable complaints that occurred in the gouty subject. Some of these were probably results of medication with impure preparations of colchicum. The term was, however, also applied to the indefinite ailment of members of gouty families who had never suffered an acute attack of gouty arthritis. In these cases the symptoms were often ascribed to an excess of uric acid proved by the finding of urate sediment in the urine! Neither this type nor an irregular type of articular gout postulated by some current writers^{17, 18} deserves recognition. The patients described, usually women, exhibit none of the characteristic findings of symptomatic gout. Their arthritis is insidious in its onset and slowly progressive, without remissions or associated tophi. As a rule, these patients are advanced in years and show only a slightly higher than normal blood uric acid. In a few cases, hyperuricemia, probably due to nephritis, and rarely a family history of gout are found. If such variations of gout occur, they should be susceptible to pathological proof, and when present generally show favorable response to the therapy administered for acute gouty arthritis. The propriety of using such terms as "visceral" or "abarticular gouty" is equally dubious.

PREMONITORY SYMPTOMS

The specific changes that presumably take place in the gouty subject between birth and the onset of the clinical illness have not been studied, but hyperuricemia has been demonstrated at an early age.^{16, 19, 20} Whether it is ever present at birth is unknown, nor are bodily alterations immediately preceding the gouty seizure, the so-called "larval state," understood. Many patients experienced no premonition of the impending attack; some even feel their best at that time. Others complain of anorexia, nausea, indigestion, melancholia, stiffness, aching, polyuria and nocturia. The diuresis may be taken as an expression of the altered mineral metabolism, whereas the other prodromes remain unexplained.

PRECIPITATING FACTORS

Considerable importance is generally attached to a number of factors said to precipitate an attack of arthritis in a patient with latent gout. Their true significance in relation to the disease has not

been determined, and it is difficult to evaluate how often they are chance associations.

Minor or major trauma has long been considered the commonest precipitating factor. The prevalent involvement of the large toes has been attributed to the chronic strain on these articulations sustained in walking or from the pressure of ill-fitting shoes. Many similar examples of injury as an antecedent to gouty arthritis can be cited.

The belief that certain foods are promotive of gout is one of the oldest medical traditions and is still accepted by a majority of competent physicians. The proponents of this theory contend that the ingestion of purine-rich articles by the gouty subject results in an accumulation of uric acid in the blood, thus inducing an acute attack of gout. Habitual dietary excesses are considered to be predisposing factors, whereas periodic indulgence supposedly serves as a precipitating force.¹² It is a most regrettable circumstance that these teachings, which are shrouded in the semisanctity of a long and venerable heritage, have never been tested by either adequate experimentation or comprehensive statistical analysis of clinical data.

Because of the far-reaching practical importance of this question, the consideration of the relevant basic facts is recommended. Since predisposition to gout is inherited, it follows that dietary factors cannot be the cause of the disease. Although it is well proved that a high purine intake raises the blood uric acid content of a gouty subject, it has likewise been shown that neither hyperuricemia nor an elevated uric acid concentration in tissue fluids is by itself always sufficient to produce an attack of gouty arthritis, even in a predisposed subject. High-purine diets do not provoke the acute illness in latent gout with any regularity, and no correlation has been possible between the degree of hyperuricemia and the frequency, severity and duration of arthritis in gouty patients. It has been found that most gouty subjects do not show an adverse response to occasional excess-purine feedings, and that in well-controlled studies covering an extended period the frequency of seizures does not vary in alternating intervals of high-purine and low-purine intake. The incidence of gout among vegetarians is much higher than is usually assumed. The natural course of the disease is characterized by sudden changes in an erratic, unpredictable pattern. The temptation for both patient and physician to fasten the responsibility for these to some tangible factor is great, but the evidence quoted here should warn one against accepting as verified the influence of dietary habits on the development and progress of gout.

It has also been stated that certain foods, regardless of their purine content, are capable of produc-

ing regular attacks in some gouty patients, supposedly as an allergic manifestation. A specific brand of cheese or wine or a particular kind of fruit or vegetable has been held responsible. Similar observations have not been reported by other investigators.

Attacks have been observed subsequent to the institution of a ketogenic²¹ or high-fat diet. Lockie and Hubbard²² proposed that the latter be used as a provocative test.

Some clinicians consider the ingestion of alcohol to be the most important of all precipitating factors. Fermented beverages are thought to be much more provocative than is distilled liquor. Others hold the mode of use a significant circumstance, considering that persons who overindulge in meat habitually partake of red wine and malt liquors, and therefore sustain the combined effect of two inciting agents. All are agreed that certain gouty subjects fare sumptuously with some regularity and that some of their attacks follow dietary and alcoholic indiscretions. This sequence, however, does not usually exist. For example, one of the patients at the Massachusetts General Hospital experienced only two attacks in twenty years, although his excesses continued throughout the symptom-free interval. Another suffered ten attacks in ten years during middle life but none during the subsequent fifteen years while his habits of eating and drinking remained unchanged. Cases of this description are by no means exceptional, and serve to emphasize that the instrumentality of alcohol in precipitating gouty arthritis is unproved. Actually, chronic alcoholics²³ have been said to show no higher and tetotalers no lower than the average incidence. Only the collection of accurate data from a significant number of cases will give the final answer.

Attacks of gouty arthritis are said to have followed the intramuscular administration of liver extract and of salyrgan, ergotamine tartrate, insulin, decholin, thiamin chloride and other medicinal agents. The case reports are too sparse to allow a conclusion as to cause and effect.

Hench²⁴ has repeatedly stressed that gout should be suspected when arthritis occurs during the first seven days following a surgical procedure, but the exact incidence of postoperative gout is unknown.

Coincidental diseases such as leukemia, polycythemia and chronic glomerular nephritis, as well as marked blood loss and transfusions, are said to have activated latent gout. Furthermore, severe purgation, foreign-protein therapy, exposure to cold and dampness and emotional upsets have been accused of producing attacks.

COMPLICATIONS

As stated previously, premature vascular disease and the anatomic and physiologic alterations re-

sulting therefrom constitute the important complication of gout. Some earlier writers^{7, 23} have stressed the high incidence of venous thrombosis, a finding that has been rare in my experience.

The appearance of persistent albuminuria and casts usually marks the beginning of a vascular nephritis that may ultimately prove fatal. The majority of gouty patients die from uremia. Because of the frequency with which nephritis occurs in gout, Hench²⁵ states that chronic arthritis associated with distinct renal impairment suggests gout until proved otherwise. Some writers speak of secondary gout caused by chronic nephritis, other renal disease or leukemia. Such cases probably represent latent gout complicated by other diseases associated with hyperuricemia. Under these conditions, it is important to obtain a detailed family history and, if possible, blood uric acid determinations on the patient's relatives.

The incidence of urinary calculi in gouty subjects is relatively high, amounting to 12 per cent in Hench's²⁵ series. An occasional patient experiences one or more bouts of renal colic prior to the first gouty seizure. Arthritis in connection with urinary lithiasis should always suggest the presence of gout. No sound theoretical explanation for the frequent association of the two conditions is known, nor has the incidence of urate stones been determined.

Previously gout was assumed to be prevalent among lead workers, hence the term "saturnine gout." It, too, was considered an example of secondary gout due, in this instance, to the vascular nephritis of plumbism. Whereas gout is more rarely a complication of lead poisoning than was previously assumed,²⁶ it may of course be associated by chance with the vascular nephritis of plumbism. Other types of arthritis occurring in a patient with hyperuricemia due to renal damage from lead poisoning may in the past also have been erroneously diagnosed as gout.

Epsileritis due to urate deposits occurs rarely.^{5, 16} Eczema and various other complications are no more frequent than in all persons of comparable age and are probably unrelated to gout.

DIAGNOSIS

The diagnosis of joint diseases is in most cases relatively easy when based on a detailed medical history and a complete physical examination. A few well-chosen laboratory tests or a therapeutic trial with specific medication are often valuable adjuncts. Biopsies may be necessary. The passage of time and further observation are indispensable.

Clinical Findings

A history of recurrent attacks of acute arthritis separated by completely asymptomatic intervals should always suggest gout, particularly in a

middle-aged man. Provided the presence of the disease is suspected, confirmation in most cases is relatively simple. The abrupt onset of severe articular pain, usually without known cause, followed rapidly by a red, hot swelling of the joint, extending beyond the articular margins, is of great diagnostic significance, especially in a first attack. Additional aids are a positive family history, positive identification of tophi and the occurrence of cuticular desquamation as the edema subsides, a finding highly characteristic of gouty arthritis. The dramatic response to full doses of colchicine, rarely observed in any other types of arthritis, is of real diagnostic significance.

Laboratory Findings

Hyperuricemia is an almost invariable feature of the disease. Its presence, therefore, if not attributable to other causes, constitutes evidence of prime importance. The serum uric acid values are rarely lower than 6 mg. per 100 cc. In the few exceptions, less than 2 per cent, they vary between 5.2 and 5.8 mg.

For the determination of uric acid, one of two methods, that of Folin²⁷ or that of Benedict,²⁸ should be employed. Both depend on the reduction of complex tungstate reagents to colored compounds. This reaction is not strictly specific for uric acid and may be enhanced or inhibited by unrelated substances present in the blood. *While neither test offers undue technical difficulties, only the greatest care in preparing the reagents and frequent control determinations assure reliable results.* The use of serum is preferable to that of whole blood. Since the distribution of urates between the plasma and the cells is a function of the bicarbonate content, specimens should be collected and centrifuged under oil if the greatest accuracy is desired. Folin's²⁹ method for unclotted blood is free from the objections to the other whole-blood methods, but since it is doubtful whether diffusion of urates from the cells is ever complete, the method should not be used if sufficient blood can be obtained for a determination on serum.

No characteristic change in serum uric acid occurs immediately prior to an acute attack of gouty arthritis. In some cases it remains unchanged; in others it may be increased or decreased. *In order to avoid erroneous interpretations, particularly of response to therapy, it is extremely important to appreciate that the blood uric acid level is inconstant and that cyclic changes occur at irregular intervals.* In one case variations between 7.4 and 14.5 mg. per 100 cc. were observed that could not be attributed to any known cause and were in no way related to the incidence of arthritis.³⁰ Various tests³¹ designated to measure the urate-concentrating power of the kidney are neither entirely satisfactory nor necessarily of diagnostic value in gout.

Analyses of joint effusions in gouty arthritis reveal uric acid concentrations in the synovial fluid similar to those in serum¹⁵; the same is true for sugar. The viscosity is reduced and the protein content increased. The total leukocyte counts may vary from 1000 to 31,000, with polymorphonuclear leukocytes ranging from 50 to 95 per cent.

Patients with acute gouty arthritis generally have a mild to moderate leukocytosis. The mononuclear count is frequently increased. The sedimentation rate may be elevated. In several cases at the Massachusetts General Hospital the rates were as high as 2 mm. per minute (the upper limit of normal being 0.4 mm. per minute³²). Evidence of mild renal impairment is commonly met with. Achlorhydria occurs no more frequently in gouty patients than in other persons. An abnormal sugar-tolerance curve, occasionally present, is of no diagnostic significance.

Roentgenographic Findings

The roentgenographic findings most suggestive of gout are well-defined, punched-out areas, usually 5 mm. or more in diameter. They are most commonly observed in the subchondral bone at the bases or heads of the phalanges. The feet are apt to show these lesions even in cases in which they have never been affected clinically. Such changes may appear late in the disease; for example, 19 per cent of the patients in one series had had gout for twenty-eight years or longer and exhibited tophi and hyperuricemia in every case, yet failed to show subchondral lesions roentgenographically.²⁵ The frequency with which these defects, the result of urate deposition in bone, are found is directly related to the severity of the disease. They may be demonstrable in the region of joints not commonly affected—for example, in the neighborhood of the sacroiliac joint. They should be distinguished from the circumscribed areas of rarefaction seen in degenerative joint disease and rheumatoid arthritis. Similar findings may be produced by the gummas of syphilis and by leprosy and yaws, as well as by tuberculosis and Boeck's sarcoid. Occasionally tophaceous deposits result in bone expansion with or without destruction, thus simulating roentgenographically a bone tumor. In addition to such abnormalities, one may find thickening, joints of soft tissues, narrowing of conspicuous marginal overgrowth and marked destruction of the articular surfaces.

Decalcification occurs in a few patients who have suffered prolonged, severe attacks involving the small joints of the feet and wrists. In these exceptional cases, the marked decalcification, joint destruction and obvious ankylosis closely approximate the changes seen in specific infectious or rheumatoid arthritis. Premature arteriosclerosis

is frequently demonstrable in the vessels of the legs and feet.

Although the x-ray findings in gouty arthritis are characteristic and consistent, they cannot be considered specific. The roentgenologist's impressions should therefore be taken only as a corroboration of a clinical diagnosis.

Provocative Tests

Experience with provocative tests at the Massachusetts General Hospital has been most disappointing, whether these were applied immediately after an attack or during a remission. This has been true of a high-purine (2.5 to 3 gm.) diet or a high-fat (250 to 300 gm.) diet or of large amounts of port wine administered singly or in combination with the diets. Failure to precipitate an attack with any regularity has led to abandonment of these tests as diagnostic aids.

DIFFERENTIAL DIAGNOSIS

Occasionally gouty arthritis is confused with traumatic joint disease, cellulitis, rheumatic fever, one of the specific infectious arthritides, rheumatoid arthritis, Heberden's nodes or acute bursitis, particularly when the last is associated with a hallux valgus deformity.

Traumatic arthritis is as a rule readily diagnosed. Articular pain and swelling follow almost immediately on a known injury. Marked inflammatory reaction of the periarticular tissue is not discernible, and the symptoms always remain confined to the affected joint. The patient exhibits none of the characteristics of the gouty subject and his arthritis never responds to colchicine therapy. It should be remembered, however, that trauma may mark the onset of acute gout as well as that of infectious arthritis. In such cases differentiation is greatly aided by aspiration and analysis of the joint fluid. An acute traumatic effusion contains rarely more than 1000 leukocytes per cubic millimeter and polymorphonuclear leukocytes ranging from zero to 20 per cent, in contrast to the higher values usually found in the other acute arthritides.¹⁵

Cellulitis or septic inflammation is frequently suspected; in fact, it is sometimes diagnosed before it has become evident that one is actually dealing with acute gouty arthritis. Occasionally, the affected joints have been incised and drained. One can readily appreciate the diagnostic difficulties offered by a patient who presents himself with a painful, red, hot swelling of the dorsum of the hand or foot, with or without lymphangitis and fever. Failure to find a skin abrasion or other portal of entry for an invading organism and careful elucidation of the past history generally lead to the correct diagnosis.

Rheumatic fever, especially in young patients, can be simulated by recurrent attacks of gouty arthritis. The clinical differentiation, however, should not be difficult. The arthritis of rheumatic fever usually follows an upper respiratory infection or other precipitating factors by seven to fourteen days. Patients frequently exhibit weight loss, nosebleeds, skin eruptions, subcutaneous nodules, tachycardia and precordial pain. The electrocardiogram often shows a prolonged PR interval and other alterations. The ultimate development of valvular heart disease is of the utmost diagnostic importance.

Specific infectious arthritis, due to a pyogenic organism, in the acute phase more nearly resembles acute gouty arthritis than it does any other type of joint disease, particularly since it is occasionally recurrent. In such cases, usually caused by the gonococcus, the clinical picture shows some similarity to that of gout, as in a patient who entered the Massachusetts General Hospital suffering from his eighth attack of arthritis. He stated that recovery from the previous seven seizures had been complete. Differentiation was facilitated by a history of a genitourinary infection and such constitutional symptoms as chills and fever preceding in close parallelism every exacerbation of arthritis. Although the inflammatory swelling of specific infectious arthritis may be severe, it is rarely so marked or occurs so precipitously as does gouty arthritis. Particularly with the aid of synovial-fluid findings, one should not encounter serious diagnostic difficulties.

Typical rheumatoid arthritis ushered in by constitutional, vasomotor and neurologic symptoms, of insidious onset and characterized by symmetrical joint involvement, should rarely if ever be mistaken for gouty arthritis. In 18 per cent of all cases, however, rheumatoid arthritis is marked by an atypical onset, and in 7 per cent it may remain atypical for a long time. In this form, an apparently healthy person experiences an acute attack of arthritis without prodromes, preceding acute illness or an obvious focus of infection. The joint involvement may be polyarticular, migratory or, occasionally, monoarticular. Recovery from the first attack is often complete, and the remission may last for a few months or even for years. The patient may have a number of attacks before the disease becomes chronic. Careful clinical observation and determination of the blood uric acid concentration facilitate the distinction between the two diseases.

The clinical features of chronic gout with ankylosis may resemble even more closely those of rheumatoid arthritis. Two such cases have been

relatively early stage of the disease, and others have been reported.^{4, 23} In one,³⁰ the onset of gout at twenty-one years of age was followed by chronic arthritis within five years. Widespread ankylosis was demonstrable at the age of twenty-eight. The diagnosis of gout was confirmed by the identification of sodium urate crystals in tophi of the ear and in the fingers, olecranon bursa and tissues of four joints. Of particular interest were the findings in the astragalotibial joint. Extensive pannus formation, responsible for complete fibrous ankylosis, simulated strikingly the gross pathologic changes of rheumatoid arthritis. Even the microscopic appearance of the synovial tissues might have been difficult to distinguish definitely from the chronic inflammatory lesions of rheumatoid arthritis, except for innumerable small urate foci. Such unusual forms of gouty arthritis are admittedly rare. They should not be confused with rheumatoid arthritis. Clinical differentiation is greatly aided by a painstaking inquiry into the past and family histories. Biopsies of nodules, tophi and synovial tissues often lead to the correct diagnosis. Analysis of the synovial fluid may or may not help to distinguish one disease from the other. The association of the two is extremely rare. A few cases have been reported, but their authenticity is questionable.

Bursitis, particularly as a manifestation of a hallux valgus deformity, has probably on innumerable occasions been mislabeled as gouty arthritis. This diagnostic error can be avoided if the infected part is carefully examined. The swelling is limited to the bursa and the immediately adjacent tissues, and the distended sac may be easily palpated. Motions of the metatarsophalangeal joint are painless within a limited range.

Heberden's nodes, classic stigmas of degenerative joint disease, consist of hypertrophic osseous changes at the articular margins of the terminal interphalangeal joints. They are insidious in development and not usually productive of severe symptoms, and may be readily differentiated from tophaceous deposits in the skin and deeper tissues surrounding these joints. Occasionally, however, Heberden's nodes are acute in onset and are then frequently confused with gouty arthritis. The distal finger joints may be painful, reddened, bulbous, fluctuant and extremely tender. Numbness and tingling of the involved fingers may also be complained of. Heberden's nodes occur predominately in women and affect the index and middle fingers oftener than the other phalanges. Tophi, common in men and rare in women, are discernible by their yellowish color. It is well known, of course, that the two disorders may be associated coincidentally or casually.

SUMMARY

The varied manifestations of gout are reviewed in detail to acquaint physicians with the disease. If this treatise serves its purpose, there should result more correct diagnoses and fewer therapeutic errors.

CASE 29401

PRESENTATION OF CASE

A fifty-one-year-old storekeeper was admitted to the hospital because of chest pain.

The patient was well until about five years before admission, when he noted the gradual onset of intermittent, substernal pain. The pain was variously described as being in the middle or just to the left of the sternum at the level of the third, fourth and fifth ribs and at times radiating to the left arm. It was unrelated to food, exercise or emotion but was sometimes intensified by deep inspiration. It lasted for a few minutes and was often followed by a feeling of discomfort for two or three hours. Sitting down occasionally relieved the pain. During the course of the next few years the pain increased in frequency and severity, so that on entry it was described as a dull, heavy sensation beginning at the lower end of the sternum, radiating to the left chest and occasionally to the left arm as far as the elbow, leaving the arm numb and heavy. The pain seemed to come on ten or fifteen minutes after he arose in the morning, persisted all day and went away one or two hours after he retired at night.

During the year or two before admission, the patient had had "considerable gas in his stomach" following meals, which was relieved by belching. There were some lower abdominal cramps and diarrhea without blood or mucus for a period of four or five weeks. He was seen by various physicians one of whom had performed gastrointestinal and gall-bladder x-ray studies and had told him that he had "colitis" and a misshapen gall bladder. The diarrhea ceased, but the abdominal discomfort continued. It was sometimes relieved by soda or a glass of whisky, and at times aggravated by eating.

About six months prior to entry, the patient developed a severe cough and wheezing dyspnea. He lost his voice for a short time. The cough was "tight" and worse in the mornings. On one occasion he raised bright-red sputum every morning for about a week. At other times however, the sputum, which was copious in the mornings, was whitish to brownish but not foul. It seemed to

increase with exertion. During that time, he felt tired but had no chills, fever or night sweats. He had lost 10 to 20 pounds in the course of the year and a half preceding entry. His appetite had remained fair, and he was able to eat "nearly everything." There was no vomiting, dysphagia or diarrhea, but he had had a feeling of nausea occasionally at night. The patient had no orthopnea but slept on two pillows to prevent coughing. He had noted the gradual onset of dyspnea on exertion, which persisted. For the two months before admission he had received two digitalis capsules daily, without improvement. All his symptoms were variously described as progressive or intermittent, with periods of remission and exacerbation. There was no history of aspiration of a foreign body or of operation on the nose, mouth or pharynx.

Physical examination showed a slightly obese man in no distress. The anteroposterior diameter of the chest was increased with somewhat diminished respiratory excursions, which seemed to be mainly diaphragmatic. The left half of the diaphragm was slightly higher and moved less than the right half. One or two observers noted a questionable dullness with diminished tactile fremitus and breath sounds at the left base, whereas two or three others thought that the lungs were clear. The left border of cardiac dullness was 10 cm. to the left of the sternum. The sounds were of good quality and regular. The aortic second sound was greater than the pulmonic. There were no murmurs. The examination otherwise was negative.

The blood pressure was 125 systolic, 85 diastolic. The temperature was 98.6°F., the pulse 84, and the respirations 32.

The blood showed a red-cell count of 5,730,000 with a hemoglobin of 18.5 gm. The white-cell count was 10,300, with 60 per cent neutrophils. The urine was normal. The stools were guaiac negative. A blood Hinton test was negative. The blood protein was 7.3 gm. per 100 cc. A Graham test was negative. An electrocardiogram revealed a rate of 90, a PR interval of 0.14 second and slight axis deviation. The T waves in Leads 1, 3 and 4 were low, and T₄ was slightly diphasic. X-ray examination of the chest showed a mass behind the heart on the left side with sharp medial and anterior borders, apparently corresponding to a collapse of a large portion of the left lower lobe. The left hilus was slightly smaller than normal. There was no respiratory shift of the mediastinum. The heart was normal in size and shape. A gastrointestinal series showed the esophagus crossing the mass in the left lower chest without being attached to it. On re-examination, however, a herniation of the cardiac portion of the stomach

*On leave of absence.

through the diaphragm was noted (Fig. 1). The stomach was apparently curled on itself as it passed through the opening so that only with the

see the film that was described in the history, but in which I could not find or recognize the shadow noted on the left side "with sharp medial and

head depressed and the patient lying on his back was the entire supraphrenic mass filled with barium. A barium enema was negative. There was no evidence of herniation of the large bowel through the diaphragm. The splenic flexure approached the diaphragm somewhat more closely than usual and moved freely with respiration.

During the first few days after admission the patient had several attacks of coughing, as well as a slight dull pain just to the left of the lower end of the sternum and considerable gas pain.

An operation was performed on the eighteenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. JOHN W. STRIEDER*: Perhaps we might see the x-ray films first. I should particularly like to

anterior borders, apparently corresponding to a collapse of a large portion of the left lower lobe.

DR. LAURENCE L. ROBBINS: This presumably is the solid mass described in the lung, and these air bubbles represent the hernia. I should say that this line demonstrates what they were trying to bring out for the medial margin of the lesion in the chest. So far as the spot film is concerned, this is the esophagus, and this the stomach; there still appears to be an area of increased density above the fundus. I do not believe that the splenic flexure is abnormal in position in the film of the colon.

DR. STRIEDER: Do you think you can see in any of the films an area that is consistent with a collapsed portion of the left lower lobe?

DR. ROBBINS: I cannot see a definite area of collapse. There is an area in the left lower lobe

*Visiting surgeon for thoracic surgery, Boston City Hospital and Massachusetts Memorial Hospitals

in which there is no air. I should think that this was its margin, with the hernia below it, because one can see a bubble. This film again shows a gas bubble in the herniated portion of the stomach. It is perfectly possible that the mass above it is in the lung.

DR. STRIEDER: Are you impressed by the pulmonary shadow itself?

DR. ROBBINS: I do not know exactly what to say. It is quite a sharply defined shadow for a hernia and it certainly seems to be surrounded by air, which would make one think it was within the lung or against the pleura.

DR. STRIEDER: We have a fifty-one-year-old man on whom an x-ray diagnosis of esophageal hiatus hernia of the stomach had been made. As I looked this over, I thought I could reconcile the symptoms with the x-ray diagnosis, which is often dangerous. There are several aspects that do not fall in line, however, and perhaps I shall devote a moment or two to these as I come to them.

In the first place, symptoms of five years' duration in a fifty-one-year-old man are not unusual for esophageal hiatus hernia or for any type of diaphragmatic hernia. Although the hernia may be present at birth, the symptoms may not occur until the patient is well along in years. It is interesting that the first diagnosis by x-ray of esophageal hiatus hernia was made at the Mayo Clinic in 1921. In 1940, Harrington* published a series of 250 cases of diaphragmatic hernia, of which 198 were paraesophageal in type. So it is by far the commonest type of diaphragmatic hernia recognized.

The pain that was variously described as being in the middle or just to the left of the sternum, radiating to the left arm, is explainable, in so far as pain in the arm is concerned, on the basis of phrenic reference due to diaphragmatic spasm. In diaphragmatic hernia, pain commonly simulates that of angina, or at least is thought to simulate that of angina. Patients may complain of severe pain in the arm in connection with their thoracic pain. Classically, paraesophageal hernia pain radiating through to the back and to the left of the spine is usually lower, but any patient may have a variety of symptoms depending on the type of hernia, the quantity of viscus herniated and the type of viscus herniated.

"Sitting down occasionally relieved the pain." That is contrary to the usual story. Most patients with esophageal hiatus hernias are relieved when they stand up or are propped up in bed because the upright position tends to reduce the hernia, if it is reducible.

"During the year or two before admission the patient had had 'considerable gas in his stomach' following meals, which was relieved by belching." This again is classic for diaphragmatic hernia. There is trapping of air above the diaphragm, causing considerable distress, and relief by belching. Consequently many erroneous diagnoses are made. Cholecystitis is a diagnosis often made when the patient's symptoms are entirely due to diaphragmatic hernia.

I cannot explain the lower abdominal cramps and diarrhea on the basis of gastric herniation alone. It is possible that at the time of these episodes the patient may have had a portion of the colon in the hernial sac, although that was never demonstrated in the films. "The diarrhea ceased, but the abdominal discomfort continued. It was sometimes relieved by soda or a glass of whisky, and at times aggravated by eating." That again is unexplainable, but apparently homely remedies do wonderful things for patients. The fact that the pain was relieved by whisky reminds me of a physician of this hospital whose symptoms were relieved by whisky although he had an ulcer of the stomach that was about to perforate when demonstrated at operation. Of course, the relief from soda seems reasonable. Patients with hernia through the diaphragm have distress because they regurgitate gastric secretions into the lower esophagus, and ulceration of the lower esophagus frequently occurs on the basis of prolonged, continued regurgitation. They often have ulceration of the stomach from the pressure of the hernial orifice on the wall of the stomach. This may give rise to hematemesis or to frank blood, or more commonly occult blood, in the stools.

"About six months prior to entry, the patient developed a severe cough and wheezing dyspnea. . . . On one occasion he raised bright-red sputum every morning for about a week." That is the ruby-hued herring that upsets our tight little argument. I have never seen a patient with diaphragmatic hernia who coughed up blood, and I find no reference to this in the 198 cases that Harrington observed at the Mayo Clinic. It is entirely conceivable, however, that the cough, dyspnea and other respiratory symptoms are explainable on the basis of hernia. We know that there is a certain amount of diaphragmatic spasm and crowding of the lung by the hernia if it is sufficiently large, which will result in shortness of breath and even wheezing. The site of the hernia makes it seem unlikely, at least to me, that the hernia could have so encroached on the lung that there was actual distortion of the bronchus to account for the cough and bloody sputum. There is no mention of bronchoscopy. If the pulmonary

*Harrington, S. W. Diagnosis and treatment of various types of diaphragmatic hernia. *Am J Surg.* 50:381-446, 1940

symptoms had been of significance I think it would have been suggested and perhaps carried out. It would have been interesting to know about it, at any rate. The other alternative, of course, is to consider whether the patient vomited the bright-red blood, rather than coughed it up, which would fit nicely into the picture, but would not explain the prolonged cough and the copious sputum unless they were caused by the emphysematous changes of advancing years.

A weight loss of 10 to 20 pounds can well occur in a patient with esophageal hiatus hernia. These patients develop a "food fear" and because of this fear or the inability to take food they lose weight. The patient stated that he was able to eat nearly everything, but closer questioning might have elicited the fact that he was on a reasonably restricted diet. There is no question that there is such a thing as a so-called "stomach cough," which we heard a great deal about years ago in the early days of sanatoriums and is still spoken of in tuberculosis institutions. Many tuberculous patients on prolonged bed rest have gastric symptoms related to hyperacidity, and with it they have a cough that is relieved when the hyperacidity is controlled. I am convinced that coughing in such cases is some sort of a reflex phenomenon since we see it clinically so often.

"All his symptoms were variously described as progressive or intermittent, with periods of remission and exacerbation." That again is typical of hiatus hernia. These patients may be perfectly well for months, during which time the stomach is in normal position. The prolonged symptoms are probably due to the adherence of the stomach in the hiatus, or its being retained there for a period of time. The patient had no history of aspiration of a foreign body or anything else to make us suspect a suppurative lesion in the lung that caused cough.

The stools were negative, although commonly with diaphragmatic hernia the stools are positive for blood because of prolonged bleeding from an erosion of the stomach, which often results in secondary anemia. Which brings me down to the point where I must make a diagnosis.

Was a bronchoscopy performed?

DR. BENJAMIN CASTLEMAN: No.

DR. STRIEDER: I do not see how I can go any farther than to say that this patient had a diaphragmatic hernia. I am not very much impressed, and I gather that Dr. Robbins is not, by the pulmonary shadow. I think that the shadow might have been due to compression of the lung.

DR. ROBBINS: Now that I have had more time to look at the gastrointestinal film, I believe that I can see a round mass above the barium-filled fundus of the stomach.

DR. STRIEDER: It is not part of the hernia?

DR. ROBBINS: I do not believe so, since it is more or less completely surrounded by air, and apparently is separate from the upper limit of the fundus of the stomach.

DR. STRIEDER: There is room for all sorts of conjecture. I cannot explain the hemoptysis on the basis of anything that we have to go on except the possibility, as Dr. Robbins has pointed out, of tumor in the lung. Given an x-ray diagnosis of a tumor in the lung, there is a certain differential diagnosis that one can go through, but actually it resolves itself into a more or less philosophic discussion concerning the exact histopathology, and the pathologists often surprise us when they tell what it is. If we can accept this shadow as evidence of a pulmonary tumor, then we have to make such a diagnosis. However, I think I shall be brash, fly in the face of the X-ray Department and refuse to be impressed by it, although that may be a serious error. Probably all these symptoms can be explained on the basis of diaphragmatic hernia of the paraesophageal type.

CLINICAL DIAGNOSIS

Esophageal hiatus hernia.

DR. STRIEDER'S DIAGNOSIS

Esophageal hiatus hernia.

ANATOMICAL DIAGNOSES

Esophageal hiatus hernia.

Bronchiogenic cyst of lung.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: Dr. Robert K. Brown operated on this patient. Since he is not here I shall read part of his operative note:

Under intratracheal ether anesthesia, a long, curved, posterolateral incision was made over the left ninth rib, and approximately 35 cm. of this rib was subperiosteally resected. Free pleural space was entered. There was a herniation in the posterior leaf of the diaphragm about 7 cm. in diameter. This was somewhat adherent to the lower lobe of the left lung. As the adhesions were separated and the lung mobilized from the diaphragm, it was found that, on the medial aspect of the basal segment of the lower lobe, a rounded, tense, 4-cm. mass presented. This seemed to be connected to a cystic mass that occupied most of the basal segment of the left lower lobe. Running from it through the diaphragm between the hernia and the esophageal hiatus were two good-sized vascular structures, one about 2 mm. in diameter, and the other about 5 mm. in diameter and rather thick walled. These were dissected free, doubly ligated and cut. They turned out to be veins, the larger having a mural thrombus in its lumen. The remainder of the basal lobe was readily freed.

It was then apparent that there were two lesions—the diaphragmatic hernia, which was easily reducible, and the cystic tumor in the lower lobe, which was thought to be a bronchiogenic cyst. It was decided to repair the hernia and remove the cyst. Since

nate from ordinary bronchiectasis. Most lung cysts are certainly of bronchial origin.

Although the preoperative diagnosis was hiatus hernia, there were several men who continually

FIGURE 2. Photograph of Bronchiogenic Cyst.

segmental lobectomy is not an absolutely clean procedure, it was also decided to repair the hernia by imbrication without opening the diaphragm. This was done, and a good approximation of normal strong diaphragm was obtained, the suture line running posterolateral in a radial direction. Mass removal of the basal segment of the left lower lobe containing the tumor was carried out.

The specimen that we received was a segment of lung containing the large cystic mass that Dr. Brown was able to feel. After fixation, section of the mass revealed a large cyst filled with gelatinous fluid (Fig. 2). Microscopic examination of the cyst wall showed it to be lined with ciliated bronchial epithelium and to contain foci of smooth muscle and cartilage. It was therefore a true bronchial cyst within the lung. Most people believe that these cysts are congenital in origin—in other words, that in the embryologic development of the lung one of the lung buds fails to develop and the bronchial secretion is unable to get out. Although we were unable to find any communication with a large bronchus, I imagine there must have been one with a small bronchus; otherwise the patient would not have coughed up blood. There was no inflammatory reaction around the lesions. Such absence of infection is often used as an argument against the theory that lung cysts origi-

asked the X-ray Department whether this lesion was in the lung.

DR. ROBBINS: With reason, I should say.

CASE 29402

PRESENTATION OF CASE

A sixty-three-year-old tobacco farmer was admitted to the hospital because of pain and weakness in the right arm.

The patient had been in apparent good health until about ten months before entry when he noted pain and weakness of the upper arm that bothered him while working. The pain increased in severity until seven months before entry, when it occurred at night and was relieved by letting the arm hang down. Chest roentgenograms at a community hospital about four months before admission were said to have shown a mass in the right upper chest. He was given a course of seven x-ray treatments over a month's time with apparently no decrease in the size of the mass. While receiving the x-ray treatments he had a paroxysmal nonproductive cough, which cleared after treatment. The pain and weakness in the arm increased in severity. The pain was in the lateral aspect of the right deltoid region, the bi-

ceps, the extensor surface of the forearm and the right ring finger. It was aggravated by lifting and by certain positions in bed. In the month before entry he developed a deep soreness in the right side of his neck. There was no weight loss, anorexia, hemoptysis, dyspnea, orthopnea, headache, giddiness or changes in the voice.

At twelve years of age "a large swelling of the

ward rotation of the right arm. There was no noticeable atrophy, masses, hyperesthesia, numbness or vascular changes.

The blood pressure was 110 systolic, 70 diastolic. The temperature was 98.6°F., the pulse 70, and the respirations 20.

The blood showed a red-cell count of 5,140,000, with a hemoglobin of 15.3 gm. The white-cell

FIGURE 1. Roentgenogram of Chest.

The mass in the right superior mediastinum lies between the trachea and esophagus. There is slight extension to the left, above the aortic arch.

neck had been drained through a midline incision." He had had typhoid fever at twenty. About twenty years prior to admission it was discovered that he had diabetes, which was controlled by diet without insulin.

Physical examination showed a weatherbeaten man in no distress. Both pupils were small and reacted to light and accommodation. The trachea was deviated to the right. No masses or lymph nodes were palpable. There was tenderness to deep pressure over the muscles in the posterior triangle of the neck. The chest was barrel shaped. The heart and lungs were normal. The shoulder motions were normal except for limitation of out-

count was 4200, with 75 per cent neutrophils. The urine showed a + test for albumin, but was otherwise normal. The blood sugar was 94 mg. per 100 cc.

X-ray examination of the chest showed a mass arising from the upper mediastinum and lying between the trachea and esophagus (Fig. 1). The mass measured approximately 13 by 13 cm. It was largely on the right side but there was apparent extension to the left. It was attached to the trachea, which was displaced to the left and posteriorly. It was probably attached to the esophagus in the region of the aortic arch. There were no pulsations. The mass appeared to change its

shape on deep inspiration and slightly on changing position. There was no shift of the mediastinum. The lungs were normal. The heart was slightly enlarged in the region of the left ventricle. The aortic arch was prominent. The diaphragm showed normal respiratory motions. The visualized bones appeared normal.

On the fifth hospital day a mediastinal exploration was performed.

DIFFERENTIAL DIAGNOSIS

DR. REED HARWOOD: Our problem is a discussion of a mass in the chest and the nerves involved by this mass.

Taking the second part first, the nerves involved appear to be the medial brachial cutaneous and the intercostohumeral on the medial side of the biceps.

These are supplied by the first and second thoracic nerves. The dorsal antibrachial cutaneous and the medial antibrachial cutaneous are the sensory nerves of the dorsum of the arm. The first of these is supplied by the fifth to the eighth cervical, and the second by the eighth cervical and the first thoracic. The ulnar nerve, which is the one involved so far as the finger is concerned, is supplied by the eighth cervical and the first thoracic. The area over the deltoid region is supplied by the supraclavicular nerve, which comes from the third to the sixth cervical nerve. It is hard to explain on the basis of a chest tumor how the patient had so much pain over the deltoid region since these nerves arise outside the thoracic cage. Similarly, the description of weakness of the arm and limitation of motion of the shoulder joint, particularly on outward rotation, I cannot explain on the basis of a lesion in the chest, because these muscles are supplied by nerves higher in the cervical region.

I shall discuss the mass that was drained at the age of twelve. I suppose that it was a thyroglossal cyst and not connected with the present illness, unless we can reason that a patient who had one embryonic rest is apt to have another elsewhere.

There are two discrepancies that I want to point out. The first is that in the physical examination the trachea was said to deviate to the right, and in the x-ray description the trachea was said to deviate to the left. The other discrepancy is that the record states at one point that the tumor arose between the esophagus and trachea and at another point that the tumor had pressed the trachea backward as well as to the left. I am going to ask Dr. Robbins to straighten me out on these two points. It does not seem possible for a tumor arising between the trachea and esophagus to press the trachea posteriorly.

DR. LAURENCE L. ROBBINS: If the record states that the trachea was deviated to the left, it is incorrect. I remember the case very well. The trachea was in the midline and was displaced anteriorly; the mass lay between the trachea and esophagus and pressed against both. It was attached to the trachea because the mass moved each time the patient swallowed.

This is the mass, chiefly on the right but with extension to the other side. The mass was smooth so far as could be determined from the films. As I said before, it was in the midline and pushed the trachea anteriorly, not posteriorly.

DR. HARWOOD: The mass is said to have changed in position.

DR. ROBBINS: That may have been a faulty observation. I examined the patient and was convinced at the time that the mass changed its shape with changes in his position.

DR. HARWOOD: Dr. Robbins evidently thought it was a cyst before operation and is now not quite so sure.

DR. ROBBINS: That was my impression.

DR. HARWOOD: There are a number of masses in the chest that I am going to exclude before considering tumors of the mediastinum. Tuberculosis and empyema can be excluded on the basis of the history. Lung tumor can be excluded because of the absence of cough and hemoptysis. Thymoma can be excluded because such tumors arise in the anterior mediastinum, and there is no evidence of myasthenia gravis. I am going to exclude lymphoma because of apparent lack of response to x-ray treatment. Because there was no tracheal tug or vascular phenomena in the arms, aneurysm seems unlikely, but one should be sure that the Hinton test was negative.

DR. BENJAMIN CASTLEMAN: The Hinton test was negative.

DR. HARWOOD: Malignant disease can be excluded less certainly, but I am inclined to think that this was not a malignant tumor, principally because the tumor was perfectly round and there were no constitutional symptoms, such as weight loss. However, I cannot exclude the possibility of a benign tumor that had become malignant.

In considering mediastinal tumors I shall mention the esophagus first. A tumor of this size in the lumen or in the wall of the esophagus would certainly cause dysphagia, which this patient did not have. Of the cystic embryonic rests, dermoid cyst is one of the more frequent ones, but it usually arises in the anterior mediastinum and often areas of calcification are seen in the x-ray films. I think it is not likely that this was a dermoid cyst. Bronchiogenic and tracheal cysts are both good possibilities. The location is correct, and such tu-

mors may be soft. A solid embryonic rest, such as a teratoma, is usually irregular in outline and shows areas of calcification. Regarding tumors of neurogenic origin, von Recklinghausen's disease may present a single tumor arising in the neural canal. This usually produces erosion of the articular facets of the vertebrae in that region, but I take it that such a lesion was not present here. Furthermore, there were no other neurofibromas noted on physical examination. A single neurofibroma of the mediastinum is another possibility. They usually arise in the posterior mediastinum and produce erosion of the ribs.

Finally, we should consider the possibility of substernal goiter. Against this is the fact that there were no masses in the neck. Most substernal goiters, not all of them, are attached to the lower pole of the thyroid. Furthermore, 90 per cent are seen in front of the trachea rather than behind it. So there is a 10 per cent chance, anatomically speaking, that it was in the correct position. In substernal goiter the enlargement is preponderant on one side and the trachea is deviated to the opposite side. The deviation begins at the hyoid bone and obtains maximal deviation at the widest part of the tumor. Since in this case there was no deviation of the trachea, I am going to say that this patient did not have substernal goiter. I am therefore led to the conclusion that he had a cyst of the trachea, possibly a bronchiogenic cyst, and that is my final diagnosis.

DR. JOST MICHELSEN: Were there no x-ray films of the cervical spine?

DR. RICHARD H. SWEET: I do not recall. At any rate, none were taken here. He had been studied extensively at a good clinic in Connecticut. His presenting symptom then was pain in the arm and shoulder girdle. There was no suspicion of a mediastinal tumor, but a film of the shoulder showed a half-moon shadow that suggested tumor, and a chest plate was obtained.

DR. MICHELSEN: The description of pain suggests involvement of the sixth and seventh nerve roots on the right.

DR. SWEET: What sort of lesion would explain that?

DR. MICHELSEN: I am not prepared to say. I am just suggesting that the distribution of the pain sounds more like root than peripheral pain.

DR. SWEET: Do you think it likely to be caused by a tumor in the chest?

DR. MICHELSEN: No; that is why I asked if x-ray films of the cervical spine had been taken.

DR. SWEET: I do not believe that the symptoms, other than the cough, were caused by the tumor.

I do not recall what I put down as my preoperative diagnosis, but Dr. Robbins and I finally concluded that it was a cyst of some kind. We considered neurofibroma.

It turned out to be a solid tumor but one of soft consistence. The x-ray films had localized it exactly; it was adherent to the trachea and had to be separated from the esophagus. Only a portion of the tumor was between the two organs, the majority of it protruding into the right side of the chest posteriorly, not anteriorly. As I freed it from its pleural covering and dissected it free, it looked like a goiter. As I followed it up I could see that its real attachments, as judged by vascular connections, were coming from the neck. I finally developed it down to a rather broad pedicle, which was obviously the lower pole of the thyroid gland, not a substernal goiter but a posterior mediastinal one. There was no evidence of goiter in the neck. The mass was so large that it could not have been removed from above.

CLINICAL DIAGNOSIS

Mediastinal cyst.

DR. HARWOOD'S DIAGNOSIS

Tracheal cyst (? bronchiogenic).

ANATOMICAL DIAGNOSIS

Colloid goiter.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: Microscopic sections confirmed the diagnosis of colloid goiter.

DR. WILLIAM B. BREED: How do you explain the symptoms?

DR. SWEET: I do not. The only symptom that the tumor caused was the cough.

DR. MICHELSEN: What about the pain? Did it continue to bother him?

DR. SWEET: At the time of discharge, the patient said that it was improved, but not completely.

It was my impression that the pain was due to a bursitis or to a cervical arthritis or something of that sort. At a subsequent follow-up visit, however, he was in an excellent state of health. Although there was still a certain amount of stiffness of the arm at the shoulder, he was completely relieved of pain.

STREPTOCOCCUS SORE THROATS AND SCARLET FEVER

DURING World War I many studies of scarlet fever and other streptococcal infections were made in the United States Army camps. Considerable information was acquired concerning the significance of these infections and their mode of spread. Since that time, the general use of the Dick test as a measure of susceptibility to scarlet fever and the classification of streptococci into specific groups and types have made possible more intelligent and more precise epidemiologic studies, and have served to clarify the relation between scarlet fever and other hemolytic streptococcus infections of the

upper respiratory tract. The application of this knowledge to recent studies of scarlet-fever outbreaks in Army camps has thrown further light on this important subject. This, in turn, has served to bring into focus certain inconsistencies in the public-health attitude toward these infections, which deserve reconsideration in the light of present-day knowledge.

Schwentker,¹ in a recent report of a commission established by the Board for the Investigation and Control of Influenza and Other Epidemic Diseases in the Army, presented a survey of hemolytic streptococci in certain Army camps. At three of the posts in which the commission's investigation was carried out there were only sporadic cases of scarlet fever, but at another post an epidemic of this disease occurred. The results of these studies are of interest and serve to corroborate the impressions gained in many other similar studies carried out in this country and in England and Germany since the introduction of the serologic classification of streptococci into Griffith's agglutinative types.

Briefly, Schwentker and the other members of the commission concluded from their studies that during an epidemic of scarlet fever most of the cases are caused by a single type of streptococcus. This type also represents a high percentage of the strains recovered from normal carriers. During endemic periods, on the other hand, no single strain predominates among the streptococci causing scarlet fever, a number of types usually being involved. These types are also found in normal carriers but they do not predominate over the other nonscarlatinal strains. They also found a definite relation between the gross streptococcus-carrier rate and the incidence of scarlet fever. The same relation held for the Group A (human virulent) streptococcus-carrier rate, as well as the carrier rate for the scarlatinal types. The changes in the gross carrier rate were due primarily to variations in the carrier rate of virulent Group A strains, and these in turn depended on changes in the rate for the carriers of the scarlatinal type.

During an outbreak of scarlet fever in a given ward these investigators found that the scarlatinal

strain of streptococcus becomes distributed throughout the occupants of the ward to a varying degree. Depending on the degree of this distribution, it fails to reach a certain proportion of the men and they naturally remain well. Among those who come in contact with the scarlatinal strain some are resistant to the organism, presumably because of an antibacterial immunity. Regardless of their Dick reactions they remain well, and either promptly eliminate the streptococcus or become carriers. Those without bacterial immunity develop evidence of clinical infection. The Dick-positive patients, that is, those who are susceptible to the toxin, develop scarlet fever, whereas those who are Dick negative have streptococcal tonsillitis without a rash.

A second clinical and epidemiologic study of an explosive outbreak of streptococcal sore throat in an army camp was recently reported by Bloomfield and Rantz.² A total of 341 cases occurred within a period of five days, and about 83 per cent of them began in the first two days. In approximately one fourth of all these cases there was a classic scarlatinal rash, which ran the usual course with eventual desquamation. In other patients there was only a trace of exanthem, and in the majority a rash was not seen at any time. However, there was no clinical indication that the patients with a rash were suffering from a disease that was in any other way different from that of the men without a rash.

These workers raise the question whether the use of the term "scarlet fever" with the implication of its fundamental difference from "acute tonsillitis" does not serve to maintain confusion and diagnostic quibbling. They believe that the entire group should be referred to as streptococcal sore throat (with or without associated scarlatinal rash). They also think that the same rules for isolation and quarantine should hold for all these cases, regardless of whether or not a rash occurs.

At the present time health departments throughout the country quarantine "scarlet fever" but not "tonsillitis," and this, according to Bloomfield and

Rantz, shows a complete misunderstanding of the subject. In Massachusetts and in many other states not only does this incongruity persist, but there are differences in the isolation and quarantine periods within adjacent subdivisions of the same state. It would be well for the state and local health departments to reconsider this problem at the present time with a view to bringing their regulations in accord with present knowledge concerning this group of infections, and take the same opportunity to standardize isolation and quarantine regulations.

HIERONYMUS FABRICIUS

FABRICIUS is best known as the teacher of Harvey. About 1600, Harvey attended the medical school at Padua, where Fabricius taught anatomy. It was there, in the old anatomical amphitheatre, which is still in existence, that Harvey heard for the first time, when attending one of the candle-light lectures of this famous teacher, a description of the valves of the veins. Fabricius was the first to demonstrate them publicly, and there seems to be little reason to doubt the inspiration Harvey received, to use Osler's phrase, from "the most distinguished teacher of the time, in the most distinguished school of Europe." The anatomical description and the function of the veins, as disclosed in Fabricius's lectures, stimulated Harvey to discover the circulation of the blood. He received at the same time an impetus to study embryology, a subject later to be markedly influenced by one of his books.

Two treatises by Fabricius, one on the formation of the egg and of the chick and the other on the formed fetus, have long remained buried in "that most excellent preservative, the Latin language." Dr. Howard B. Adelmann,* professor of histology

**The Embryological Treatises of Hieronymus Fabricius de Aquapendente: The formation of the egg and of the chick (De Formatione Ovi et Pulli) and the formed fetus (De Formato Foetu).* A facsimile edition, with an introduction, a translation and a commentary by Howard B. Adelmann, Ph.D. 883 pp. Ithaca, New York: Cornell University Press, 1942.

and embryology at Cornell University, has translated these into English, with the addition of a brief biography of Fabricius, an essay on embryology before the time of this great anatomist, an analysis of the treatises and a bibliography of the known editions. The translations are given in full, and facsimiles of each work are reproduced; there are numerous notes and commentaries, a list of references and an excellent index. This publication is one of the recent outstanding scholarly productions in the history of medicine. Furthermore, the book, published by the Cornell University Press, is a superb example of the work of a modern press.

Fabricius's position in embryology is not particularly easy to assess. It is correct to refer to him as the most distinguished teacher of his time, and as Adelman has pointed out, the embryologic treatises represent no mean achievement. In fact, some believe that they are of even greater anatomical importance than his work on the valves of the veins.

Fabricius lacked, as did most of his contemporaries, what Singer has called "complete speculative freedom." Needham was, moreover, impressed by Fabricius's "genius for exsuccous and formal discussions." Osler wondered how Fabricius, a teacher of wide learning and remarkable powers of observation, "could have been so blinded as to overlook the truth which was tumbling out, so to speak, at his feet." Dr. Adelman believes that Fabricius's faults, particularly his subservience to authority, were probably unavoidable—"a fault Fabricius shared, not only with Vesalius who preceded him, but also with many who came after, even Harvey. He adds: "The basic explanation, moreover, is not far to seek. We are all children of our times; we all see with the eyes of the centuries that have preceded us; truth dawns but slowly on the human mind."

MEDICAL EPONYM

GRADENIGO'S SYNDROME

Giuseppe Gradenigo (1859-1926), professor of ophthalmology at Turin, published a paper enti-

tled "Über circumscripte Leptomeningitis mit spinalen Symptomen und über Paralyse des N. abducens otitischen Ursprungs [Circumscribed Leptomeningitis with Spinal Symptoms and Paralysis of the N. abducens of Otic Origin]," which appeared in the *Archiv für Ohrenheilkunde* (62: 255-270, 1904). A portion of the translation follows:

There exists a peculiar symptom complex in the association of acute otitis media (with or without reactive mastoiditis) and isolated paresis or paralysis of the N. abducens on the side corresponding to the aural lesion, and without the occurrence of other local or general signs of disease. . . . The syndrome under discussion is characterized chiefly by three symptoms, which are intimately related to one another and which ordinarily are complained of by the patient himself: acute inflammation of the middle ear, persistent pains in the temporal and parietal region and paralysis of the N. abducens.

DEATHS

DASCOMBE — OTHO L. DASCOMBE, M.D., of Waltham died September 26. He was in his sixty-fourth year.

Dr. Dascombe received his degree from Johns Hopkins University School of Medicine, in 1905. Following in ternship at Waltham Hospital, he was appointed a staff member in 1918. He was a fellow of the Massachusetts Medical Society and a member of the American Medical Association.

A sister and a brother survive.

LELAND — GEORGE A. LELAND, JR., M.D., of Brook line, died September 22. He was in his fifty-eight year.

Dr. Leland received his degree from Harvard Medical School in 1911. He then became house officer at the Massachusetts General Hospital and was associate surgeon there at the time of his death. He was a member of the staff of the Collis P. Huntington Memorial Hospital, associate surgeon of the Palmer Memorial Hospital, consulting surgeon of the Massachusetts Eye and Ear Infirmary and of the Addison Gilbert Hospital in Gloucester and a member of the staff of the New Hampshire Memorial Hospital at Concord. He had been instructor for fifteen years at Harvard Medical School.

He was a member of the Massachusetts Medical Society, the American Medical Association, the American Surgical Association, the American College of Surgeons, the New England Surgical Society, the New England Cancer Society and the New England Obstetrical and Gynecological Society.

His widow, his mother and a daughter survive.

BOOK REVIEW

Renal Lithiasis. By Charles C. Higgins, M.D. 12¹/₂ cloth, 140 pp., with 18 illustrations. Springfield, Illinois: Charles C Thomas, 1943. \$3.00.

This short monograph is based on the Beaumont Lectures on Renal Lithiasis, delivered by the author. More than half the book deals with a discussion of the etiology of renal stone and of its relation to faulty diet and vitamin A deficiency. Included in this chapter is the technique of stone analysis. This is followed by a brief review of the surgical management of cases of renal stone. A short chapter on the dietary treatment and prevention of kidney stones, with a list of sample diets, concludes the book.

The book is far too elementary to be of value to the established urologist. The chapter on surgical management is sketchy, and the discussion of the dietary treatment and prevention of kidney stones will remind the average surgeon of the limited success he has had with this form of therapy.

From the student's point of view, the survey of the literature on the etiology of renal lithiasis suffers by being far too biased in favor of dietary imbalance and vitamin A deficiency as the main causes of renal stone. There are many significant papers that point to the incompleteness of the evidence for such a concept of stone formation in the experimental animal, and the relation of diet to the formation of renal stones in man is even more tenuously established.

NUMBER 16

GLOBAL MALARIA*

BRIGADIER GENERAL JAMES STEVENS SIMMONS, M.C., A.U.S.†

WASHINGTON, D. C.

SINCE December, 1941, when the United States entered the present global war, American soldiers have been sent to many parts of the world. Members of our armed forces are now stationed from Greenland's icy mountains to India's coral strand. In these regions, they are exposed to a variety of climates ranging from the extreme cold of the frigid zone to the intense heat of the tropics. They are also exposed to the innumerable infections of these areas, and therefore the Medical Department of the Army must be prepared to fight disease on a global scale. At the present time there is no malady known to man that may not be encountered by American troops, but the most important of all these disease hazards is malaria.

DISTRIBUTION

The present freedom from malaria of the northern United States and the reduced prevalence of the disease in the South have led to a tendency to underestimate the military importance of this serious infection. This is unfortunate, for even in this country, with its extensive facilities for malaria control, about a million persons are infected each year, and the death rates per 100,000 population have varied from 3.5 in 1935 to 0.9 in 1941.

The United States Army has had a long experience with malaria, in both peace and in war, at home and abroad. Never before, however, has it been faced with exposure to the disease in so many different geographic regions, in each of which the epidemiology differs depending on local mosquito vectors and other factors. Therefore, before indicating our experience with malaria and the scope of the present control program, the epidemiology of malaria from the global aspect will be briefly considered.

It has long been known that malaria is one of

the most important diseases of man. Some years ago Manson¹ remarked, "Directly and indirectly it [malaria] is the principal cause of morbidity and death in the tropics and sub-tropics." Osler² referred to malaria as "the greatest single destroyer of the human race." Today, more than four decades after the discovery of the means of its transmission by mosquitoes, malaria remains a major scourge, exceeding all others in reducing the vitality and impeding the industrial development and political progress of the inhabitants of many tropical, subtropical and temperate countries.

The exact world prevalence of malaria is not known. From a study reported by the League of Nations in 1932 it was concluded that in sixty-five countries over 17,000,000 cases were treated in one year. Obviously, only a small proportion of the total number of patients are treated. In India, for example, each year only 8,000,000 to 10,000,000 are treated out of a total of about 100,000,000 patients, and of these from 1,000,000 to 3,000,000 die.

The world distribution of malaria is indicated in Figure 1. According to Strong³ the disease is prevalent between 45° north latitude and 40° south latitude. The indigenous malaria belt extends from 60° N in Europe (Russia and southern Sweden) to 30° S in Africa (Natal), to 40° S in South America (Argentina), and rarely to 20° S in Australia (Queensland).

EPIDEMIOLOGY

The epidemiology of malaria varies greatly in different parts of the world. In the United States, for example, the most important vector of malaria is *Anopheles quadrimaculatus*. This mosquito breeds by preference in the still, fresh water of pools, lakes and swamps. Naturally, the problem of malaria control here is vastly different from that in Trinidad, where one of the important vectors, *A. bellator*, breeds in water-holding air plants that grow high above the ground on the limbs of immortal

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 25, 1943.

†Director, Preventive Medicine Division, Office of the Surgeon General, United States Army.

trees. There are many other important species in the western hemisphere, each of which has its peculiar breeding habits requiring special methods of control.

The chief vector in West Africa is *A. gambiae*, a domestic mosquito that breeds in any kind of standing water, hoofprints, cart tracks, borrow

primarily in pools and is found in such places as drying river beds, overflow pools, borrow pits, hoofprints and cart tracks, and in slowly running irrigation water. This is a plains mosquito that is not found in the hills above an elevation of 3500 feet. It is interesting to note that this mosquito, which caused the great epidemic in Ceylon in

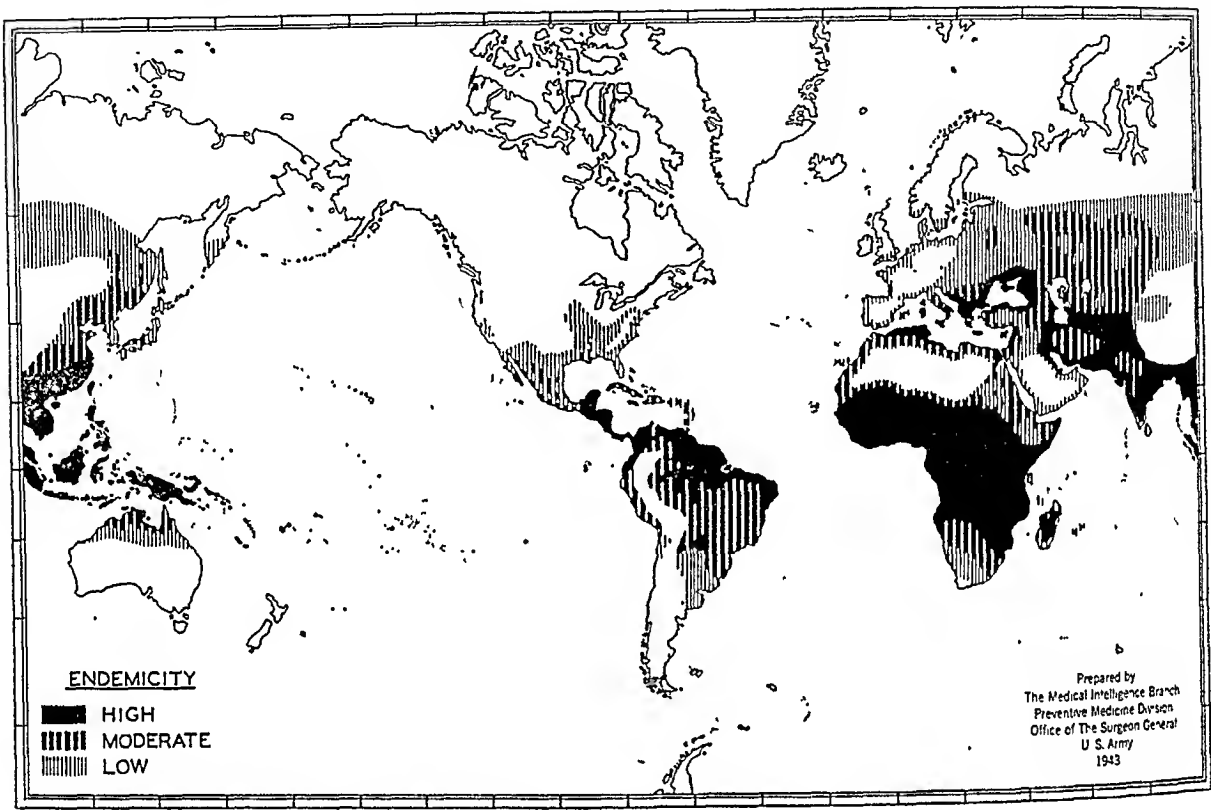

FIGURE 1. Global Distribution of Malaria.

pits, or marshes and even along the edges of slowly moving streams. This is the African mosquito that, in 1930, was transported to Brazil, where it succeeded in colonizing and where, in 1938, it caused the greatest epidemic of malaria ever known in the Western Hemisphere. Fortunately, owing to an energetic campaign by the Brazilian Government in co-operation with the Rockefeller Foundation, *A. gambiae* has apparently been eradicated from Brazil. However, it still remains a great hazard in large areas of Central Africa from the west coast across to the Nile Valley, and even into Eritrea on the Red Sea.

In India there are a number of important malaria vectors with widely different habits. In Bombay, for example, there is *A. stephensi*, a thoroughly domesticated anopheline that, like the yellow-fever mosquito, *Aedes aegypti*, breeds in wells and in standing water in and around houses. Another important vector in India, and the only one in Ceylon, is *A. culicifacies*. This mosquito breeds

1934-1935, is also responsible for the great epidemics that have occurred from time to time in the Punjab of northwestern India.

Another important malaria vector in India is *A. fluviatilis*, which breeds along the edges of foothill streams and irrigation ditches in southern India. It is not normally found at elevations below 1000 or above 5000 feet. A similar mosquito, *A. minimus*, a sunshine and running-water breeder, occurs in central and northeastern India, northern Bengal, Assam, Burma and South China. This stream-breeding mosquito was responsible for a malarial infection rate of 100 per cent in the Chinese troops who escaped from Burma through Assam into India. Undoubtedly, it is as great a hazard to military operations along the Burma border as are the Japanese themselves.

In the Malay Peninsula the principal vector is *A. maculatus*, which breeds by preference in seepage water. There is also a salt-water breeder in southern Malay and throughout the Dutch Indies

and southern Bengal known as *A. sundaicus*. This mosquito breeds in brackish-water marshes and in fishponds and causes a great deal of malaria.

In the Philippines, malaria is important only in the areas where the vector is *A. minimus* var. *flavirostris*, a shady foothill-stream breeder. It was this mosquito that transmitted malaria in Bataan.

In southern Europe the main vectors are races of

and use of improved control methods have resulted in a satisfying decrease, and for the year 1939 the admission rate for the Army at home and abroad was only 3.8 per 1000.

Present Malaria Program

During 1940, the Surgeon General of the Army took steps to expand and revise the Army's plans

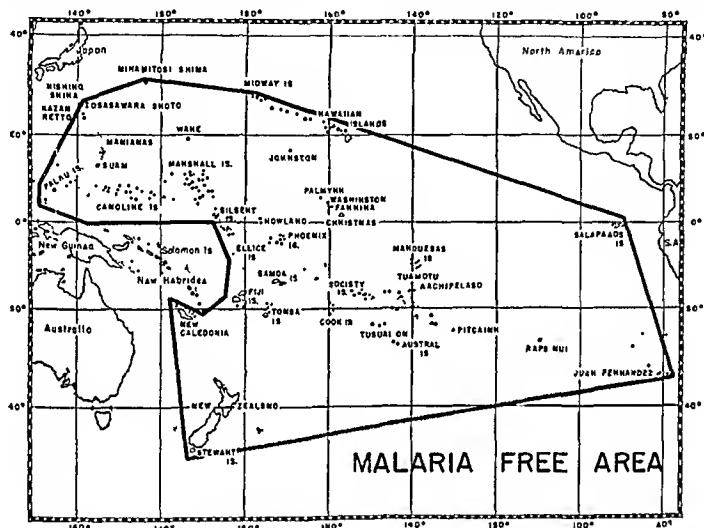

FIGURE 2. Map Showing the Malaria-Free Area in the South Pacific.

the species *A. maculipennis*, which differ markedly in their habits.

There are many islands in the South Pacific where malaria does not exist because of the absence of anopheline mosquitoes (Fig. 2).

These differences in the breeding habits of the anopheline vectors of malaria in different parts of the world create innumerable difficult problems in the military control of the disease, and a careful survey of each situation is required before effective control can be accomplished.

THE ARMY'S EXPERIENCE WITH MALARIA

Previous Malaria Rates

The United States Army has always been exposed to malaria. The annual malaria admission and death rates per 1000 population for more than a century are indicated in Figure 3. Before 1900 the rates were extremely high, especially during periods of war. Since that time the development

for malaria control in order to meet whatever military situations might arise. This control program included the following general measures:

The establishment of the Section on Tropical Disease and Malaria Control in the Preventive Medicine Division of the Surgeon General's Office, which co-ordinates all the Army's anti-malaria activities.

The establishment of the Commission on Tropical Diseases, composed of civilian consultants to the Secretary of War, as a part of the Preventive Medicine Division. (Serving on this commission are some of the country's best experts in malaria control.)

The organization of the Subcommittee on Tropical Diseases of the National Research Council to advise the Surgeon General on policies concerning the treatment and control of tropical diseases, especially malaria.

The initiation and co-ordination of a comprehensive research program dealing with malaria

that has been undertaken with the advice of the National Research Council and the approval of the Committee on Medical Research of the Office of Scientific Research and Development, office for Emergency Management. (Many separate institutions are making studies, and many thousands of dollars are being spent monthly in the

derogatory to atabrine that are being circulated. The Army is glad that it has adequate supplies of this drug.

The control of malaria in the field depends largely on measures that the soldier can apply for himself. The first of these is the prophylactic use of atabrine or quinine, which should be re-

FIGURE 3. Annual Admission and Death Rates (per 1000) for Malaria in White Enlisted Men in the United States Army, 1819-1941.

search for more effective antimalaria drugs; also much valuable research on insecticides and mosquito repellents is being done in close cooperation with the Bureau of Entomology and Plant Quarantine of the United States Department of Agriculture.)

Specific Measures

The malaria-control program includes control measures applicable to permanent camps, posts and stations, and measures that can be used to protect troops living in the field.

The control measures used in permanent installations include all the standard methods employed in civil communities, such as the following: an effective antimosquito campaign, including the elimination of mosquito breeding places by drainage or filling, the destruction of aquatic forms with larvicides and the killing of adult mosquitoes in buildings with insecticide sprays; screening and the use of bed nets in living quarters or other buildings; and the treatment of all infected persons with antimalaria drugs. At this point I wish to warn against the misleading and false rumors

served for emergencies, since neither of them really prevents infection. Both drugs, however, are useful, since they usually prevent the development of clinical symptoms so long as they are taken. This makes it possible for the soldier to stay on his feet and carry out a mission in spite of malarial infection. For at least three years the Army has been concerned with extensive investigations in the search for a more effective malaria prophylactic for use in the field. The second group of measures include the use of bed nets, head nets and mosquito-proof clothing, when indicated and practicable. The third is the use of the new mosquito repellents, which are safe and highly effective. The last measure is the use of freon-pyrethrum aerosol sprays in endemic regions.

Results of the Control Program

The results obtained in the Army's malaria-control program during the recent emergency and present war may be considered in two categories—first, the program in the continental United States, and second, the program abroad.

Control in the United States. At the beginning of the recent mobilization it was feared that the rapid expansion of the Army might cause an increase in malaria among troops in this country. Plans were therefore made early in 1940 to strengthen all facilities for the control of the mosquito vectors in the United States and in our permanent tropical possessions. This program on military reservations has been supplemented by an extra-military program carried on by the United

It has also included the development and procurement of the newly discovered, highly effective mosquito repellents and sprays and of protective nets. Special malaria-survey and malaria-control units staffed by malariologists, entomologists, parasitologists and sanitary engineers have been sent to our fighting fronts in various parts of the world.

The malarial infection rates in certain overseas regions where protection is difficult are naturally comparatively high and in certain areas they have

States Public Health Service, working through state and local health departments. As a part of the Army program, sanitary engineers were commissioned and assigned to key positions throughout the Army. An enormous mosquito control campaign was organized and carried out in 1941 at the cost of almost \$2,000,000. During that year the malaria rate not only failed to rise, but actually dropped to an all-time low of 1.7 per 1000. During 1942 the campaign was intensified, and approximately \$3,000,000 were spent. The malaria rate was one third as high as in 1941, namely, 0.6 per 1000. This excellent record cannot be surpassed.

Control overseas. As indicated previously, it is infinitely easier to control malaria among troops living under the stabilized conditions of this country than among those living in the field abroad. By anticipating conditions among our troops overseas, however, it has been possible to set up a control program that is comparatively effective. From the beginning, special facilities have been developed for obtaining information about the incidence and the epidemiology of malaria in all parts of the world. All troops sent abroad have been provided with specific information concerning the disease hazards and the methods of meeting them in the regions concerned. The planning has included provisions for safeguarding, augmenting and distributing the Army's supplies of quinine and atabrine and of various materials for mosquito control.

at times been a matter of some concern. However, on the whole, rates have not been excessive.

In Table 1 are indicated the admission rates for malaria and other diseases in various overseas theaters compared with the rates for similar diseases at home. For obvious reasons the strengths and locations are not shown.

Generally speaking, the health of our troops everywhere has been excellent. The disease rates in all temperate-zone theaters compare favorably with those in the United States, and in some regions they are actually lower than at home. The incidence of malaria is highest in the tropical theaters and among troops in combat areas. It is believed that with the more extensive field use of the new insecticides and repellents the situation even in these areas will improve.

CONCLUSION

In conclusion it is desired to express the appreciation of the Surgeon General of the Army for the whole-hearted way in which the entire medical profession of this country has supported his program for the prevention of all diseases, including malaria. It is also desired to re-emphasize the importance of malaria as a widespread potential hazard to American troops abroad, and to bring to attention the urgent need of more effective methods for its control. I know of no contribution that could be made to American medicine at this time that would be of greater value to this country and to humanity

than the discovery of an easily administered and effective drug for the prevention of malaria among troops in the field. With the support and help of the medical profession, the search for this important drug will continue in the laboratories of our country.

NEWER CONCEPTS OF GONORRHEA*

SAMUEL N. VOSE, M.D.†

BOSTON

THE remarkable developments that have taken place in every line of endeavor related to the fight against the gonococcus in the last few years have led to a radically altered approach to the management of gonorrhea and a somewhat more optimistic outlook regarding its eventual control. The purpose of this paper is to discuss briefly several phases of this problem, with particular reference to the new opportunities and responsibilities of the practitioner in the light of changing concepts of diagnosis, treatment and prevention.

Gonorrhea, under present conditions, presents a threefold problem. The advent of war has reversed a prior trend and has resulted in a considerable increase in the incidence of this disease, thereby creating a problem of military importance. The public-health aspects of the infection are well recognized. The disease remains, however, as much as ever the personal concern of the patient and his physician. In spite of the activities of the federal and state governments and the magnificent work of various social-service agencies, the ultimate objective of complete eradication of this plague can be attained only through the co-operation of all agencies concerned. With income levels rising, the proportion of civilian patients seeking treatment from the private physician instead of the clinic may well increase. Only if the private physician realizes and accepts his responsibilities and avails himself of the supplementary facilities provided by other agencies will the lot of the patient be improved by such a change. At present, it is perhaps too much to say that the clinic patient receives on the whole better care than the private patient, but certainly the collateral activities such as follow-up and the discovery of contacts are far better organized in the clinic than can ever be possible in private practice. By making use of the supplementary services offered by governmental and other agencies, however, the private doctor can vastly increase his effectiveness in the management of single cases

and his contribution to the solution of the larger problem.

Improvements in methods of diagnosis are principally concerned with the increased reliance on cultural methods to supplement the smear. Formerly considered a difficult and unreliable laboratory procedure, during the last few years culture of the gonococcus has been developed to a point where it is considerably more reliable than is the smear, especially in chronic cases and in the examination of the secretions of the cervix and the prostate gland. Although culture and smear agree in the majority of cases, those in which a positive culture is found with a negative smear outnumber considerably those in which the converse is true. In some cases reliance on clinical observation is the only possible means of diagnosis. A complete history and careful examination may establish a diagnosis even in the face of negative bacteriologic findings, and it must be remembered that in the case of a suspected contact, the male urethra is the best culture medium existent.

Limitations of the use of the culture in private practice are many, and at present perhaps prohibitive for its routine use in all communities. Uniformly reliable results are obtained only in laboratories staffed by technicians having special training and facilities. Mediums must be fresh; the transportation of material for any distance or delay in plating and incubation appreciably reduces the percentage of positive cultures, and overgrowth of other organisms often interferes with satisfactory examination. For following the progress of the average case, the private doctor should depend principally on clinical signs and the stained smear. Where the diagnosis is in doubt, however, or where it is sought to establish proof of a cure, the use of cultures is almost mandatory, even if obtained at considerable inconvenience. The evidence of less than three negative cultures at weekly intervals is not conclusive. Recent experimental work on the transportation of material for culture, notably by Dr. Oscar Cox,¹ of Boston, raises the hope

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 26, 1943.

†Professor of genitourinary surgery, Boston University School of Medicine; surgeon-in-chief, Genitourinary Department, Massachusetts Memorial Hospitals.

that the availability of this method may be greatly increased in the near future.

Diagnostic measures other than bacteriologic deserve some discussion, especially in the case of so-called "chronic gonorrhea"—a condition that has happily been much less frequent in recent years. Distinction should be drawn between the drug-resistant cases, in which positive smears or cultures indicate the persistence of living organisms, and those in which gonococci cannot be demonstrated in the secretions. In the latter group diagnosis must depend principally on clinical methods, since experience has shown that in only a small proportion of cases is reliance to be placed on the complement-fixation test. Positive results are fairly reliable, but to negative reports little significance can be attached. Clinically, the persistent purulent or crusting discharge at the meatus—the "morning drop"—is almost invariably due to the presence of a large-caliber urethral stricture, a condition that can be detected only by the use of the bulbous bougie—a valuable yet much neglected instrument. Another frequent cause of chronic gonorrhea is infection of the prostate and seminal vesicles, in which case microscopic examination may reveal an excess of leukocytes in the secretion. Following a definite attack of gonorrhea, the finding of pus in the prostatic fluid usually means a persistence of the infection, although it should be borne in mind that a nonspecific prostatitis may have preceded the gonorrheal infection. Urethral stricture and prostatovesiculitis account for the bulk of cases of chronic gonorrhea in males. In females, cervicitis is outstanding as a focus for latent gonorrhea, whether or not it is accompanied by adnexal disease.

The only excuse for mentioning such well-known facts is the frequency with which they are ignored in practice. It has recently been my experience to see a patient who had been treated by bed rest for six weeks on two different occasions on account of persistent urethral discharge. Sulfonamide drugs had brought about disappearance of gonococci, but the discharge had persisted. Massage of the prostate had been carried out on one or two occasions, but no sounds or bougies had been passed. Calibration of the urethra revealed a large-caliber stricture in the anterior urethra, dilation of which brought about the rapid disappearance of the discharge. It goes without saying that no manipulation should be done in the presence of a positive smear.

In a broad sense, a discussion of diagnostic methods may include tests of cure. This is an extremely important matter, and the term "cure" means different things to different people. To the bacteriologist it means the disappearance of organ-

isms from the tissues. To the clinician it should mean not only the elimination of gonococci but the restoration of tissues to a normal condition. To one patient it may mean cessation of the discharge, whereas to another it may signify an unattainable state of bliss that he never hopes to reach. In the latter type of patient the fear of gonorrhea constitutes a disease in itself, and the added assurance afforded by a negative culture is a boon to both patient and physician and well worth almost any inconvenience to secure.

In acute cases that respond quickly and favorably to chemotherapy, the disappearance of discharge and shreds from the urine, together with three or more negative cultures of urethral and prostatic secretions at weekly intervals, may be considered adequate proof of cure. If cultural facilities are not readily available, a much longer period of observation is necessary. Opinion differs concerning the advisability of examining the anterior urethra for stricture in this type of case. As a urologist, I find it difficult to discharge a patient as cured without first assuring myself of the absence of stricture in the anterior urethra, as well as of the normal condition of the prostatic secretion. The passage of a bulbous bougie several weeks after the cessation of symptoms and the disappearance of organisms can do no harm if reasonable care concerning technic is observed and if the disease has been cured. If it has not been cured, the sooner the fact is detected the better.

In chronic cases, the problem is much more difficult. In addition to the disappearance of discharge and shreds and repeated negative cultures, the lapse of several months without recurrence of signs, with the patient under frequent observation, constitutes the best indication of permanent cure. Here again, serologic tests are of limited value, and provocative measures, such as the ingestion of alcohol, are not to be recommended. They are of doubtful value and are not devoid of danger.

With respect to therapy, an excellent pamphlet on gonorrhea issued by the Massachusetts Society for Social Hygiene² in 1936, and circulated for some years thereafter, reads as follows:

The treatment of gonorrhea depends upon keeping all the infected parts that can be reached clean and free from pus, and upon helping the membranes to get well. There is no medicine which will cure it quickly. . . . There is no medicine which, taken by mouth, will cure gonorrhea, or even be of much help.

This was sound doctrine in 1936, as it had been for many years before. The above situation should be compared with that existent at present. The amazing efficacy of chemotherapy has in all but a few cases removed the management of gonorrhea from its status as a urologic procedure into the category

of medical treatment. To such an extent is this true that the urologist, as such, feels some embarrassment in speaking on this subject, except in the way of valedictory. Certainly a disease in which well over 90 per cent of cases are permanently cured by oral ingestion of a drug, and in which suppurative complications have almost disappeared, can call for little action of a surgical nature. That disregard of surgical principles may be disastrous, however, is attested by the occasional patient who appears with the meatus occluded by a wad of cotton under the foreskin and wondering why his infection has failed to respond to the new drug.

The chemotherapy of gonorrhea has received such thorough discussion in the last few years that extended comment is unnecessary. It is generally agreed that most acute cases respond to a dosage of 20 gm. of the chosen drug, distributed over five or more days. If cure does not result from the first course or if cultural proof of cure is not obtainable, a second course of similar dosage should be given. For routine use, sulfathiazole is the drug of choice. Sulfadiazine appears to be equally efficacious, but it is more expensive and its lack of toxicity is largely a theoretical advantage, since serious reactions from sulfathiazole in the dosage mentioned above are rare. Newer drugs at present under trial have little to offer over sulfathiazole. Attention to general hygienic measures and avoidance of alcohol and sexual activity are of course essential. A large fluid intake is desirable. In the average case, rest in bed is not necessary and the patient's occupation need not be interrupted.

Cases resistant to sulfonamide drugs form an interesting group. It is generally considered that cases resistant to one of these drugs show little response to others of the group, and that an increase in dosage is of little value. This is true in general, although exceptions occur. One very resistant case in my experience was treated by the usual methods without effect. A massive dose of sulfapyridine was given over a twenty-four-hour period preliminary to a contemplated fever treatment, and the patient showed such marked improvement that the heat treatment was considered unnecessary and complete recovery ensued without it.

Several courses are open for the treatment of those cases in which response to the routine administration of sulfathiazole is not satisfactory. A shift to another drug of the sulfonamide group and a period of bed rest for ten days or two weeks are the first measures to be tried. Gentle local treatment of the types in common use prior to the advent of the sulfonamide drugs will in a few cases tip the scales in favor of recovery. Fever therapy properly administered produces a cure in a large percentage of cases, but has definite disadvantages.

It requires extensive facilities and constant supervision, and is not without danger to life. Only serious complications or extremely refractory infections justify its use, and then only in otherwise healthy subjects. Results are seemingly better if a preliminary large dose of a sulfonamide drug is given during the preceding twenty-four-hour period. Treatment by various types of vaccines or filtrates has in my experience been extremely disappointing and in some cases serious complications have been attributed to their use. Their field of usefulness is extremely limited.

Other chemotherapeutic agents such as penicillin may be extremely useful in the treatment of sulfonamide-resistant cases. This subject is now under investigation, and *in vitro* tests show that the gonococcus is extremely sensitive to the action of penicillin. According to a recent report,³ penicillin has shown great promise in the treatment of gonococcal infections in man. Further work on this subject will be awaited with interest.

It is in the field of prevention and control that the private practitioner can find the most important of the new opportunities afforded by recent innovations. The establishment of state clinics on a large scale and the large amounts of money spent by the federal government in research on gonorrhea are indicative of the importance of this problem. The value of the work of the social services of large institutions and private agencies such as the Society for Social Hygiene cannot be overrated. As a result of all these activities, the means and organization are now available to bring about the eradication of this disease if properly employed. The above agencies cannot do the job alone, however, and the large number of cases in which the private doctor constitutes the only contact with the patient increases his responsibility.

Measures that help to prevent the spread of gonorrhea include, first, the continuation of treatment until cure is established. A full discussion of the situation on the occasion of the patient's first visit goes a long way toward gaining confidence and preventing a lapse of treatment. A certain proportion of treated cases become asymptomatic carriers, and it is in this group that cultures as tests of cure are of extreme importance. If adequate facilities for culture are not available nearby, the reference of the patient to a laboratory in a large center should if possible be made.

Perhaps one of the most important ways in which the private doctor can co-operate in the prevention of gonorrhea is in reporting lapsed cases and suspicious contacts to his state department of health. In the past such co-operation in regard to the venereal diseases has not been so wholehearted as in the case of other communicable diseases. The splendid report recently published by

Dr. E. B. Howard and others⁴ on the epidemiologic investigation of syphilis and gonorrhea in the Army and Navy in Massachusetts is evidence of the excellent results that can be obtained by well-trained and experienced professional personnel in utilizing information regarding contacts. The Massachusetts Department of Public Health is eager for the co-operation of the private physician and will make the best use of any information that can be furnished.

The general practitioner is occasionally called on for advice concerning prophylaxis. It has always been my opinion that thorough washing with soap and hot water, together with micturition immediately after exposure, will in most cases prevent gonorrhea. The external application of calomel ointment and the injection of 1 per cent Protargol into the anterior urethra give added assurance. Recently a report on the oral use of sulfathiazole as a prophylactic has appeared in the literature.⁵ It appears to be highly effective, reducing the incidence of gonorrhea and chancroid in exposed soldiers to a remarkable extent. In single doses of 5 gm. it is well tolerated. Unfortunately, the ef-

fect of a repetition of this dose at frequent intervals over a long period of time is uncertain as regards both cumulative effects and sensitization, and further experimentation seems necessary before the method can be recommended for wide use.

* * *

In conclusion, it may be stated that recent developments in the management of gonorrhea have placed it in the group of diseases that are both preventable and curable. The private practitioner occupies an important position in any program looking to eventual eradication of gonorrhea.

SUPRALEVATOR ABSCESS

EUGENE A. GASTON, M.D.,* AND LYMAN O. WARREN, M.D.†

FRAMINGHAM, MASSACHUSETTS

SUPRALEVATOR abscess is a rare disease with which few surgeons have had an extensive experience. The fairly numerous papers on the subject have consisted chiefly of brief reports in which there has been little discussion of diagnostic and therapeutic problems and particularly scanty reference to the surgical anatomy involved. A recent case at the Framingham Union Hospital has prompted this review of the subject. The diagnosis of supralevator abscess has not previously been made during the fifty years of the hospital's existence.

Infections occurring about the rectum and anus have been classified as infralevator and supralevator according to their anatomic relation to the pelvic diaphragm. Green¹ has subclassified these infections as follows:

Infralevator infections:

Cutaneous: consisting of folliculitis surrounding the anal margin

Marginal: infection at the anal verge not affecting the sphincters.

Ischio-rectal: infection of the ischio-rectal space usually arising from infections about the crypts of Morgagni.

Supralevator infections:

Superior pelvic-rectal.

Retrorrectal.

Submucous or mural: occurring in the submucosa of the rectal wall.

Infralevator infections are relatively frequent and their surgical treatment is well understood. This paper deals with those infections lying above the level of the pelvic diaphragm. In order to understand the problem of supralevator abscess, a brief review of the relevant anatomy is in order.

ANATOMY AND PATHOLOGY

The well-developed fascial layer covering the iliopsoas muscle in the iliac fossa descends over the brim of the pelvis, at which, at the linea terminalis, it is adherent to the periosteum and below which it becomes known as the endopelvic fascia. Descending on the pelvic surface of the obturator internus muscle for a short distance, this endopelvic fascia undergoes a tendinous condensation or thickening that extends along the entire lateral wall of the pelvis. It is from this area of thickening, the arcus tendineus, that the lateral portion of the levator ani muscles takes origin. These muscles, arising on each side of the pelvis, insert into a median

*Instructor in surgery, Boston University School of Medicine, visiting surgeon, Framingham Union Hospital, Framingham, Massachusetts

†Formerly, resident surgeon, Framingham Union Hospital.

raphe. The more anteroposterior or medial fibers, arising from the posterior surface of the pubes, are directed posteriorly along the sides of the prostate or vagina to blend with the longitudinal muscle of the rectum near the anal margin² and

stalks, and along them extend the middle hemorrhoidal vessels.

The pelvic peritoneum covering the front and sides of the rectum extends downward for a variable distance to form the pouch of Douglas. It

FIGURE 1. Frontal and Median Sections of the Pelvis Showing the Extent of a Superior Pelvirectal Abscess.

Note the extension of the abscess toward the base of the bladder, which frequently results in bladder-neck obstruction.

continue to their insertion on the sacrum and coccyx.

At the arcus tendineus the endopelvic fascia divides into three layers (Fig. 1). The most lateral of these layers descends over the pelvic surface of the obturator internus and pyriformis muscle and is known as the obturator fascia. It forms the lateral wall of the ischiorectal space. The remaining two layers of pelvic fascia are intimately related to the superior and inferior surfaces of the levator ani muscles and are known as the diaphragmatic fascia. The inferior layer of diaphragmatic fascia, also known as the anal fascia, after covering the inferior surface of the levator ani is inserted into the side of the anus and forms the medial wall of the ischio-rectal space. The superior layer of diaphragmatic fascia, also known as the rectovesical fascia, after covering the superior surface of the levator is reflected over the side of the rectum—over the prostate and bladder in the male and over the upper vagina, cervix and bladder in the female. All the pelvic organs in both sexes are thus encased in a fascial sheath that is continuous with the superior layer of the diaphragmatic pelvic fascia.

Lateral fibrous condensations extend from the fascial encasement of the rectum on each side to the lateral portions of the sacrum. These comprise the lateral ligaments of the rectum, or rectal

does not come in contact with the levatores ani but is reflected onto the bladder in the male and onto the cervix and uterus in the female. Between the pelvic peritoneum and the superior surface of the levatores ani there is thus a potential space that contains adipose tissue. It extends from the fascial covering of the prostate or vagina anteriorly to the sacrum posteriorly, and between the superior layer of diaphragmatic fascia on each side. This is the supralelevator space, which is divided transversely by the rectum and rectal stalks into anterior and posterior compartments. The anterior compartment has been designated as the superior pelvirectal space, and the posterior compartment is called the retrorectal or presacral³ space.

The supralelevator space is continuous with the ischio-rectal space through the separations between the levator ani and coccygeus muscles, with the gluteal and obturator regions by way of the sciatic notches and obturator foramina,⁴ respectively, and with the extraperitoneal space of the remainder of the abdomen. Suppuration in the supralelevator space may extend through or around the levatores ani into the ischio-rectal space to point in the skin of the perineum. It may, however, point in the gluteal region or the groin, or extend upward into the retroperitoneal and perirenal spaces. In male patients the inflammatory reaction frequently ex-

tends anteriorly about the structures at the base of the bladder, causing acute urinary retention. In view of the many reported cases in which urinary retention has been a prominent part of the clinical picture, it is surprising that this fact has not received more emphasis.

A considerable difference of opinion exists concerning the route by which infection reaches the supralevator space. A careful study of the reported cases indicates that, in the majority, the route of infection remains undisclosed even in those cases that come to autopsy. A notable exception is the case reported by Meyers⁵ in which a twenty-three-year-old man was gored by a cow, the horn piercing the rectal wall just above the levator ani. An abscess developed in the superior pelvic space, perforated the obturator fascia laterally, extended through the great sciatic notch to the gluteal region, and eventually opened through the skin of the buttock. Cure was effected by preliminary colostomy followed by excision of the sinus.

Most writers agree that infection of the supralevator space is likeliest to occur as a result of infection occurring about the mucocutaneous line in the crypts of Morgagni. Miles³ states that supralevator infections always spread from a septic lesion of the rectum or anus by way of lymphatics that extend laterally from the rectum in relation to the levatores ani, a *modus operandi* that Hibshman⁹ considers of the first importance. Several authors⁶⁻⁸ hold that trauma to the rectum above the level of the insertion of the levatores ani by an ingested foreign body may occasionally be the etiologic agent. In the case presented below, the patient attributed his symptoms to a prune pit swallowed two days before. No evidence of trauma to the rectum was found on repeated proctoscopic examination, and no foreign body was recovered in the contents of the abscess.

Morrissey⁹ states that from 82 to 94 per cent of perianal and ischiorectal infections occur in men, and that in about 75 per cent of these there is a history of a previous gonococcal infection. The resulting low-grade nonspecific infection due to secondary bacterial invaders may flare up, spread from the prostate and seminal vesicles, and cause a vesicointestinal fistula or, "depending on the direction and extent of the inflammatory process, [may] end in ischiorectal, superior pelvic or posterior pelvic abscess and, by lymphatic extension, localized suppuration about the kidney." Morrissey further points out that whereas prostatic abscess is usually limited in its spread by the rectovesical fascia (of Denonvilliers), infection perforating the seminal vesicle may escape directly into the superior pelvic space. Morrissey's

theory is supported by Drucek,⁸ Bullock¹⁰ and Ingegno and Spitz,¹¹ yet none of these writers present a case that was proved to result from suppuration arising in the genital apparatus. Morrissey's suggestion is, nevertheless, an interesting one, and the process described is anatomically possible. In the case reported below, an extended effort was made to demonstrate evidence of infection in the prostate and seminal vesicles, but without success.

Although it is true that the majority of cases reported have been in men, many have also been reported in women. In fact, the 5 cases reported by Bacon and Reuther¹² occurred in females. In the fifteen-year period from 1928 to 1942, a total of 82 cases in which a diagnosis of fistula in ano, perianal abscess or ischiorectal abscess was made were treated at the Framingham Union Hospital. Of these, 35 (43 per cent) occurred in females, a figure that certainly does not correspond to that suggested by Morrissey. It has been amply shown by Buie¹³ and others that this type of infection arises in the anal crypts.

Infection in the ischiorectal space may extend upward through the pelvic diaphragm to involve the supralevator region. Thompson and Dunphy¹⁴ have reported 3 such cases.

Other routes of infection of the supralevator spaces have been mentioned as possibilities but rarely if ever reported. These include cases resulting from caries or sepsis of the pelvic bones, from retroperitoneal sepsis arising from perforations in the gastrointestinal tract, particularly from appendicitis and diverticulitis, from infection arising in the female genital apparatus, especially postpartum or post-abortion endometritis, and so forth. Finally, infection may be carried directly to the supralevator space by the blood stream.

CLINICAL PICTURE

The clinical picture of supralevator abscess may be extremely confusing, particularly in the early stages. Usually the infection first manifests itself as a general malaise associated with more or less fever and leukocytosis. After a variable period—a few days to two months in the reported cases—during which constitutional symptoms become slowly or rapidly worse, the patient begins to note pelvic discomfort, frequently described as a swelling in or about the rectum. This discomfort is often temporarily relieved by defecation. Gradually symptoms of low-intestinal obstruction with increasing constipation often associated with intermittent diarrhea supervene. In men the inflammatory reaction frequently extends to, or compresses, the structures about the base of the bladder, causing urinary symptoms of varying severity (Fig. 1). Not infrequently acute urinary

retention is the presenting complaint, and this, associated with fever and leukocytosis, may point strongly to the urinary tract as the seat of the lesion. Eventually the symptoms of a deep-seated abscess with severe, localized pain, chills, fever and extreme leukocytosis present themselves.

The diagnosis is usually established by examination of the rectum by palpation, instrumentation or, preferably, both. In the early stages, tenderness may be elicited on palpation at a point slightly above the anal sphincters, usually limited to one side in a superior pelvirectal abscess and posteriorly in a retrorectal abscess, and possibly associated with some localized injection and edema of the rectal wall. Later, as it becomes well formed, the superior pelvirectal abscess tends to surround more or less completely the front and sides of the rectum, pushing in the walls so that a pronounced narrowing of the rectal ampulla is readily seen and felt, but this narrowing differs from that caused by neoplastic disease in that overlying mucosa is intact. Barium enema x-ray studies may be helpful in demonstrating the narrowing. At this stage the retrorectal abscess may push forward the posterior wall of the rectum and be palpable as a tender swelling extending upward for a variable distance. Extreme pain elicited on firm pressure over the skin between the tip of the coccyx and the anus is said to be an important diagnostic sign.¹⁵ In the later stages an abscess arising in one of the subdivisions of the supralelevator space tends to surround the rectum completely by penetrating the rectal stalks. In late and untreated cases, extension to the gluteal regions, groin and so forth may take place.

Urologic studies have not been frequently reported, even in those cases presenting evidence of obstruction of the bladder neck. Certainly careful palpation of the prostate and seminal vesicles should be done in an attempt to determine whether the infection is arising from these structures. Cystoscopic examination was made in the case presented below with essentially negative findings.

TREATMENT

As with suppuration in all other parts of the body, adequate incision and drainage is the only treatment. With reasonably early diagnosis and surgically adequate drainage, spread of the infection to the less accessible regions of the pelvis and sinus formation may be effectively prevented. Well-directed sulfonamide therapy may be a useful adjunct to adequate surgery in preventing such complications. In cases presenting evidence of low-bowel obstruction or extensive sinus formation, temporary sigmoidostomy may be of definite

value in putting the pelvic colon and rectum at physiologic rest.

The surgical approach to the superior pelvirectal space may be made by a longitudinal or T-shaped incision lateral to the anal sphincter. The fat of the ischioirectal space is traversed by sharp and blunt dissection until the levator ani muscle is identified by palpation. This muscle and its ensheathing fascia are divided in an anteroposterior direction, perpendicular to the direction of its fibers, and the superior pelvirectal space is entered. Transverse division of the levator fibers is evidently harmless and allows for better drainage than if the muscle bundles are merely separated. Should the abscess extend horseshoe-like around the front and side of the rectum, bilateral drainage through both ischioirectal spaces will allow through-and-through irrigation and improved drainage.

Drainage of the retrorectal space may be done by an incision parallel with and slightly lateral to the coccyx and lower sacral segments. The soft tissues are incised until the presacral pelvic fascia is identified. This structure is divided to allow entrance into the retrorectal space.

Hayden¹⁰ reports good results in several cases of superior pelvirectal abscess by instituting drainage through the rectal wall at the lower end of the abscess where it bulges into the rectum. Drainage is facilitated by inserting a 12-mm. rubber tube into the cavity and allowing it to protrude through the anus. Hayden warns against making incisions through both the rectal wall and the ischioirectal space and against incising the rectal wall after the abscess has extended into the ischioirectal space, since, in either case, there is danger of producing a high fistula.

CASE REPORT

A 61-year-old, Russian-born Jew was admitted to the Framingham Union Hospital on April 21, 1942. Ten days before admission, he noted malaise and cramping lower-abdominal pain, which he attributed to having swallowed a prune pit 2 days previously. These symptoms were not severe, and he continued working until the 4th day of his illness, when he began to develop headache, fever and generalized muscular aches and pains. A physician found rales at the bases of both lungs posteriorly and recorded a temperature of 103°F. A tentative diagnosis of pneumonia was made and the patient was given sulfathiazole, without improvement. The following day he noted difficulty in getting the urinary stream started and some burning on urination, and passed only small amounts of urine at a time. There was no incontinence, but the dysuria became progressively worse and this, together with fever, was the chief complaint. Twenty-four hours before admission, he suffered acute urinary retention for which catheterization was required. For the 4 or 5 days immediately preceding admission the bowels did not move in spite of repeated enemas, the abdomen became

moderately distended, and the patient complained of fullness in the rectum. There was no nausea or vomiting.

The past history included typhoid fever at the age of 21, a productive cough for many years, attributed by the patient to cigarette-smoking, and prolapsing hemorrhoids with occasional rectal bleeding for at least 20 years.

Physical examination revealed a poorly nourished man of small stature who appeared to be moderately acutely ill. The temperature was 101°F., the pulse 86, and the respirations 26. An adenoma about 1 cm. in diameter was palpable in the isthmus of the thyroid gland. The chest showed limited but equal excursion on both sides. At the lung bases, particularly the left, were numerous moist rales. The heart was not enlarged and the rhythm was regular, but there was a harsh systolic murmur over the aortic area. The blood pressure was 175/75. The abdomen was slightly distended and peristalsis was hyperactive, but there was no tenderness or other evidence of peritoneal irritation, and no masses could be felt. Rectal examination disclosed a firm, slightly irregular and practically nontender mass extending upward from the level of the upper border of the prostate as far as the examining finger could reach. The rectal mucosa overlying the mass was unbroken, as was demonstrated by repeated proctoscopic examination, and the mass caused a marked constriction of the rectal ampulla. This constriction was largely produced by displacement of the lateral walls of the rectum toward the midline, and to a lesser extent by posterior displacement of the anterior wall. The prostate was small and completely nontender, and the seminal vesicles could not be felt. The prostatic secretion was normal on microscopic examination. The posterior rectal wall did not appear to be involved. There was no tenderness over either ischioanal space. Proctoscopic examination, in addition to demonstrating the constriction, which would not allow the instrument to pass, showed some injection of the rectal mucosa. There was a rosette of internal and external hemorrhoids, but no evidence of recent sepsis or trauma to or around the mucocutaneous line. Cystoscopic examination revealed slight injection of the trigone but no other abnormalities of the bladder or prostate. The ureteral orifices were normal, but the ureters were not catheterized.

The white-cell count was 32,000, with 97 per cent neutrophils. There was no anemia, and blood-chemistry studies were within normal limits. X-ray examination (Fig. 2) demonstrated narrowing of the rectal ampulla, but the remainder of the colon showed no abnormalities. The chest showed evidence of chronic bronchitis. The bones of the lumbar spine and pelvis were within normal limits.

The patient was placed on constant urethral-catheter drainage and was given small doses of sulfathiazole by mouth. On this regimen the temperature and white cell count rapidly approached normal. During the early part of the hospitalization, enemas were productive of gas and feces, and the symptoms of obstruction suffered prior to admission were partially relieved. The palpable portion of the rectal mass remained unchanged, but after several days symptoms of low intestinal obstruction became more acute.

Because the symptoms of low colonic obstruction were associated with some increase in abdominal tenderness, laparotomy was performed on May 2. Exploration of the peritoneal cavity revealed no abnormalities except in the pelvis, where a mass that appeared to be inflammatory

in origin extended upward from the pelvis, surrounding the rectosigmoid and elevating the peritoneum of the pelvic floor. No evidence of diverticulitis was found. There was moderate distention of the entire colon. A long-loop sigmoidostomy was done.

Following the sigmoidostomy, the patient's condition improved. The temperature, pulse and white-cell count returned to normal and the rectal mass began to regress.

FIGURE 2 Barium Enema Showing Narrowing of the Rectal Ampulla.

A urethral catheter is in place.

On the 10th postoperative day, the urethral catheter was removed and the patient was able to void satisfactorily with no residual urine. Because of the striking local and general improvement, further surgery was delayed in the hope that complete regression would take place. By the 14th postoperative day, the mass was much smaller and the constriction of the rectal ampulla allowed the easy passage of two fingers. Thereafter there was no further regression, and on the 17th postoperative day softening of the mass was noted, particularly on the left side. On the following day, the supralevator space was opened by dividing the fibers of the left levator ani muscle, which was approached through the left ischioanal space. About 180 cc. of foul-smelling pus was evacuated from an abscess cavity that extended anteriorly to the opposite side of the rectum, but that did not extend posteriorly because of the rectal stalks, which were easily identified by palpation. The evacuated pus showed no growth on either aerobic or anaerobic culture.

Following drainage of the abscess, the patient did well and was discharged on the 8th postoperative day. At home the abscess was irrigated daily, but on June 21

he was readmitted to the hospital because the sinus tract leading to the abscess cavity had contracted sufficiently to prevent adequate drainage. Lipiodol injection of the abscess cavity at that time showed it to extend horseshoe-like around the front and sides of the rectum (Fig. 3).

FIGURE 3. *Lipiodol Injection of the Abscess Cavity One Month after the Institution of Drainage.*

More adequate drainage of the abscess was obtained, not only by enlarging the incision previously made on the left side of the anus, but also by making a second incision on the right side, with division of the fibers of the right levator ani muscle. This allowed satisfactory through-and-through irrigation and drainage and, except for a brief interval when a superficial abscess of the abdominal wall required drainage, improvement was progressive and satisfactory. The drainage wounds were kept open until the abscess cavity had closed with granulation tissue, after which the sinuses were allowed to close.

On August 8, the wounds were found to be completely healed. The perirectal mass had completely disappeared, but scar-tissue induration was still readily palpable. On January 4, 1943, 7 months after the abscess had been drained, this induration had completely disappeared and proctoscopic and x-ray studies revealed the rectal ampulla to be normal. The patient was therefore readmitted for closure of the colostomy, which was accomplished without incident. Since then he has enjoyed normal bowel and sphincteric function and has remained well.

DISCUSSION

This case presents several interesting features. The first is that an initial diagnosis of pneumonia

was made. This mistake has been frequently commented on in the literature, and is due to the late appearance of localizing symptoms. The patient had a chronic bronchitis with rales at both bases that were undoubtedly of long standing and were in no way related to the course of the present illness, but that when combined with symptoms of hidden sepsis pointed strongly to the chest as the source of the symptoms.

The second point of interest is the marked local and general improvement that followed sigmoidostomy. As has been stated, this operation was done because of the gradual progression of symptoms and the signs of low-intestinal obstruction. The rapid regression of the mass and the fall of the white-cell count and temperature to normal following the operation gave hope that the products of suppuration would resorb completely without recourse to further surgery. In view of the subsequent course of the disease, it appears that this hope was ill grounded. In cases presenting complicated sinus tracts, sigmoidostomy would undoubtedly prove a valuable preliminary step.

The frequency with which urinary symptoms are present, often as the chief complaint, has been previously commented on and is well illustrated by this case. Cystoscopic examination revealed no intrinsic cause for the obstruction of the bladder neck, which was probably due to extension of the inflammatory process to the structures about the base of the bladder or to pressure on these structures by the mass. Urinary symptoms have not been reported in cases occurring in females.

SUMMARY

The anatomy of the supralelevator space is reviewed, together with a résumé of current theories concerning the routes by which infection takes place. It seems logical to assume that such infection usually arises in the mucocutaneous line and is carried by lymphatic drainage to the supralelevator space.

The clinical picture of supralelevator abscess is essentially one of prolonged sepsis, associated with a perirectal mass and, eventually, with pelvic pain and low-intestinal obstruction. Male patients frequently present symptoms of obstruction of the bladder neck of greater or less severity. The diagnosis is not difficult if the condition is kept in mind.

Treatment consists in early diagnosis followed by adequate surgical drainage. Preliminary sigmoidostomy is occasionally indicated in cases seen late in the disease or in which fistulas are present.

A case successfully treated by surgery is reported.

THE INTRAVENOUS USE OF LANATOSIDE C*

JOSEPH H. NICHOLSON, M.D.†

LAWRENCE, MASSACHUSETTS

IT IS the purpose of this paper to discuss the parenteral use of digitalis glycosides, and to report on the intravenous use of a new glycoside of *Digitalis lanata*, Lanatoside C.

Certain questions regarding the intravenous use of digitalis frequently arise. The physician may ask the following: Is intravenous digitalis therapy necessary? Is it safe? Has it any advantages over other parenteral means of giving digitalis, such as the subcutaneous or intramuscular route? How does Lanatoside C given intravenously compare in action and safety with the other glycosides of digitalis?

It is generally agreed that the average case of cardiac decompensation can be treated effectively by the oral use of digitalis. There are, however, patients with cardiac decompensation with severe symptoms of failure produced both by rapid and irregular and by rapid and regular ventricular action who are often urgently in need of digitalis. Rapidity of action may predominate over all other considerations.

The customary method of full digitalization involves distribution of the drug in such a manner as to produce its full effect within two or three days. The usual method is to give it in divided doses. The average full dose is rarely recommended, for the reason that it is too large for sensitive patients and may result in toxic symptoms. Robinson¹ gave from 15 to 25 cat units of digitalis in a single dose to a series of 26 patients with auricular fibrillation and observed slowing of the heart rate in two to five hours, with the maximum effect in fifteen to twenty-four hours. Although he encountered no reaction in his series, he did not advocate the general use of his method. One and

a half grains of the powdered leaf of digitalis per ten pounds of body weight is a useful working guide, but there is a definite variation in its effect, some patients needing more and some less. It has also been shown that U.S.P. preparations of digitalis when assayed by the frog method vary by as much as 300 per cent.² It can thus be seen that a single dose based on weight carries much uncertainty and danger, even though it may be fairly rapid in action.

Furthermore, many patients with chronic passive congestion have nausea and vomiting and thus must be given digitalis by some other route than the oral one. Levy³ has been an advocate of the rectal route, but according to White⁴ the rectal administration of digitalis, either as a suppository or an enema, is unnecessary and unpleasant. It certainly is not a procedure that invites common usage.

The digitalis glycosides have been administered by the subcutaneous and the intramuscular route. Both are to be condemned. These glycosides when given subcutaneously are intensely irritating; they cause considerable soreness and induration and at times sloughing. Likewise, when given intramuscularly they cause soreness and induration. Clarke⁵ found that a 27 per cent larger dose of digitofolin was needed to produce toxic symptoms when given intramuscularly than when given intravenously. Moreover, the reliability of absorption by the former route in cardiac decompensation is highly uncertain. In addition, patients with cardiac decompensation who are unconscious require other methods of administration than the oral one.

Since there is definite indication for the intravenous use of digitalis glycosides it was decided to investigate a new one, Lanatoside C, to determine its rapidity of action and safety when given intravenously.

*From the Lawrence Municipal Hospital, Lawrence, Massachusetts

†Visiting physician, Lawrence Municipal Hospital (on leave of absence).

travenously, and in the light of these factors, to compare it with other preparations already investigated and in common use. The results are reported below.

In addition to *Digitalis purpurea*, another plant, *D. lanata*, yields digitalis glycosides. In recent years much work has been done on the latter species, and complete chemical elucidation of its products has been accomplished by Smith,⁶ Stoll^{7,8} and other workers.

D. lanata contains three glycosides, known as A, B and C. The A and B components, deprived of one glucose and acetyl radical by enzymatic action, are present in *D. purpurea* in the form of digitoxin and gitoxin. The C component (Lanatoside C) has no chemical relation with the glycosides of *D. purpurea*. Smith has shown that it differs from the genins of other glycosides derived from *D. lanata* and *purpurea* by the structure of its aglucone, digioxigenin. Stoll classified the relation between the two digitalis plants by isolation of all their cardioactive glycosides, together with the products of their enzymatic hydrolysis.

The initial pharmacologic analysis of Lanatoside C was carried out by Rothlin.^{9,10} Its toxicity for the cat and frog was established, and preliminary investigation of its cumulative properties and absorption from the gastrointestinal tract was made. It was found that Lanatoside C is well absorbed and that it has a marked cumulative effect on the heart of the frog and the cat, similar to that of digitoxin. Clinical interest in this substance began with the pharmacologic work of Moe and Visscher¹¹ on heart and lung preparations. Their study suggested that Lanatoside C is the least toxic and the most potent of the *D. lanata* glycosides. Essex, Herrick and Visscher¹² directed their interest toward the problem of the effect of these glycosides on the coronary blood flow and blood pressure of dogs. By inserting a *Thermotromuhr* into the coronary artery, they established that doses of Lanatoside C below the nausea-producing level had no effect on the coronary blood flow of trained dogs. The blood pressure showed no change following intravenous injections of the therapeutic dose.

Lanatoside C is a crystalline substance. Biologic assay is not necessary and its dosage may be determined gravimetrically rather than by the cat-unit method, once its therapeutic efficacy has been established. It is not subject to changes in potency, since it is a chemically pure substance containing no enzymes.

Lanatoside C (Cedilanid) was furnished* for these experiments in ampule form. Each cubic

centimeter of the solution contained 0.2 mg. of the drug. Fahr and La Due¹³ have determined that 8 cc. of the solution intravenously is the optimum digitalizing dose. This was the amount used in the cases reported below.

The slowing of the heart rate in auricular fibrillation as such patients come under the influence of digitalis is a simple and graphic method of observing the onset of the action of digitalis. In order, therefore, to test the efficacy of Lanatoside C, it was decided to study the heart-rate changes in 22 selected cases (Table 1). All these patients had

auricular fibrillation, and none, with one exception, had received digitalis in any form for at least one month. All the patients had original apical rates of at least 120 per minute, determined by stethoscope. Counts were made every five minutes for the first hour and hourly thereafter. The patients remained in bed for at least twelve hours before medication was given in 2 cases in which it was thought that withholding the drug might endanger life. The intravenous route was used in all cases. No other medication was used. Electrocardiograms were made in all cases, to rule out thrombosis of the coronary artery.

The average age of the patients was fifty-four years. There was no classification regarding the severity of decompensation. There were 6 cases of rheumatic heart disease with mitral stenosis and regurgitation, 2 cases of hypertensive heart disease and 14 cases of arteriosclerotic heart disease.

In all cases the heart rate, irrespective of its original level, dropped to 85 or below within twelve hours after receiving Lanatoside C. The average period of fall was three hours and fifty-four seconds. In 2 cases there was a rapid drop, in one

*By the Sandoz Chemical Works, Incorporated, New York City.

from 144 to 72 within fifteen minutes, and in the other from 136 to 71 within thirty minutes. There appeared to be no correlation between the rapidity of drop in the series as a whole and either the original rate or the degree of decompensation.

Figure 1 shows the reactions of apical rate during the first hour at fifteen-minute intervals and each hour thereafter in 4 cases. These are representative of the series. In all the cases there was a drop of 15 to 80 beats within fifteen minutes after

FIGURE 1.

giving the drug, with an average drop of 24 beats. All the patients felt better within half an hour after receiving the medication.

In no case were there any untoward reactions. One patient had been partially digitalized without my knowledge. He received the usual dose, after which he experienced nausea and mild vomiting for two days. Fahr and La Due¹³ gave full digitalizing doses (8 cc.) Lanatoside C intravenously to 4 patients who, unknown to them, had previously been completely digitalized. They developed only transient nausea. Hrenoff¹⁴ and Sokolow and Chamberlain¹⁵ also found no evidence of toxicity when the drug was given intravenously.

For comparison of Lanatoside C with the glycosides of *D. purpurea* regarding rapidity of action and safety following intravenous injection, the study by Pardee¹⁶ offers an acceptable basis. His work included the use of digalin, digifolin and digiton. He found definite slowing of the heart fifteen minutes after the drug was given, with a greater decrease in the next fifteen minutes. From

then on for two or three hours the rate became slightly lower, remaining at that level for twelve to twenty-four hours, with some increase after that time. The dosage was 1 minim per pound of body weight. Pardee advised, however, that the doses be given in fractional amounts rather than in single doses for fear of toxicity. Many of his patients had apical rates of between 90 and 110, which are much lower than any of those in this series. Although there was a fairly rapid drop within thirty minutes in his cases, no rate dropped below 80 in that period. In general, the rapidity of drop was not so marked as that observed with Lanatoside C. This is in accord with the findings of Sokolow and Chamberlain.¹⁵

SUMMARY

Intravenous digitalis therapy may be necessary when rapidity of action is desired and when the patient is unable to take medication by mouth, owing to nausea and vomiting or to unconsciousness. Lanatoside C (Cedilamid) given intravenously has a wide margin of safety, requires no fractional dosage, and is rapid in action. It appears to have a definite advantage over the glycosides of *D. purpurea*.

MEDICAL PROGRESS

TREATMENT OF SINUSITIS

ROBERT L. GOODALE, M.D.*

BOSTON

THE purpose of this report is to present certain points in the recent literature concerning the treatment of sinusitis that seem sufficiently important to emphasize, without attempting to catalogue all the papers on this subject. In common with a good many other medical problems, the treatment of the diseases of the paranasal sinuses is the object of a good deal of controversy. In an article by Bowers¹ entitled "Practical Points in the Diagnosis and Treatment of Sinusitis" many of these controversial points are mentioned. He notes the lack of agreement among laryngologists and urges that the following points be borne in mind:

Geographic location, since infections act very differently in different parts of the country.

The type of practice (institutional, clinic or private).

The reputation of the author. Is he mightier with the pen than with the scalpel? What is his technic in handling situations? For example, he may state flatly that inflation of the ear is of little value. Does he know how to inflate an ear? If he does, his statement is worth careful consideration; if not, it is worthless. The same thing holds true in all nasal treatment; the skill and dexterity of the operator play a great part in the success or failure of any given procedure.

The author's criterion of success and the measuring rod with which he approaches his work. Definitions vary; what one man calls chronic is not so regarded by another, and ideas as to what constitutes a cure differ widely.

ACUTE SINUSITIS

Practically all authors agree on a conservative approach to the problem of acute sinus infection. In the early stages, rest in bed, applications of heat and the mildest local application possible to obtain drainage are all that is necessary. Henley² advises rest, warmth, vasoconstrictors, vitamin C, chemotherapy, and avoidance of surgery in cases that are not complicated by orbital or intracranial extension. In selected acute cases he uses nasal irrigations consisting of a solution of ephedrine or Neo-synephrine. He also advocates bacterial antigens, foreign proteins and sulfonamide drugs. In cases in which there is inadequate drainage, after giving the above conservative methods a fair trial

he punctures and irrigates the antrum. He is not certain that short-wave and x-ray therapy are of value in the acute congestive stage. In fulminating infection with extension he advocates chemotherapy as an adjunct to surgical drainage. Wishart³ in considering sinusitis in children also advocates conservative treatment unless complications threaten.

As is generally known, the treatment of acute cases has become much more conservative than formerly. Most sinuses subside in the early stages under simple nonsurgical treatment. The treatment of an acute sinus that is not draining presents another problem. If it does not drain, a reaction takes place in the lining membrane and in the surrounding bony wall. The disease passes from the acute to the chronic stage, and so long as acute infection exists there is danger of an orbital complication, osteomyelitis of the frontal bone or extension into the meninges. In the case of an acute nondraining maxillary sinus, a puncture through the lower meatus or irrigation through the natural ostium is indicated. From a study of the anatomy of the natural ostium Bowers¹ concludes that irrigation of the antrum by this route is neither impracticable nor impossible. He thinks that the antrums are retainers of nasal infection and form the keystone to most nasal pathology. In the case of the frontal and ethmoid sinuses the question of technic arises. In general, intranasal operations in acute ethmoiditis and frontal sinusitis are frowned on. Certainly where there is evidence of extension into the orbit the intranasal approach seems illogical. With more familiarity regarding the external approach and a greater knowledge of the cause of failure in frontoethmoidal surgery, much more satisfactory results are being obtained.

There are some exceptions to the above statement. Brown⁴ believes that in children frontal sinusitis calls for intranasal ethmoidectomy, and adds that there should be no interference with the nasofrontal duct. Snow⁵ discusses orbital complications in simple disease, and concludes that early operation and an external approach are necessary.

Boies⁶ brings up again the question of a simple trephining operation for drainage of the frontal sinus in selected cases. These patients suffer from an empyema of the frontal sinus, and drainage under conservative care seems inadequate. Inas-

The articles in the medical progress series of 1941 have been published in book form (*Medical Progress Annual*, Volume III, 678 pp. Springfield, Illinois: Charles C Thomas, 1942. \$5 00).

*Instructor in laryngology, Harvard Medical School, associate surgeon, Massachusetts Eye and Ear Infirmary.

much as in these cases trauma may cause osteomyelitic complications, it is extremely important to obtain drainage. Boies advocates a simple trephination through the floor of the sinus early in the course of the disease.

CHRONIC SINUSITIS

In chronic sinusitis changes have already taken place in the mucous membrane of the sinus and to some extent in the surrounding bony wall, so that the disease perpetuates itself. The primary factor may be poor nasal drainage during the acute stage or repeated nasal infections that in the course of time have left their mark. Some writers consider other causes, such as dietary disturbances, endocrine imbalance and allergy.

Smith⁷ discusses the management of the nose and the paranasal sinuses in asthma, and advocates treatment by the allergist and the internist before local measures are undertaken. The allergist's study must be thorough to be effective, and requires the co-operation of the rhinologist, especially in children. Smith advises against surgery until the allergy factor is controlled, and even then favors conservative surgery.

Solis-Cohen⁸ discusses the use of specific vaccines in the treatment of chronic sinusitis, but he discourages their use for the prophylactic treatment of acute exacerbations of chronic latent sinusitis, pointing out that severe and harmful reactions may ensue should the organism be the same as that present in the sinus. He first injects intracutaneously in the forearm four test doses. One consists of 0.05 cc. of plain broth, and the other three, 0.05 cc. of the broth culture so diluted that the first contains 1,000,000 to 50,000,000 organisms, the next a tenth to a thousandth of this number, and the last a tenth to a thousandth of the second dose. The smallest amount that gives a slight local reaction is injected therapeutically. Each subsequent dose is regulated in accordance with the general and local reactions produced by the preceding one. A dose is given every five days. Solis-Cohen points out that vaccine therapy may be of no benefit to patients with chronic sinusitis when there is suppuration in a sinus that is not draining or when the sinusitis is secondary to an untreated primary focus of infection, such as diseased tonsils.

In considering surgery for chronic sinusitis, the general picture must certainly be considered. An effort should be made to determine whether the sinusitis is the sole disease from which the patient is suffering, or is part of a more complicated picture, such as sinobronchiectasis or sinusitis and bronchial asthma, or focal evidence of infection in other parts of the body.

In an article by Harper,⁹ certain general symptoms are given greater emphasis than heretofore. These are fatigability and mental depression. Fatigability is especially important in aviation medicine. Bullwinkle¹⁰ mentions sinusitis as a cause of fatigue. It has long been known that the average patient with even a moderate degree of chronic sinusitis feels below par and finds it difficult to keep up in his work, which, for an aviator, may be fatal. The same author in discussing nasal accessory sinusitis in aviation medicine states that patients in whom chronic maxillary sinusitis has been treated by the so-called "radical antrum" or Caldwell-Luc operation may be accepted for service, but those who have had a radical frontal or ethmoid operation are dangerous risks. Harper⁹ advocates the Caldwell-Luc operation for chronic maxillary sinusitis, and points out that there is a marked improvement in well-being following this operation, especially in children. In cases of ethmoiditis he approaches the ethmoid sinus through the antrum by the transantral route. In discussing failure in radical surgery, he points out that inefficient treatment is the most frequent cause. Residual bony infection may likewise result in a recurrence of sinusitis. Chronic infection of the sinus alone is comparatively rare. In cases of multiple sinus infection the key to the situation is the ethmoid sinus. This is especially true in frontal sinusitis. In a study of failure in frontal-sinus surgery, I¹¹ found that incomplete ethmoidectomy, as well as failure to remove the frontal-sinus floor completely, was a common cause of reinfection. When one considers the anatomic relations of the ethmoid labyrinth, especially noting the orbital extensions of the ethmoid, the importance of this sinus becomes apparent.

Bowers¹ evaluates certain standard operations. He recommends the Caldwell-Luc operation when there are marked constitutional or tracheobronchial symptoms together with pronounced roentgenographic evidence of disease. The technical steps that he emphasizes are as follows:

- Remove every vestige of membrane.
- Make as large an opening as possible into the inferior meatus.
- If necessary remove a portion of the inferior turbinate to ensure that the opening is not blocked by the turbinate.
- Remove the ethmoid cells through the antrum if they are diseased.
- Pack the opening into the inferior meatus with gauze, but do not pack the antrum.
- Remove the gauze by degrees during the next five days, thus producing some bleeding and thereby adding to the clot in the antrum.

Do not irrigate; use dry agents only in aftertreatment. Dust sulfanilamide powder into the nose and antrum cavity.

At the Massachusetts Eye and Ear Infirmary great care is insisted on to avoid injury to the inferior turbinate, and removal of a portion of it is considered inadvisable. The advantage of a postoperative clot is not clear. Sulfanilamide powder is of great advantage at the time of operation when dusted into the denuded bony cavity. Bowers¹ speaks of the replacement of the mucous membrane lining by a fibrous tissue that may obliterate the antral cavity. Birdsall,¹² in an article discussing the treatment of sinusitis in recruits, points out that postoperatively the antrum shows a thickening due to this formation of fibrous tissue. He cautions that x-ray evidence in operative cases is not a criterion for evaluating the status of the sinusitis in a recruit. The only sign of cure, according to him, is the relief of symptoms.

Patterson¹³ discusses external operation on the nasal sinuses. In considering the surgical approach to the frontal and sphenoid sinuses he emphasizes the importance of the ethmoid labyrinth. The frontal sinus, he states, should always be explored through its inferior wall, the extent of the operation depends on the severity of the disease and the anatomic and pathologic conditions found after the sinus has been opened.

This brings up the question of the type of operation to be performed. There are three classic operations: the Lynch frontal sinus operation, consisting of the removal of the entire floor of the frontal sinus, together with its lining, and complete ethmoidectomy and exploration of the sphenoid sinus if it is involved; the Killian operation, in which the supraorbital bridge is preserved with its periosteum intact; and the obliterative operation, in which the floor, the anterior wall, the entire mucous-membrane lining and often the posterior wall of the frontal sinus are removed.

Patterson¹³ in discussing the obliterative operation advocates the removal of the anterior and inferior wall, together with all the mucous membrane covering the posterior wall. From the experience at the Massachusetts Eye and Ear Infirmary this removal of the mucous membrane is considered essential, since the overlooking of even a small area of mucous membrane inevitably leads to the formation of a mucocele.

Peele and LeJeune¹⁴ mention a direct method for irrigation of the sphenoid sinus by injection with an opaque medium. They discuss the symptoms of sphenoiditis, which are worth mentioning here. In an epidemic of influenza in New Orleans in March, 1940, there was a high incidence of

debility due to sphenoiditis. The symptoms noted among these patients were as follows: headaches radiating from the eyes to the occiput and down the back of the neck and occasionally to the mastoid process; nasal discharge and obstruction; anosmia; aural symptoms due to disturbances of the Eustachian tube by postnatal discharge; blurred vision, photophobia and repeated changes in refraction; retrobulbar neuritis; and changes in mental attitude, believed by the writers to be constant and characteristic in chronic cases, and involving depression, memory defect and irritability. A great many of the patients with mental symptoms were labeled "neurotics," and the diagnosis was occasionally confused with brain tumor. Peele and LeJeune advocate irrigation and, in the cases that cannot be cleared up by this method, operation.

In studying injuries of the frontal and ethmoid sinuses, Calvert and Cairns¹⁵ analyzed 128 cases of traumatic injury to the frontal and ethmoidal sinuses. These cases are interesting from an etiologic standpoint, since they arose from war conditions in Great Britain. Some of the injuries were received in traffic accidents during blackouts, and others were a direct result of bombing. The chief causes are listed as follows: motorcycle accidents (44 per cent), motorcar collisions (19 per cent), being struck by motorcars (9 per cent), bombing, machine-gunning and so forth (8 per cent) and airplane accidents (6 per cent). Seventy per cent of the injuries consisted in compound fracture into the nose or through the skin. In 35 per cent of the series there was anosmia. Twenty-one patients had cerebrospinal rhinorrhea. Of these, 11 were treated conservatively, with 7 recoveries, and 10 were operated on, with 9 recoveries. Nine patients had arocele. Of these, 3 were treated with a dural graft and recovered. Six were treated conservatively, with 4 uncomplicated recoveries. One patient died from meningitis and 1 recovered from it.

In discussing the operative procedure, this author states that if the patient is in good condition, the dural tear should be repaired immediately. If he is in poor condition he should be treated for shock and given chemotherapy and the wound should be cleaned of dirt and debris under local anesthesia. In gross fractures radical removal of the walls of the sinuses should be done. Calvert and Cairns point out, however, that infection of the sinuses was infrequent in these cases.

CASE 29411

PRESENTATION OF CASE

First admission. A thirty-four-year-old housewife entered the hospital because of fainting spells and smothering sensations.

Thirteen months before admission the patient caught a cold, which was followed by a persistent cough, wheezing and a smothering sensation in the chest. The wheezing was inconstant and improved considerably after she got rid of her dog; the smothering sensation, however, persisted so that at times she had to rush to the window for fresh air. She developed extreme nervousness and emotional lability. The cough continued, and three months before admission she noticed that she sweat freely, especially at night. There was no fever or hemoptysis, but she had lost 50 pounds in three months.

At the age of thirteen, she bore an illegitimate son, the father being her brother-in-law. A second pregnancy terminated in an abortion. At seventeen she was operated on for "pus tubes." At eighteen she tripped while dancing and fell, injuring her back and fracturing her coccyx, for which she was hospitalized a year. At twenty-two, while unhappily married, she developed attacks of unconsciousness, which had continued to date. The attacks were preceded by a sensation of falling through space; they lasted from two to five minutes and were followed by a "low feeling."

The patient's father died of Miner's asthma and "leaking valve," and her mother of a "stroke."

Physical examination showed a well-developed and well-nourished plump woman lying quietly in bed. The lungs were clear. The heart size was not made out. A short blowing systolic murmur was heard in the third interspace to the left of the sternum. The abdominal and pelvic examinations were essentially normal. The reflexes were hyperactive. The pupils were regular, equal and contracted, even in the dark; they reacted to light and accommodation.

The blood pressure was 138 systolic, 88 diastolic. The pulse was 90, and the temperature and respirations normal.

*On leave of absence

The red-cell count was 4,640,000, with a hemoglobin of 15 gm., and the white-cell count 17,700, with 70 per cent neutrophils. The urine and stools were normal. A blood Hinton test was negative. The cerebrospinal fluid was normal and gave a negative Wassermann reaction. The blood bromide was normal, and all skin scratch tests were negative.

Shortly after finishing the physical examination, following an uneventful trip to the bathroom, she was found unconscious in bed with the eyelids fluttering and the pupils still contracted, although they reacted to light. All attempts to rouse her were unsuccessful. Her pulse and blood pressure were not affected. There were no tonic or clonic movements and no spasticity or changes of reflexes. No effect of carotid pressure on the heart rate could be demonstrated. She gradually regained consciousness, complaining of feeling poorly and of a sensation of falling through space. On the following day she vomited frequently and had two "spells." There were rapid mood changes from hilarity to extreme depression.

A roentgenogram of the chest revealed enlargement of the heart to both sides in the region of the ventricles and auricles. The pulsations were normal. The hilar vessels were surprisingly normal. A gastrointestinal series showed markedly thickened gastric rugae and extensive pyloric spasm but was otherwise normal. An electroencephalogram was within normal limits.

She was placed on Dilantin, 0.1 gm. three times a day, and phenobarbital, ¼ gr. four times a day, following which the attacks stopped. The patient was discharged on the thirteenth hospital day with a diagnosis of epilepsy.

Final admission (thirteen months later). The patient re-entered the hospital because of dyspnea. Her condition had remained about the same but dyspnea had progressively increased, especially after periods of increased activity. Six months before entry she was seen by her physician, who found considerable cardiac enlargement and an enlarged liver. There was no edema. An electrocardiogram revealed normal SR waves. The PR interval was 0.20 second, and the QS interval 0.14 second; the P waves were unusually broad; the QRS complex was slurred in all leads; T₁ and T₂ were inverted; there was evidence of left bundle-branch block. The patient was given digitalis, but owing to signs of toxicity the dose was finally established at 1.5 gr. five times a week. She was placed on a reducing diet and lost 20 pounds in six months. Five months before entry she coughed up slightly blood-streaked sputum, and once a definite presystolic murmur was heard. One month before admission she began to notice abdominal

swelling and pain in the right lower quadrant. Five days before admission she caught "cold" and developed anterior and posterior pleural pain on the right, which subsequently disappeared. There were no chills or fever. For several months she

The temperature was 97°F., the pulse was 80, and the respirations 20.

The white-cell count was 13,200, and the hemoglobin 14.3 gm. The urine showed a + test for albumin and many bacteria. The vital capacity

FIGURE 1 *Roentgenogram of Chest.*

felt food stick in the esophagus at about the level of the third rib.

Physical examination showed essentially the findings recorded at the time of the previous admission, with the following additions. She was dyspneic, even while sitting. The heart was 4 cm. to the right of the midsternal line and 3.5 cm. outside the left midclavicular line. The sounds were of good quality but distant at the apex. The mitral first sound was not snapping, and the pulmonic second sound was greater than the aortic. The lungs were clear except for a few moist inspiratory rales at the right base. The liver dullness extended from the fourth rib to 7.5 cm. below the costal margin in the right anterior axillary line; it was 9 cm. below the right costal margin in the midclavicular line, 10 cm. below the xiphoid, and 11 cm. below the left costal margin.

The blood pressure was 140 systolic, 68 diastolic.

was 1000 cc. (33 per cent of normal). An electrocardiogram showed normal rhythm, with a rate of 80; the QRS complexes in Leads 1, 2 and 3 were wide; T₁ was inverted, and T₂ and T₃ upright. The sedimentation rate was normal. The prothrombin time was 28 seconds (normal, 17 seconds). The hematocrit was 53 per cent. The nonprotein nitrogen was 16 mg. per 100 cc., and the cholesterol 170 mg.

A roentgenogram of the chest revealed marked enlargement of the heart since the first admission (Fig. 1). The enlargement was diffuse. The pulsations were small and rapid. There was enlargement of what was probably the right ventricle. There was a shadow in the left oblique view that could be interpreted as an infarct in the region of the second interspace anteriorly. The diaphragm was low on both sides but showed normal respiratory motion, and there was a small amount of

fluid in the right costophrenic angle. The left main bronchus was elevated. Fluoroscopy was unsatisfactory.

The day after admission, when on the way back from the X-ray Department, she had an attack of unconsciousness similar to those already described. On the evening of the second hospital day, she complained of a sore right shoulder, and on the following morning she began to have pleural pain at the right base anteriorly and posteriorly. She developed a cough productive of bright-red, blood-streaked, mucoid sputum. There was dullness at the right base posteriorly, with suppressed breath sounds and fine rales. Similar rales and a suggestion of a pleural friction rub were heard anteriorly. The lower extremities were not edematous or tender. Fluoroscopy following this attack showed an area of density in the apex of the middle lobe and a small amount of fluid in the right pleural cavity. There were linear areas of density in the left midlung. For the next two days she complained of nausea and vomiting and severe hypogastric pain, which was finally relieved by a copious, light-brown, nonbloody, unformed bowel movement. On the third hospital day she was given 8500 units of heparin intravenously and 300 mg. of dicoumarin by mouth, followed by 10,000 units of heparin and 200 mg. of dicoumarin the next day and 2000 units of heparin the third day. On the same day a blood Hinton test was reported negative but the Wassermann reaction was positive. Two repeated Hinton examinations were positive.

On the fifth hospital day the patient's legs were carefully examined for a possible source of pulmonary emboli. Slight pain was elicited on dorsiflexion of the right foot but no swelling or cyanosis was present. On the following day, during the intravenous injection of heparin, she became unconscious for three minutes, at which time she was completely flaccid and moderately cyanotic without any convulsions. The pulse was slow and strong.

For the next five days she had repeated attacks of pleural pain on one or the other side, with rales and dullness, cough and bloody sputum. The prothrombin time on the eleventh day was 87 seconds (normal, 17 seconds) and the hematocrit was 62 per cent. On the ninth and tenth hospital days she had several attacks of unconsciousness lasting four or five minutes each, similar to those seen previously. The chest pain continued without much change. Bloody sputum and a friction rub were inconstant, but rales and decreased breath sounds persisted over the bases.

On the thirteenth hospital day, eleven days after a menstrual period, she had vaginal bleeding, at

first slight but then profuse. This persisted for three days. On the same day she developed severe pain in the right anterior chest, with cough and bloody sputum. The prothrombin time was 98 seconds (normal, 17 seconds), and the hematocrit 54 per cent. She was placed on potassium iodide, 20 drops daily. During the next twenty-one days she had two other attacks of pain in the left chest, as well as epigastric pain, with cough and bloody sputum. She also had four or five attacks of unconsciousness similar to those previously described. The prothrombin time had decreased to 31 seconds, and the hematocrit was 55 per cent.

During her entire illness the blood pressure remained about 150 systolic, 75 diastolic, the pulse about 90, the respirations 25, and the temperature between 99 and 100°F. The urine usually showed a ++ test for albumin and some red and white cells. She received dicoumarin and heparin almost daily, as well as eight injections of Mercupurin and thirteen doses of digitalis, 1.5 gr., over twenty days.

On the twenty-first hospital day the patient was found dead.

DIFFERENTIAL DIAGNOSIS

DR. EARLE M. CHAPMAN: The first paragraph of the history seems to indicate that the patient had pulmonary disease. Anything that leads to night sweats and a 50-pound weight loss should be considered a rather serious illness. The cough and wheezing that improved by getting rid of her dog make one think that this was an asthmatic episode. I do not know that we should call it asthma, however.

The past history offers tremendous psychiatric possibilities. One could talk on that for the rest of the hour, but I am going to skip over it and say that such events are apt to lead to any complication, especially asthmal. The fainting attacks were not psychiatric manifestations but were quite classic for epilepsy. She had an aura, and then a depressed feeling after the attack.

The patient is described as being plump after losing 50 pounds, so that she must have been obese at one time. I take it that the pupils were small even in the dark. I should like to know the size of the pupils. Of course, Argyll-Robertson pupils are small, being under 2 mm. in diameter.

DR. BENJAMIN CASTLEMAN: They measured 3 mm.

DR. CHAPMAN: They were not small enough for Argyll-Robertson pupils.

I wonder if ineffectual straining at stool had anything to do with the attack of unconsciousness that occurred at the time of the first admission.

I am not aware that people with epilepsy are precipitated into an attack by straining at stool, but the point is raised.

The fact that the pulse and blood pressure were not affected during these attacks is important and leads me to believe that she did not have a carotid-sinus syndrome, Adams-Stokes's disease or some other sort of cardiac arrhythmia that was responsible for the unconscious spells.

After having entertained the suggestion that these attacks were epileptiform, I am surprised to find that the electroencephalogram was normal. This does not help us to establish a diagnosis, but I am sure that one can have epilepsy without a positive electroencephalogram.

The electrocardiogram indicates rather severe myocardial injury and suggests the possibility that this person had had coronary occlusion with myocardial infarction of the anterior wall. One thinks of damage to the myocardium by infection, but there is nothing in the history to indicate this.

The presystolic murmur must be accepted for a fact. It is here in print, and it is an important observation. I presume it was heard at the apex.

I interpret the blood spitting five months before entry as the first sign of pulmonary infarction. The abdominal swelling and pain suggest congestion of the liver, edema and beginning heart failure. The dysphagia is a surprising symptom. There was atypical, generalized enlargement of the heart to both sides. Apparently no murmur was heard later on. The pulmonic second sound was greater than the aortic, which, at thirty-four, is abnormal. The other signs lead one to believe that the patient had congestion in the pulmonary circuit. I assume that there was no aortic regurgitation, since no diastolic murmurs are mentioned and the diastolic pressure was 68.

The elevation of the left main bronchus is a significant observation. On consultation with my friends in the X-ray Department they assured me that the only thing that leads to that is enlargement of the left auricle, which we know was present here. Apparently the right auricle seldom, if ever, leads to elevation of the bronchus. The enlargement of the left auricle fits in with the dysphagia, since impingement on the esophagus would probably lead to difficulty in swallowing at that level.

From the story of the attacks of pain and treatment it seems likely that the patient was suffering from some type of intravascular thrombosis. It does not disclose the source, and we have not enough evidence to say definitely. It is interesting that the first Hinton test was negative and a later one was positive.

"Slight pain was elicited on dorsiflexion of the right foot but no swelling or cyanosis was present." I think they are telling us that the Homans's sign was positive—just a little, possibly, but positive nevertheless.

"For the next five days she had repeated attacks of pleural pain on one or the other side, with rales and dullness, cough and bloody sputum." She apparently was having showers of pulmonary infarcts.

Reconstruction of this case is difficult, to put it mildly. The patient seems to have had epilepsy of twelve years' duration, and under the standard treatment for that disease the attacks cleared up and she was much better. The epileptic attacks seem to have been separate from the other disease, which was chiefly pulmonary. She had asthmatic-like symptoms, with a cough, for thirteen months; then five months before the last entry she had an episode of what sounds like pulmonary infarction, and one month before entry the onset of congestive heart failure. The strange thing is that apparently she developed a positive Hinton test between the two admissions, so that sometime in the thirteen months before the last entry she must have acquired syphilis or one of the reports was a laboratory error. One wonders if changes in the blood serum, owing to some intravascular process, which she obviously had, could have caused a change in the proteins of the blood that would have resulted in this positive reaction. We know that several things cause false positive tests, such as serum sickness and recent vaccination.

As I have said, the problem here is, if possible, to decide what type of heart disease this patient suffered from and what was the mechanism of the failure that led to an afebrile condition with showers of pulmonary infarcts. Against subacute bacterial endocarditis are two facts—the patient had no fever and the hemoglobin was 14 gm. With prolonged endocarditis a fever and significant anemia are almost the rule. The results of blood cultures are not mentioned.

DR. CASTLEMAN: They were not done.

DR. CHAPMAN: It seems that there was a thrombosis in the vascular system, and we have some evidence for believing that it was in the veins, because of the positive Homans's sign.

DR. LAURENCE L. ROBBINS: The films show diffuse enlargement of the heart, but I do not believe that I can help in localizing the type of lesion. The enlarged right ventricle is this shadow on the oblique film. The small shadow in the second interspace is consistent with an infarct. There is relatively little elevation of the left main bronchus.

DR. CHAPMAN: With this evidence it is diffi-

cult to make what would be an easy diagnosis—rheumatic heart disease with mitral stenosis. In support of this we have the following facts: the typical sort of cardiac enlargement, a presystolic murmur, a loud pulmonic second sound and changes in the electrocardiogram that indicate myocardial damage. There is nothing in the history that suggests rheumatic infection, and that makes the diagnosis unlikely to me.

Did she have congenital heart disease, with pulmonary-valve disease, pulmonary stenosis or an interauricular septal defect producing changes in the electrocardiogram? The murmur described was in the third left interspace, and it was the only murmur described while she was in the hospital. Blood cultures should certainly have been taken. There is a possibility that the gonococcus was involved, which frequently attacks the pulmonary valve.

The third thing to consider is coronary heart disease with infarction of the anterior wall which the electrocardiogram indicates. I cannot possibly make this diagnosis on clinical grounds.

The fourth choice is syphilitic heart disease. She had a rather stormy sexual history, with certainly one venereal infection and perhaps another.

This woman must have had a thrombus somewhere in the venous system or in the right heart. I do not believe, however, that she had thrombosis in the veins of the leg. She had no edema, and no symptoms pointing to the pelvic veins or the deep leg veins as being the cause of the emboli to the lungs. So I am going to assume that they arose in the chambers of the right heart, probably the ventricle but possibly the **auricle**.

Of these four types of heart disease I do not see how one can make a definite diagnosis on the evidence at hand. Syphilis rarely attacks the right side of the heart and certainly there was no sign that the patient had aortic disease or aortic regurgitation, which is the usual pathologic change in syphilitic heart disease. Therefore, I must fall back on some other type, and the commonest of these is rheumatic heart disease. Dr. Robbins told me that elevation of the left main bronchus is seldom, if ever, seen with right-heart enlargement, such as one would have with pulmonary stenosis: Sosman's article¹ establishes this quite clearly. Hence, my final diagnosis is rheumatic heart disease, with mitral stenosis, possibly pulmonary stenosis and certainly thrombosis on the right side of the heart.

DR. CONGER WILLIAMS: The first time we saw the patient on the last admission she had not had a positive Hinton test. Since she had cardiac enlargement without any murmurs and, so as far as

we could tell, without a previous etiologic factor, we considered the possibility of Fiedler's myocarditis,² which gives a picture much like this and sometimes lasts as long as one and a half years. The repeated episodes of pulmonary embolism, which are caused by mural thrombi in the right heart that break off and go to the lung, are consistent with Fiedler's myocarditis. It was possible that she had had syphilis for twenty years. She was first exposed at thirteen. We had no evidence for aortic disease and were never able to hear a diastolic murmur. When the Wassermann test was reported positive, we considered an even more improbable diagnosis,—diffuse syphilitic myocarditis,—and we had to leave it at that and await the autopsy findings.

CLINICAL DIAGNOSES

Fiedler's myocarditis?
Diffuse syphilitic myocarditis?
Multiple pulmonary infarcts

DR. CHAPMAN'S DIAGNOSES

Epilepsy.
Asthma.
Pulmonary infarcts.
Rheumatic heart disease, with mitral stenosis and thrombosis in right side of heart and possibly pulmonary stenosis.

ANATOMICAL DIAGNOSES

Syphilitic aortitis, with involvement of aortic valve and mouths of coronary arteries.
Occlusion of left coronary orifice.
Myocardial fibrosis.
Myocardial infarct, healed.
Cardiac hypertrophy.
Pulmonary infarcts, multiple.
Chronic passive congestion of lungs and liver.
Central necrosis of liver.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The heart was symmetrically enlarged and weighed 610 gm. The entire aorta, but more marked in the ascending aorta and arch, showed the characteristic appearance of syphilitic aortitis. There were raised pearly-gray areas in the intima, such as one seen in the more recent type of syphilitic aortitis, surrounded by the chronic, more usual type of stellate scarring and linear "tree-barking." This was confirmed microscopically by the finding of marked elastic-tissue destruction in the media and lymphocytic infiltration around the vasa vasorum. The mouth of the left coronary artery was completely occluded, and that

of the right markedly constricted. The commissure between two of the cusps showed definite separation, indicating that syphilis had involved the aorta in the sinuses of Valsalva. There must have been some regurgitation, and I cannot understand why a diastolic murmur was not heard. Further evidence that there was regurgitation was the definite flattening of the trabeculae carneae of the left ventricle. There were numerous small grayish-white scars throughout the myocardium, and on the anterior wall a larger healed infarct on which an old organized thrombus was still present. Since the main left coronary ostia was completely occluded, the heart was being supplied by the right coronary artery, which was capacious and had formed a good collateral circulation with the left.

Numerous microscopic sections taken throughout the myocardium showed focal areas of scarring of the type not infrequently seen in a patient with coronary disease. There were no areas of lymphocytic, monocytic or plasma-cell infiltration to suggest a syphilitic myocarditis.

I have to interpret the case as being one of primary syphilitic aortitis with so much involvement of the ostia of the coronary arteries that the resultant anoxia had produced focal scarring of the myocardium. One might possibly think of a burned-out syphilitic myocarditis, but with the ostia of the left coronary completely occluded and the right somewhat narrowed there is sufficient reason for the myocardial fibrosis.

The lungs showed numerous infarcts of various ages. There was no source on the right side of the heart, and I believe that it was in the deep veins of the leg. The liver showed marked central necrosis and evidence of congestive heart failure.

DR. JACOB LERMAN: Was there anything in the brain?

DR. CASTLEMAN: We did not have permission to examine the brain.

CASE 29412

PRESENTATION OF CASE

A twenty-six-year-old man entered the hospital complaining of pain and stiffness in the back of three months' duration.

The patient stated that he was born with an open spina bifida but that it had closed over. Soon after birth, his mother noted a thin-walled sac over the lumbar region posteriorly. This was treated with alcohol sponges and it shriveled up soon after.

When the patient was fourteen months old, x-ray examination of the lumbar spine and pelvis showed no bony abnormality and there was no positive evidence of spina bifida.

The patient was reasonably well until three months before entry when, while playing golf, he

FIGURE 1. Roentgenogram of Lower Spine.

noticed some stiffness in the midlumbar region. The following day each time he drove a golf ball he felt what he termed a "pull" in the region of the left sacroiliac joint. A constant cramp-like pain was noted in the same region and this continued until admission. Within a week of the onset of this pain he noted that, when rolling over in bed or when suddenly getting up, he felt a sudden "flash of pain" radiating to the left sacroiliac region. An osteopath treated him with prostatic massage and hot enemas; within two or three weeks the flashes of pain disappeared, but the constant pain grew progressively worse. Four weeks before admission, while he was taken to his commu-

y hospital by ambulance, he felt something hard pressing into his back. That evening all the toes of both feet began to feel numb, and within four or five days the numbness had spread to include

FIGURE 2. Roentgenogram of Lumbar Spine following Injection of Lipiodol.

all of both feet. Three weeks before entry he noted that his legs were somewhat shaky and weak, and a few days later he was not able to control his legs as well as he had formerly. At about this time he noted numbness over the knees, and rotating his head or pressing upon something with his feet always led to lumbar discomfort. On two or three occasions during the two weeks before entry, when excited, he became incontinent of urine and once, while laughing, incontinent of feces. His legs gradually became weaker, and he entered the hospital for therapy.

Physical examination showed a well-developed and well-nourished man with an old spina-bifida scar and surrounding hair growth in the midlumbar region. Both legs were markedly weak. There was hypesthesia of both legs, the posterior

aspect of the right thigh, the posterior aspect of the lower half of the left thigh and the medial aspect of each buttock, as well as over the sacrum and lower lumbar region. The left biceps reflex was greater than the right, and the right knee jerk greater than the left; there were bilateral ankle clonus and Babinski signs, more marked on the right. The lower abdominal and cremasteric reflexes were absent.

The temperature, pulse and respirations were normal.

Examination of the urine was negative. The blood showed a white-cell count of 6500, with 69 per cent neutrophils.

X-ray examination of the spine and pelvis showed marked widening of the neural canal throughout the lumbar region (Fig. 1). The intervertebral disk was absent between the second and third lumbar vertebrae, and these two bodies were in contact with one another. There was no actual fusion or deformity of the bodies. An anatomical variation was present at the lumbosacral region — namely, a partially fused vertebra with large transverse processes. Although the canal was greatly widened, there was no erosion of the lateral masses, and no unusual soft-tissue shadow. There was no interference with the natural curves of the spine. Three cubic centimeters of lipiodol introduced into the spinal canal at the twelfth thoracic interspace showed complete obstruction about 1 cm. below the needle, with a cap formation (Fig. 2). No obstruction was met to the cephalad flow of lipiodol up to the seventh thoracic interspace. A blood Hinton test was negative. A lumbar puncture was negative, the total protein being 26 mg. per 100 cc.

An operation was performed on the seventh hospital day.

DIFFERENTIAL DIAGNOSIS

DR. JOST MICHELSEN: It is obvious that this patient had a space-occupying intraspinal lesion opposite the first lumbar vertebra. The lipiodol injection at the twelfth thoracic interspace showed complete obstruction about 1 cm. below the needle, with a typical cap formation. Two questions remain to be answered. What type of tumor was found at operation? Did it occupy the extradural or intradural space, or both?

We are told that the spinal canal was greatly widened throughout the lumbar region without erosion of the lateral masses. The combination of such bony changes and cord compression has been described as a characteristic syndrome in extradural cysts.¹ These cysts supposedly develop from a congenital diverticulum of the dura mater

or a herniation of arachnoid through a congenital defect in the dura. The fact that this patient had other congenital abnormalities, which I shall discuss later in more detail, is also in favor of an extradural cyst. In only 1 of 10 cases reported so far, however, was the cyst located in the lumbar area; it usually occurred in the midthoracic region, and was more frequent in adolescents than in adults.² Moreover, enlargement of the spinal canal may be found with other extradural tumors as well as with intradural tumors.

The only conclusion that one may draw is that the lesion was of considerable size, since the widening involved all the lumbar vertebrae. Therefore, neurofibroma and meningioma, the commonest intraspinal tumors, can be ruled out. Ependymomas are occasionally very large. They frequently occur in young adults, and the lumbar region is one of their favorite sites. They also produce widening of the spinal canal. One would expect, however, erosion of the dorsal portions of the vertebral bodies with such marked changes of the interpediculate spaces.

Aside from the enlargement of the canal the lumbar spine showed other abnormalities. The intervertebral disk between the second and third lumbar vertebrae was absent. There was sacralization of the fifth lumbar vertebra. Probably both were congenital anatomic variations associated with the spina bifida that was observed at birth.

Concerning the spina bifida, no evidence of a defect in the closure of the vertebral arches was obtained on admission, but there was a scar in the midlumbar region surrounded by a local overgrowth of hair; furthermore, the peculiar neurologic findings could be well explained by traction exerted on the spinal cord as a result of its attachment in the lumbar region.

The neurologic findings were peculiar because a lesion whose upper level is opposite the first lumbar vertebra cannot produce pyramidal symptoms unless the normal relation of the vertebral column and spinal cord is disturbed. In adults the cord ends at the first or second lumbar vertebra. Even if the difference between the knee jerks is discarded, the bilateral ankle clonus indicates involvement of the pyramidal tracts at or above the fourth lumbar segment, which normally lies opposite the eleventh or twelfth thoracic vertebra.

The pyramidal disorder was probably produced by the tumor itself. If it was due to an associated lesion, a myelodysplasia, which is frequently associated with spina bifida, might have to be considered. The other and better alternative is to assume that the lumbar segments were lower than normal.

At an early fetal stage, the spinal cord occupies the entire length of the vertebral canal. Later, the spinal column grows more rapidly than the spinal cord. The latter, firmly attached to the brain, is drawn upward until the final well-known relation of vertebrae and cord is attained. Attachment of the cord in the lumbar region, as a result of malformations there, exerts downward traction, which interferes with the normal adjustment, which, I believe, occurred in this patient. The cord was anchored at the site of the intraspinal malformation.

It is also justifiable to assume, in view of the absence of any other clue in the story, that the cord compression was due to a tumor that belongs in the group of congenital lesions. Its exact nature can hardly be determined on the basis of the available evidence. It was pointed out that the lesion probably was of considerable size. An extradural cyst is still a good possibility. A search in the literature revealed that cysts of congenital origin have also been found intradurally.^{3,4} Both are uncommon. Intraspinal dermoid or epidermoid tumors are also rare in the lumbar region. Lipomas are not infrequently associated with spina bifida, but the whole picture is so puzzling that one may expect something unusual. That is as far as I can go.

CLINICAL DIAGNOSIS

Tumor of cauda equina.

DR. MICHELSEN'S DIAGNOSES

Congenital space-occupying intraspinal lesion (tumor or cyst in the lumbar area).
Downward displacement of cord, with associated myelodysplasia?
Congenital abnormalities of lumbar spine.

ANATOMICAL DIAGNOSIS

Epithelial ependymoma of filum terminale.

PATHOLOGICAL DISCUSSION

DR. CHARLES S. KUBIK: I shall read part of Dr. Mixter's operative note:

There was a definite cleft in the third lumbar vertebra, by fusion of the spinous processes. On exposure of the dura, a mass could be made out, lying at the level of the lower edge of the first lumbar vertebra and the upper edge of the second. An extension of the dura into the cleft in the third lumbar vertebra was freed up, and the dura was opened throughout the extent of the laminectomy. An oval tumor, 3 by 0.5 cm., was found lying within the roots of the cauda equina, as seen through the dura. This tumor seemed to arise from some structure, probably the filum terminale, in the cauda equina. The roots of the cauda equina were matted together down to the level of the

spina bifida occulta—a normal finding in spina bifida occulta. There was adherence of a few posterior roots to the dura at the level of the spina bifida occulta. The mass was carefully dissected out but was ruptured during the later part of the dissection. It contained turbid, brownish fluid, and it seemed to be a cholesteatomatous cyst with some evidence of bleeding within the cyst. So far as I could make out, all the cyst wall was completely removed. The adherent nerve roots were freed from the dura lower down and were allowed to drop back with the rest of the cauda equina.

The tumor measured 2.5 cm. in length and 1.8 cm. in diameter. A large part of it consisted of a cyst, filled with pale-gray, semigelatinous material and lined with columnar and cuboidal epithelium. Some of the cuboidal cells were ciliated and contained a row of granules just beneath the ciliated surface. They resembled cells often found in a persistent central canal of the spinal cord in infants, and indicate that the tumor was an ependymoma.

DR. W. J. MIXTER: The patient made a good convalescence but the left leg was somewhat spastic at the time of discharge. Several weeks later he reentered the hospital following a bout of alcoholic

excess; there were retention of urine, loss of rectal control and weakness and spasticity of the left leg. Examination suggested a large functional element but the spasticity, of course, could not be explained on that basis. A lumbar puncture performed below the level of the operative scar showed no evidence of block. He recovered gradually from this episode and was discharged with full control but still somewhat spastic.

I believe that the spasticity was probably due to some congenital anomaly of the dorsal cord rather than to traction on nerve roots, since no evidence of such traction was seen at the time of operation.

A recent report states that the patient is doing well, but I imagine that examination would still show evidence of spasticity.

WHEN JOHNNY COMES MARCHING HOME

"NEVER," said Winston Churchill, coining one of his most famous epigrams, "have so many owed so much to so few." He referred, of course, to the defense of England by the Royal Air Force in those desperately heroic days of 1940. The tribute was sincere—it was deserved—and no reward was offered.

We Americans, more mercurial and having suffered so much less, find it necessary to twist our eagle's tail feathers quite frequently, to hear him scream. True, we also have an aggregation of

stout-hearted young men in our services who are rendering excellent accounts of themselves wherever they may be—in the air, on the land, on the restless surface of the ocean and in its waveless depths. They are for the most part modest youths, but by our very idolization of them we are making their eventual return to a civilian status doubly difficult.

It has been the grim duty of occasional generations of youths, in peace-loving countries, to forsake their normal ways of life and to assume the unaccustomed burden of arms, for a time, in defense of the peace that they have always cherished. Their countries owe them a great debt of gratitude for their sacrifices, but they owe them an additional and still greater practical debt—that of helping them eventually to return to useful citizenship so that they may at last enjoy the benefits for which they fought.

The very nature of the hero-worship, for the most part unwelcome and unsought, to which they are subjected tends to unsettle them and unfit them for the necessary readjustment to life on Main Street. As one of our more youthful senators recently remarked to the personnel of a bomber station somewhere in England, "When you come back there'll be nothing too good for you!" We all agree with the enthusiastic young senator, but we wish that his vague promise might have been left unvoiced, and we should like, incidentally, some clear exposition of what we really do owe our men when they return from their complex battle fronts.

The discharge of this debt should certainly assure them peace and security, for that they will have won for everyone, but above all it should extend the opportunity to become rehabilitated as useful, contented, contributing members of a society that they have helped not so much to preserve as to remake, we trust, on a better plane. We do not want them to have a month of adulation followed by a long period of idleness and gradual deterioration punctuated by bonuses, nor do we have the present intention of forcing this year's

fracture. It was high time that an authority made such a selection as has the writer of this textbook—that is, one or two practical and efficient methods that have proved to be safe and generally successful for each of the various types.

After adequately outlining the basic principles of dealing with simple and compound fractures, Dr. Caldwell proceeds to deal specifically with the usual types of fracture, illustrating the methods followed with many line drawings.

The possessor of this volume will be spared a great deal of confusion when he attempts to decide from perusal of present-day literature what is the best method to apply in some puzzling case that has turned up in his practice.

NOTICES

NEW ENGLAND DERMATOLOGICAL SOCIETY

The regular meeting of the New England Dermatological Society will be held in the Skin Out Patient Department of the Massachusetts General Hospital on Wednesday, October 20, at 2 p.m.

SALEM TUMOR CLINIC

A teaching clinic will be held at the Salem Hospital on Friday, October 29, at 9 a.m. The speaker will be Dr. Richard B. Cattell, who will discuss certain aspects of "Carcinoma of the Bowel." A member of the staff will present a survey of some of the hospital cases.

Physicians are cordially invited to attend.

AMERICAN HUMAN SERUM ASSOCIATION

A meeting of the American Human Serum Association will be held at the Children's Hospital, Philadelphia, from 9:30 a.m. to 4:00 p.m. on Friday, October 22, during the war symposium conducted by the American Association of Military Surgeons. A program covering various aspects of shock and its treatment, plasma and blood transfusions, the use of convalescent serums and so forth will be given by authorities in their respective fields. All physicians, particularly those attending the meeting of the American Association of Military Surgeons, will be welcome.

WINTHROP COMMUNITY HOSPITAL

The monthly staff meeting of the Winthrop Community Hospital will be held on Thursday, October 28, at 9 p.m. at the hospital. Dr. William Dameshek will speak on the subject, "Problems of Hematology of Interest to the General Practitioner."

Physicians, nurses and medical students are cordially invited to attend.

BOSTON DISPENSARY

A clinical staff meeting of the Boston Dispensary will be held at the Pratt Hospital Auditorium on Friday, Octo-

ber 29, at 12:30 p.m. Dr. John W. Strieder will speak on the subject, "Modern Aspects of Surgery of the Heart." Luncheon will be served at 12 noon.

All interested persons are cordially invited.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, OCTOBER 21

THURSDAY, OCTOBER 21

*9:00-10:00 a.m. Medical clinic. Dr. S. J. Thinnhauser. Joseph H. Pratt Diagnostic Hospital.

5:00 p.m. Epidemiologic Factors of Rheumatic Fever. Dr. T. Duckett Jones. Seminar on Diseases of Children. Main amphitheater, Children's Hospital, 300 Longwood Avenue, Boston.

*8:00 p.m. New England Pathological Society. Auditorium of the Boston University School of Medicine.

FRIDAY, OCTOBER 22

*9:00-10:00 a.m. Some Observations on Heart Murmurs. Dr. Samuel Levine. Joseph H. Pratt Diagnostic Hospital.

SATURDAY, OCTOBER 23

*10:00-11:30 a.m. Medical staff rounds. Peter Bent Brigham Hospital.

MONDAY, OCTOBER 25

*12:15-1:15 p.m. Clinicopathological conference. Peter Bent Brigham Hospital.

TUESDAY, OCTOBER 26

*9:00-10:00 a.m. Medical clinic. Dr. S. J. Thinnhauser. Joseph H. Pratt Diagnostic Hospital.

*12:15-1:15 p.m. Clinicorontgenological conference. Peter Bent Brigham Hospital.

2:00-4:00 p.m. Myasthenia gravis clinic. Out Patient Department, Massachusetts General Hospital.

WEDNESDAY, OCTOBER 27

*9:00-10:00 a.m. A Clinical Discussion of Granuloma Inguinale with Differential Diagnosis. Dr. F. M. Thurmon. Joseph H. Pratt Diagnostic Hospital.

*12:00 m. Clinicopathological conference. Children's Hospital.

*Open to the medical profession.

WARTIME RESPONSIBILITIES OF THE UNITED STATES PUBLIC HEALTH SERVICE*

WARREN F. DRAPER, M.D.†

WASHINGTON, D. C.

THE recent trend of events in the war has been encouraging. The fight, however, is still far from won. For years the United States Public Health Service has had its own battle to wage—a battle against death, disease and suffering. Our job is pretty much the same in war or peace. It is heightened, of course, and brought into sharper focus by the exigencies of war; but our function remains always clearly and simply one of maintaining the Nation's health—by "holding the line against preventable disease."

The first eighteen months of war have given the federal health authorities an opportunity to evaluate their health-protection measures and to clarify those problems most likely to need wartime amplification. The health of the Nation, as measured by death rates and the incidence of communicable diseases, remained good during 1942. Provisional data indicate that the general death rate for 1942 is the lowest ever recorded, 10.3 per 1000 population, as compared to 10.5 for 1941. The increase of fatal accidents in industry almost offset the reduction in deaths from automobile accidents.

One of our functions is the prompt control of epidemic diseases, a threat to the war effort. There have been substantial increases in two epidemic diseases and the outbreak of a new infection among war workers.

Meningococcal meningitis, also known as cerebrospinal fever, caused much loss of life in the first war. In 1942 the incidence of the disease was well above the expected level. This year to date over twice as many cases were reported as for all of last year. The final figures for 1943 will probably show the greatest rise in meningococcal meningitis since 1913. Yet the situation today is much more hopeful than it was twenty-five years ago, when there was no satisfactory treatment. It has

been found, for instance, that prompt administration of sulfonamide drugs will save a great majority of patients and is more effective than the combination of drugs and serum. In some reports to the Public Health Service, the fatality rate has been as low as 5 per cent.

Endemic typhus fever, which increased in 1942, has shown a continuing rise throughout 1943. A year ago an Office of Typhus Fever Control was established with headquarters at Atlanta, Georgia, to assist threatened communities in combating this rise. Surveys of rat harborages are made by this office, buildings are rat-proofed, and rats are destroyed. The Public Health Service also assists the Army in the rodent control of military establishments. In addition, we have been carrying on typhus research for a number of years. One of our officers has developed a vaccine believed to be the most effective of any known for the prevention of typhus. Experiments in the production of lice repellents are also encouraging.

Late in 1941, an epidemic eye infection, known as keratoconjunctivitis, appeared in the shipyards of the West Coast and spread through war industries there, and has since attacked numerous industrial groups in other sections of the country. The probable cause of the disease is a virus. It is not a fatal infection, but disables workers for from two to eight weeks and occasionally impairs vision through injury to the cornea. The Public Health Service has widely publicized the conditions among professional workers in state and local governments, the medical field and private industry. Recommendations for the control of this disease have been made. There is, however, no specific cure.

The Public Health Service quarantine authorities are on hand wherever necessary to guard the home front. The great impetus of air traffic—the increased speed of travel—has made it possible for a person to contract any of the quarantinable or

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 25, 1943.

†Assistant to the Surgeon General, United States Public Health Service, Washington, D. C.

tropical diseases in distant parts of the world and to reach the United States before the condition has become manifest. Commercial and military aircraft are now examined by medical officers for the presence of disease, passengers are kept under surveillance, and planes are disinfected. Ships touching our ports are inspected for infestation by rats. New ships constructed for the wartime merchant marine incorporate the Public Health Service rat-proofing specifications.

Although reports of infectious diseases from enemy-occupied countries are incomplete, the Public Health Service keeps tabs on the world-wide incidence of disease. We have knowledge of thousands of cases of typhus throughout Europe and Africa. Recent reports show that gastroenteritis, tuberculosis, typhoid fever and trachoma are prevalent in North Africa, and malaria in Morocco and Egypt.

The problem of returning troops infected with various tropical diseases has been studied by the Public Health Service, the Army, the Navy and the National Research Council. These diseases include filariasis, a disease of the lymph nodes for which there is no preventive treatment and no sure cure, and schistosomiasis, also a stubborn long-term disease. The means of transmission in other countries is known, and the Division of Zoölogy of the National Institute of Health is making an extensive study of potential vectors of these two exotic diseases in this country.

At the request of the Navy, a project for controlling the breeding of the mosquito that transmits dengue and yellow fever was instituted at Key West, Florida. Other projects of this type are being undertaken in Texas and South Carolina; they may also be needed at other points along the Atlantic seaboard. The problem of yellow fever has grown more acute as a result of plane travel between this country, West Africa and South America. A vaccine has been produced for this disease. The Public Health Service at the request of the War Department now supplies all the needs of the Army for yellow-fever vaccine to immunize troops.

The control of epidemic diseases, however, constitutes but a small part of the wartime activities of the Public Health Service. Another of our duties is the provision of medical care for merchant seamen and for the entire personnel of the Coast Guard, including the SPARS. Others treated at the marine and contract hospitals are veterans, civil-service personnel injured in line of duty and other legal beneficiaries. These hospital activities have of course been increased by the war. Our program for medical and hospital care of merchant seamen, for example, has been greatly expanded in a co-operative effort with the War Shipping

Administration. Formerly a vast majority of sea-going merchant vessels had no first-aid or sanitation service of any kind. The United States Marine Hospital Corps School in Brooklyn, New York, graduated its first class of two hundred and thirty-nine pharmacist's mates on March 12 after six months of intensive training. This training program and other services—such as the psychiatric treatment of merchant seamen—are joint programs of the Public Health Service and the War Shipping Administration.

At the request of the Secretary of War a number of medical officers, engineers and sanitarians have been assigned to duty with the Army. We have men in each of the ten service commands, at the School for Military Government in Charlottesville and in Panama, Trinidad, Australia, Alaska and North Africa. Several who were on duty in the Philippines have been reported as prisoners of war. Industrial-hygiene experts are serving with the Ordnance Branch of the Army. A number of men have been assigned to duty in different parts of South and Central America in connection with the prevention of the spread of disease from one country to another, and in this country also a group of men are supervising sanitary conditions along the Pan American Highway.

Thousands of Public Health Service personnel are now working in several hundred war areas on assignment to the states, with others assigned to special regional and liaison programs. These are engaged in general public-health work, in industrial-hygiene services, in malaria, typhus, yellow fever and tuberculosis control and in the Civilian Defense plasma-bank programs.

In addition, we offer direct and co-operative services to such war agencies as the Federal Public Housing Authority, the War Production Board, the Federal Works Agency, the Office of Civilian Defense and the War Manpower Commission.

A very important part of our wartime work is assistance in the provision and training of professional personnel. As is generally known, there is an urgent shortage of physicians and dentists in certain critical war areas. Whenever it is impossible to meet the demands for medical care through the Procurement and Assignment Service, the Public Health Service is called on to meet them. Because of the shortage of nurses for the Army, the Navy and essential civilian tasks, we have attempted to increase the supply by stimulating enrollment in schools of nursing and by retraining inactive nurses.

A great portion of our work today is concerned with direct research on wartime problems. Studies now under way for the military authorities include an effort to find a preventive for malaria, the so-

lution of many intricate problems involved in combat flying, improvement in typhus-fever vaccine and other studies that, for military reasons, I cannot describe. Suffice it to say that the military authorities consider these studies of urgent importance.

Research concerning the toxicity and potential dangers of new substances prior to their introduction into industry is constantly going on. These studies are of the utmost industrial importance at this time.

Recently a member of the staff of the National Cancer Institute has succeeded in transforming normal cells grown artificially in the test tube into cancer cells by exposing the cultures to extremely small amounts of a coal-tar chemical that has long been known to induce cancer when injected into experimental animals. The transformed cells when reinjected into animals of the same species from which they were derived have grown rapidly, invading the other tissues of the body and finally killing the animals. It is probable that this contribution will lead ultimately to the discovery of the cause of cancer, since it demonstrates conclusively that the cancer process is started in single cells and is not dependent on constitutional conditions of the whole body. Owing to the increasing recognition of the high incidence of primary cancer of the lung, the National Cancer Institute has made a study of dust collected from a number of industrial cities. It was found, in two successive years, that these dusts contain tar that produces malignant tumors in mice. It is important that these studies be continued. Work is proceeding along the line of developing a chemical treatment for cancer, since the limitations of x-ray and surgery in the treatment for cancer are well recognized. Interesting leads have already been obtained from substances of bacterial origin. Work is now being done at the Cancer Institute on the development of methods for accelerating the healing of war wounds. Wound healing involves the study of cell growth and proliferation, a field with which research workers in cancer are thoroughly familiar.

A method for relieving the pain of childbirth was developed by two young officers of the Public Health Service at the Marine Hospital in Stapleton, New York, in the past year. Leaders in the medical profession consider this an outstanding contribution. It is an application of the principles of local anesthesia in that it is essentially a process whereby the larger nerves supplying the part of the body involved remain anesthetized throughout the period of painful labor. Mothers remain completely conscious throughout, and, having experienced this relief, are most enthusiastic about the method. The baby being born is not at all af-

fected. Physicians who have witnessed demonstrations have been greatly impressed. The technic is somewhat difficult and requires special ability on the part of the physician. The method is known as continuous caudal analgesia. Possibilities for its use exist in fields of surgery other than obstetrics. The originators have demonstrated their technic at a number of medical schools and are receiving many requests for additional demonstrations.

With the tremendous growth in industry there has been a correspondingly increased need for looking after the health of the workers in the shipyards and munitions plants and for the expansion of health and sanitation activities in all war-industrial areas. For many years we have carried out studies on industrial hygiene. These have now been expanded, field staffs have been organized, and intensive programs to ensure the health of the industrial workers have been instituted. This is done by direct inspections of plants, especially government arsenals, and through forty-four industrial-hygiene units—in thirty-six states, four cities, two counties, the Tennessee Valley Authority and the District of Columbia. The work of state units is so integrated with that of the Public Health Service that a nationwide organization now exists that, if properly implemented, can serve effectively to guard the health of war workers. In connection with the protection of the health of industrial workers, a great deal of work has had to be done in war-industry areas, which grew up nearly overnight in connection with the lack of health and sanitation facilities.

Virtually all Public Health Service research, of course, has been turned to new problems rising from wartime needs. A number of our activities have been in force for a long time, however, although they have been given an additional impetus by the global war. Such are the programs for the control of venereal disease, tuberculosis and malaria.

Mobilization, vast industrial expansion and other conditions of war furnish ideal mediums for the spread of venereal disease. The Public Health Service has co-operated with the military authorities and state and local health organizations in improving conditions in many war-boom communities caught with no defense against venereal infections. The thirty-three hundred venereal disease clinics in the country last year represent a rise of 300 per cent over 1938. Over 10,500,000 treatments for syphilis were given by public-health officers last year, and 64 per cent of the men rejected for military service because of syphilis have already been brought under treatment. Twenty-two rapid-treatment centers for women who are spreading the

disease have been established, and we expect to have sixty more by the end of 1943. Our methods include the new intensive treatments for syphilis and the use of sulfonamide drugs for gonorrhea.

In anticipation of an expected war rise in the incidence of tuberculosis, the Public Health Service strengthened its prevention program by establishing an Office for Tuberculosis Control shortly after the war began. X-ray examinations have been given to nearly 250,000 people, over 160,000 of these being war workers in shipyards, ordnance plants, air depots and other essential war establishments. It is planned to extend the program to include the families of war workers and draft rejectees. All Coast Guard recruits are now examined by this method. We have also been examining Mexican laborers imported into the United States for work in agriculture, mining and rail-roading. The x-ray examinations are made by

means of a cheap microfilm technic and the use of portable 35-mm. photofluorographic units.

The Public Health Service has had the primary responsibility for the control of malaria in all areas adjacent to naval and military establishments. This work has involved the organization of physicians, engineers, entomologists and other health personnel in a functional and co-operative unit for the basic purpose of eradicating the malaria mosquito. We have protected millions of war workers against the disease. As a result of these activities, too, the Army in 1942 reported the lowest annual malaria rate in its history, 0.6 per 1000 men.

* * *

All this gives a rough idea of what is being done by the United States Public Health Service to maintain the health of the Nation. Much has been and is being accomplished, but much, of course, still remains to be done.

THE EFFECT OF SULFANILAMIDE POWDER ON THE HEALING OF STERILE AND INFECTED WOUNDS*

With Special Reference to Tensile Strength and Ascorbic Acid Content in the Scar

CHESTER M. JONES, M.D.,† MARSHALL K. BARTLETT, M.D.,‡ ANNA E. RYAN, B.A.,§
AND GLADYS D. DRUMMEY, B.S.¶

BOSTON

LOW tensile strength of healing wounds in scorbutic guinea pigs was reported by Lanman and Ingalls¹ in 1937 and by Taffel and Harvey² in 1938. In previous communications we³ have demonstrated a direct relation between tensile strength and ascorbic acid content of healing wounds and the ascorbic acid intake in both guinea pigs and human beings.

Further studies of wound healing in guinea pigs maintained at varying levels of vitamin C intake are reported here. The chief object of these experiments has been to determine whether sulfanilamide powder placed in wounds produces any deleterious effect on the healing process. Such a study has seemed particularly timely at the present moment, when the use of this preparation in war wounds has attained such proportions. Although there can be no doubt of the efficacy of a procedure of this kind in controlling wound sepsis, it has seemed pertinent to ascertain whether the indiscriminate use of such a chemotherapeutic agent may interfere in any way with the for-

mation of adequately healed wounds. In addition, we have studied the ascorbic acid content and tensile strength of healing wounds in the presence of induced wound infection or focal infection experimentally produced at a distance from an operative wound, with and without local sulfanilamide therapy and at various levels of ascorbic acid intake.

PROCEDURE

The animals forming the basis of the experiments were divided into three main groups. Group A included guinea pigs of comparable size and age that were maintained on a scorbutic diet throughout the period of study; Group B included animals on the same scorbutic diet with a daily supplement of 1.5 mg. of ascorbic acid; Group C was made up of animals on the same basic diet with a daily supplement of 15 mg. of ascorbic acid. The basic scorbutic diet was that used in previous experiments and originally described by McCullough.⁴ The ascorbic acid supplements were given in aqueous solutions and were administered orally twice a day by medicine dropper. The animals were maintained on these diets for a preliminary

§Technician, Massachusetts General Hospital.

period of two weeks, previously found to be adequate to establish a tissue level of ascorbic acid.

At the end of this period, an incision of the abdominal wall was made in all the animals, with the following complementary procedures on the basis of a preliminary subgrouping:

Subgroup 1 (control group): No other procedure.

Subgroup 2: Sulfanilamide powder inserted into operative wound.

Subgroup 3: Infection induced distant from operative wound.

Subgroup 4: Infection induced distant from operative wound; sulfanilamide powder inserted into operative wound.

Subgroup 5: Infection induced in operative wound.

Subgroup 6: Infection induced in operative wound and sulfanilamide powder inserted.

The operative procedure was as follows. Under ether anesthesia and surgical asepsis, a midline abdominal incision was made extending from the xiphoid to a point just below the umbilicus. A strip of tissue adjacent to the wound and consisting of the full thickness of the abdominal wall was excised for a control ascorbic acid assay. The peritoneum and muscular layers were closed in a single layer with a running suture of fine silk. The skin was closed in a similar manner in Subgroups 1 and 3. In Subgroups 2 and 4, 0.1 gm. of sulfanilamide powder was sprinkled over the muscle suture before closing the skin. In Subgroups 3 and 4, an infection distant from the operative wound was produced by subcutaneous inoculation with 1 cc. of a broth suspension of a blood-agar culture of beta-hemolytic streptococci. This inoculation was made from three to six hours postoperatively and a walled-off abscess invariably resulted at the site of the inoculation. In Subgroups 5 and 6, the muscle layer was smeared with a ground-up culture of beta-hemolytic streptococci before closing the skin incision, but in the latter group 0.1 gm. of sulfanilamide powder was sprinkled over the streptococcal smear before closing the skin incision.

In each main group the same dietary conditions that had prevailed preoperatively were continued throughout a ten-day period of healing, at the end of which time the animals were killed and the scars were assayed for ascorbic acid content of the tissue and for tensile strength (Table 1). The ascorbic acid content was determined by the method described by Bessey.⁶ The tensile strength was measured by the application of a direct pull

on the healing scar. The apparatus consisted of a 5-cc. glass syringe with collars mounted on the barrel and plunger. Each collar carried a bar pivoted at the center bearing two pins 1 cm. apart. The pivot provided an equalized pull on the tissue mounted on the pins when tension was applied by means of weights placed on the platform. The tissue was mounted on two rather than four pins to allow duplicate determinations on each wound through the use of narrow strips of tissue. As a result of these duplicate determinations, it became evident that there was considerable variation by this method and that only gross differences should be considered as significant. The tensile strength recorded is the weight necessary to rupture the muscle layer rather than the skin layer, as in every case the skin separated first. In scars of high tensile strength the adjacent tissue by which the specimen was mounted tore before the scar itself ruptured. For this reason, figures for tensile strength represent comparative, not absolute, values.

RESULTS

The results obtained in these three groups of animals were as follows:

Group A. As might have been expected from previous studies, the operative wounds in all animals on a scorbutic diet with no ascorbic acid supplement showed little or no evidence of healing. In most cases, although there was some healing of the muscle layer, the skin edges at the site of the abdominal incision fell apart when the sutures were removed. The area of the scar was edematous and inflamed, and in a large percentage of the animals only a scab or a brittle layer of necrotic tissue was formed. Although the muscle layer showed evidence of healing, it required but slight traction to separate the wound. The average tissue ascorbic acid level in this group was very low, regardless of the experimental procedure employed. In the preoperative specimens it averaged 0.32 mg. per 100 gm. of tissue, and in the scars excised after ten days, 0.66 mg. Correspondingly low tensile strengths were noted, the average for the group being the equivalent of a pull of 157 gm. The preoperative values of tissue ascorbic acid in this group corresponded closely to the results reported previously by us³ (0.23 mg. per 100 gm.). Regardless of the additional procedure utilized, no essential difference was noted in any of the animals regarding wound healing, ascorbic acid content of the operative scar or tensile strength. It will be noted that even in this vitamin C-deficient group there was no important deviation from the general average of scar-tissue ascorbic

acid content or of tensile strength in those cases where sulfanilamide powder was introduced into the wound. The lowest figures for tensile strength were those recorded in the animals in which the operative scar had purposely been infected (Subgroups 5 and 6).

Group B. A distinct contrast was observed in the animals maintained on a scorbutic diet plus a supplement of 1.5 mg. of ascorbic acid. As was to be expected, the average ascorbic acid content of the tissue was markedly higher than in the frankly scorbutic guinea pigs of Group A. The average tissue content of ascorbic acid in the preoperative specimens was 0.81 mg. per

and 5.14 mg., respectively. The average figure for tensile strength, 825 gm., was essentially the same as that noted in those receiving a smaller supplement of vitamin C. In one pig (Subgroup 5) with an infected operative wound, a section of the scar that was badly infected and oozing showed a tensile strength of only 125 gm., but the remainder of the wound, which was clean and well healed, resisted a pull of 825 gm.

Although there were occasional wide variations in tissue and scar vitamin C values and in estimations of tensile strength, these were exceptional and in no way altered the trend of the figures obtained

100 gm., nearly three times that found in the scorbutic animals. In the ten-day scar the average figure of 2.34 mg. per 100 gm. was obtained, nearly a fourfold increase. The tensile strength of the scar was more than five times greater than that in Group A, the average being 853 gm. In these guinea pigs failure of the scar to heal completely was evident only in animals with induced infection in the operative wounds, and this was observed only in those not treated with sulfanilamide (Subgroup 5).

Group C. The guinea pigs in Group C, in which the diet was supplemented by the daily administration of 15 mg. of ascorbic acid, likewise showed excellent wound healing and, as was to be expected, high ascorbic acid assays of both the preoperative tissue and the scar,—1.56 mg.

in the three main groups. In general, the variations seemed to depend on the nutrition of the animals and on the presence or absence of intercurrent infection. The appearance of the healing wounds in the Group C animals was distinctly better than that noted in those which received a smaller supplementary feeding of vitamin C. In view of a striking increase in ascorbic acid concentration in the scar tissue, the failure to record an increased tensile strength was surprising. Such an apparent discrepancy may be accounted for by the fact that it was rarely possible to measure higher tensile strengths than the average recorded figures because by the method employed the adjacent tissue failed to withstand the additional traction caused by increased weight.

A point of some interest was noted in the scorbutic animals (Group A). In Subgroup 3 distant

infection was produced by experimental abscess formation at a site far from the operative scar. At the end of the ten-day postoperative period it was possible to isolate in the operative scar, which was poorly healed, the same strain of organisms that had originally been used in producing the abscess.

An additional point of interest lies in the apparent effect of vitamin C and sulfanilamide therapy in reducing the mortality in all groups incident to the experimental procedures involving wound infection (Subgroups 5 and 6). During the course of these experiments 30 animals died before the expiration of the ten-day postoperative period. Tissue studies on these animals were not included in the results tabulated in Table 1. Death apparently resulted from infection or infection together with vitamin C lack. In Table 2 are given the mor-

to depend on the general condition of single animals. Occasional discrepancies in the estimations of tensile strength were undoubtedly due to inadequacies in the technical method employed. Nevertheless, the trends in the three main groups were consistent. Failure to obtain maximum increases in the tensile strength of scars commensurate with the increase in ascorbic acid content following high supplements of vitamin C was probably associated with a technical failure to register values above certain levels because of the relative weakness of adjacent tissues. It is highly probable that the greater supplements of vitamin C were associated with the formation of extremely strong scars.

From the results obtained, it is clear that the use of sulfanilamide powder under varying experimental conditions in no way retarded healing or resulted in inefficient scar formation. Further-

CLASSIFICATION	GROUP A			GROUP B			GROUP C		
	NO. OF ANIMALS	NO. OF DEATHS	MORTALITY %	NO. OF ANIMALS	NO. OF DEATHS	MORTALITY %	NO. OF ANIMALS	NO. OF DEATHS	MORTALITY %
Subgroup 5— Wound infection without sulfanilamide	18	13	72	11	10	71	6	1	17
Subgroup 6— Wound infection with sulfanilamide	7	3	43	5	1	20	6	1	17

tality figures as they occurred in the three main groups. Of the scorbutic animals (Group A) with streptococcal infection of the operative wound and no supplement of ascorbic acid, 72 per cent succumbed. Where sulfanilamide powder was placed in the wound, 43 per cent of a smaller group died. Of the animals receiving a daily supplement of 15 mg. of ascorbic acid (Group B), 71 per cent failed to survive when sulfanilamide powder was not used. When the drug was employed, however, only 20 per cent died. Among the animals receiving a maximum daily supplement of 15 mg. of ascorbic acid (Group C), only 17 per cent died. The use of sulfanilamide had no apparent effect on this mortality.

DISCUSSION

Although occasional single determinations of tissue ascorbic acid and tensile strength varied considerably, no important discrepancies were noted. In entire accord with previous results,² it has been shown that vitamin C lack in guinea pigs is associated with low tissue values for ascorbic acid, poor wound healing, low ascorbic acid values and correspondingly low tensile strength in healing scars. Minor variations in ascorbic acid values appeared

more, the analysis of vitamin C content of postoperative tissue specimens and ten-day scars reveals no evidence that sulfanilamide caused a deviation of ascorbic acid away from scar tissue or increased the need of ascorbic acid in the production of a normal strong cicatrix. In the presence of serious ascorbic acid lack the use of the drug was not effective in promoting better wound healing and a single local dose did not adequately control wound infection. In all three groups of animals there seemed to be one constant factor contributing to poor wound healing. This factor was local infection in the wound. In those animals receiving adequate or massive supplements of ascorbic acid, wound infection was more nearly controlled by sulfanilamide therapy. In the few cases where the infection was not completely controlled, a strong scar was not obtained. An excellent illustration of this fact has already been mentioned in the preceding section. In this case the tensile strength of the uninfected portion of the scar was nearly seven times that of the adjacent portion of the scar, which still showed evidence of sepsis. Obviously, impaired healing was due not to the deleterious action of the drug but to its failure to control completely the local in-

marily an infiltrative, inflammatory process, it may be combined with or replaced by sclerosis, atrophy and scarring of the mucosa. The chief

gross features are hard, infiltrated tissues, hard, granular, atrophic mucous membranes that bleed

The disease must be differentiated from several other conditions with which it may be confused. In the early stages, syphilis and lupus may be considered, and the later, more extensive process may suggest cancer or leprosy. The slowly progressive nature of the lesion, usually beginning before the age of forty, a history of origin in the nares or palate and a gradual spread to the entire nasopharynx emphasize the unusual nature of the process. Negative blood Wassermann reactions and failure to respond to antisyphilitic therapy exclude syphilis. Involvement of the lip may suggest keratosis follicularis (White's disease), which, however, is associated with general skin changes. Periarteritis nodosa, in which there are granulomatous lesions in the gastrointestinal tract, may be excluded by the absence of pain locally and in the abdomen. Since those affected frequently care for horses, chronic glanders must be excluded, and this may be done by bacteriologic studies and the Strauss reaction. Ultimately, a biopsy should be performed, which will lead to the correct diagnosis.

Microscopically, the lesion shows characteristic changes the dominant features of which are the inflammatory process and the presence of numerous, large, swollen, vacuolated endothelial cells con-

FIGURE 3. Minute Abscess in the Squamous-Cell Layer ($\times 750$).
It is filled with bacilli and polymorphonuclear leukocytes; none of the organisms are phagocytized.

readily on manipulation and a marked fetid odor. Frequently cancer or tuberculosis is the initial clinical diagnosis, because of the prolonged course of the disease.

taining encapsulated bacilli. These cells were first described by Mikulicz¹⁰ in 1876, and the organism believed to be the cause of the infection was isolated by Frisch¹¹ in 1882. This bacterium is al-

most identical with Friedländer's bacillus (*Klebsiella pneumoniae*).

CASE REPORT

A 66-year-old man, born in Poland, had been a resident of Berkshire County, Massachusetts, for many years. During most of that time he had worked intermittently as a laborer and lived in the country under simple hygienic conditions. He was seen for the first time by a physician in September, 1928, when he visited Dr. F. S. Gospodarek of Adams, Massachusetts, complaining of a mouth condition that he stated had been present at least five years

FIGURE 4. Endothelial Leukocytes in the Epidermis ($\times 1600$).

One contains bacilli with well-developed capsules; the other, bacilli without capsules.

and that had begun to interfere with eating and swallowing. He was certain that the trouble began after a tooth extraction. The mouth was tender but not painful. He had not lost weight and recalled no gastrointestinal symptoms. No other member of the family, which included four children, showed evidence of similar changes in the mouth or nose.

Examination showed a dusky-red, thickened, granular, indurated lesion involving the hard and soft palate. In addition to small and large granulations on the surface there were many deep grooves mingled with grayish areas, apparently cicatrices. The uvula was absent. The process involved the postpharyngeal wall as far as one could see, and also the gum margin of the upper jaw on the left side. On palpation the palate and contiguous buccal mucosa were exceedingly hard, suggesting a scirrhous carcinoma. Manipulation resulted in free bleeding from the surfaces. The nose and upper lip were apparently not involved, but a discharge was present in the nostrils, as well as a foul, fetid odor.

Sections of a small fragment of tissue from the hard palate showed an inflammatory lesion characterized by the presence in the epithelium and subepithelial tissue of large, pale, rounded cells of endothelial type, each containing clear, foamy cytoplasm and as many as forty

somewhat regularly distributed minute rods lying in clear spaces (Figs. 1-5). In some cells the organisms possessed well-defined capsules; in fields where the capsules were absent there were numerous polymorphonuclear leukocytes. The nuclei were small, round and pyknotic and placed in the centers or peripheries of the cells.

Cultures of the nose and palate on a variety of mediums yielded mixed growths in which large, clear, colorless mucoid colonies were a prominent feature. They developed best on human blood agar and attained a diameter of 10 mm. The organisms were short, plump, nonmotile, gram-negative rods with rounded ends, and varied in size from 2 to 8 microns, depending on the growth period. The bacterium was very aerobic, growing best on or near the surface and forming in broth a thick pellicle. Gelatin and Loeffler's serum were not liquefied. Litmus milk was faintly and slowly acidified, and in the various carbohydrate mediums, except lactose, there was acid production but no gas. The organism did not develop on highly acid mediums. Indole was not produced. Cultures were odorless, and the organism resisted drying for 2 weeks.

The patient was next seen in October, 1939. He was then a short and emaciated man and weighed only 90 pounds. Because of increasing difficulty in breathing, a tracheotomy had been performed several months previously. The breath from the tracheal tube was extremely

FIGURE 5. Endothelial Leukocytes Filled with Bacilli of Rhinoscleroma ($\times 1100$).

fetid. The voice was fairly audible. There were no external signs of the disease about the nose or lips.

Examination of the mouth disclosed a greatly contracted oral cavity. The deformed, thickened, granular, scarred palate was drawn down toward the base of the tongue, reducing the oral cavity to about a fourth of its normal volume. The process involved the buccal mucosa, particularly on the left side, to which the base of the tongue was adherent. The tonsils were not visible. The tongue was soft and coated. The anterior gum margins were not involved by the process. Slight rubbing of the palate surfaces resulted in free bleeding. The nasal mucosa was markedly congested but did not resemble the oral membrane. During the preceding 12 years the patient had received only local treatment. As he was living on a remote farm and was somewhat indifferent to medical advice, therapeutic procedures were not adhered to.

A second biopsy was performed in October, 1939, and

sections showed the same type of pathologic change described above. The endothelial cells containing Frisch bacilli were much more abundant than previously. Numerous colonies of the same organism were obtained on plain agar slants from the mouth but fewer colonies from the nose. Cultures made from the fingers by impressing them on agar plates also yielded a few of the same type of colony, and swabbings from the rectum yielded an abundant growth of colonies identical with those obtained from the mouth. Thus, an organism of the Friedländer type was isolated from the nose, mouth, fingers and rectum that was identical with the bacillus isolated 11 years previously.

The patient died in March, 1942, about 20 years after the onset of the disease. The lesion had become slightly more extensive, the fetid odor was more pronounced, and the patient could not breathe without a tracheotomy tube but swallowed liquids well. The terminal symptoms indicated failing heart action. Permission for autopsy was not obtained.

The organism was apparently a member of the coliaerogenes group. It was cultivated in broth and as much as 2 cc. of 18-hour broth cultures was injected subcutaneously and intraperitoneally into guinea pigs and intraperitoneally and intravenously into rabbits, but symptoms were not induced. Subcultured over a period of 14 years the organism still retains its original characteristics and resembles members of the genus *Klebsiella*.

The bacterium corresponds closely with *K. rhinoscleromatis*, described in 1882 by Frisch.¹¹ He believed it to be the cause of scleroma and by injections into the nasal septum of rats was able to produce small tumors. Many other workers have

been unable to develop lesions in ordinary laboratory animals with injections of this organism, and its etiologic role is still uncertain.

* * *

In this case report the points deserving special attention are the specific pathologic changes of the disease, the presence of capsulated gram-negative bacilli in the large endothelial cells and the constant presence in ordinary cultures of *Klebsiella rhinoscleromatis*.

I am indebted to the late Dr. Frank B. Mallory for assistance in the diagnosis and for the photomicrographs.

CLINICAL NOTE

PROLONGED URETERAL OBSTRUCTION WITH RECOVERY FOLLOWING ADMINISTRATION OF SULFADIAZINE AND SULFATHIAZOLE*

MAJOR SAMUEL J. SUGAR, M.C., A.U.S.†

FORT DEVENS, MASSACHUSETTS

RENAL complications following the use of sulfapyridine,^{1,2} sulfathiazole^{3,4} and sulfadiazine^{5,7} may be of serious consequence, with death in some cases rapidly following the development of anuria and uremia. On the other hand, sulfan-

Prolonged toxic reactions following the administration of sulfanilamide and its derivatives are unusual. Review of the literature fails to reveal reports of persistent urinary findings after the sulfonamide has been stopped. The normal pattern of toxicity is manifested by its appearance during administration and its prompt relief on discontinuance. The case reported below is uncommon in that ureteral obstruction persisted for more than two months after discontinuance of the sulfonamide and was completely relieved by ureteral catheterization and irrigation.

CASE REPORT

A. L., a 27-year-old soldier, was admitted to the Medical Service of the Lovell General Hospital on June 11, 1942, complaining of generalized malaise and fever with some aching of the legs and arms of 1 week's duration. On June 9, there had been an attack of vomiting, which was attributed to overeating. The day before admission he felt feverish and the temperature was 101°F. Physical examination was entirely normal, and the patient denied having venereal disease. He had previously been observed

FIGURE 1. Dilatation of the Left Upper Ureter, Kidney Pelvis and Calyces Due to Obstruction of Ureter by Sulfonamide Crystals.

FIGURE 2. Normal Ureter and Kidney Pelvis after Obstruction of the Left Ureter Was Relieved by Catheterization and Irrigation.

ilamide is much less likely to injure the kidney seriously.⁴ According to Keefer,⁸ "it is rare indeed for a patient who has shown signs of renal insufficiency during sulfonamide therapy to continue to show them following the termination of treatment." Most authors agree on the treatment of acute manifestations of renal complications; namely, discontinuance of the drug, forcing of fluids and ureteral catheterization and irrigation when oliguria persists or anuria develops.

at this station in May, for German measles and after 1 week's stay was discharged apparently fully recovered.

Examination showed a well-developed and well-nourished man who appeared ill but not seriously so. The temperature was 99.8°F., the pulse 88, and the blood

*From the Medical Service, Lovell General Hospital, Fort Devens, Massachusetts.

†Assistant chief of medical service, Lovell General and 16th General Hospitals, Fort Devens.

pressure 130/90. The only abnormal physical finding was mild circumorbital edema.

The initial urinalysis revealed a moderate amount of albumin. Microscopic examination of the sediment showed abundant white cells with frequent clumping, an occasional pus cast and 5 to 7 red cells per high-power field. A Kahn test was negative. The sedimentation rate was markedly increased. The white-cell count was 13,000, with 63 per cent polymorphonuclear neutrophils, 7 per cent stab forms, 4 per cent eosinophils, 23 per cent lymphocytes and 3 per cent monocytes. The red-cell count was 4,400,000, with 100 per cent hemoglobin. The blood nonprotein nitrogen was 43.5 mg. per 100 cc. Daily urinalyses revealed persistent albuminuria, pyuria and hematuria.

With these findings in mind, the patient was questioned further and gave the following history. On May 15, after sexual relations 3 days previously, he noted a thin, watery urethral discharge associated with burning, itching and frequency of urination. He consulted a civilian physician, who prescribed sulfadiazine, of which he took 44 gm. over a period of 10 days. At the completion of this course of therapy, the discharge persisted and there was pain in the left upper quadrant of the abdomen associated with the passage of yellowish brown urine. After all medication had been discontinued for 10 days, sulfathiazole was prescribed and 12 gm. was given in 2 days. Ten days later malaise and fever were noted and were the chief complaints on admission.

It seemed likely that the patient was suffering from sulfonamide lithiasis. Accordingly, fluids were forced, the urine being observed closely in an effort to clear the genitourinary tract. In spite of adequate fluid intake and output, the abnormal urinary findings continued. A scout film of the abdomen showed no signs of calculus. On July 13, intravenous and retrograde pyelograms revealed poor function of the left kidney with considerable dilatation and blunting of pelvis and calyces. The lower four fifths of the left ureter was not visualized. There were no visible urinary calculi (Fig. 1). On July 17, the left

ureter was catheterized and 10 cc. of foul-smelling, turbid urine was recovered. Microscopic examination revealed many red cells but no organisms. Guinea-pig inoculation was negative for tuberculosis. On July 25, examination of a centrifuged specimen of urine revealed numerous white cells, many sulfadiazine crystals and a chemical determination of 218 mg. of sulfadiazine per 100 cc. The patient became afebrile soon after admission. On August 18, the ureters were again catheterized. The left kidney pelvis was irrigated with diluted acetic acid and a dark, grumous urine with heavy sediment was recovered. Following this a steady drip of clear urine was observed coming from the left ureter. Urograms revealed complete disappearance of the previously described dilatation of the left upper urinary tract, with normally appearing kidneys and ureters (Fig. 2). Following this the patient had an uneventful recovery, the urine cleared, the sedimentation rate fell, and blood urea nitrogen and renal-function tests returned to normal. The patient was returned to full duty on October 29.

SUMMARY

A case of hydronephrosis and hydroureter with recovery that occurred after prolonged obstruction by sulfonamide crystals is reported.

MEDICAL PROGRESS

PANCREATIC INSUFFICIENCY AND THE CELIAC SYNDROME

SIDNEY FARBER, M.D.*

BOSTON

THE chronic failure of nutrition in infants and children described by Gee¹ in 1888 under the term "the coeliac affection" is recognized today as a syndrome rather than a disease entity always caused by the same etiologic factor. Only in recent years has an approach been made to an understanding of some of the conditions that produce the celiac picture. Gee himself remarked that "naked-eye examination of dead bodies throws no light upon the nature of the coeliac affection," and Parsons² in the Rachford Lectures described the results of pathological studies in true celiac disease as follows: "The finding, after much scratching about, of some small grains of reward in the shape of an alteration in a few cells does not seem sufficient to justify an exulting cackle, but rather should stimulate research in other directions."

Morbid anatomy has indeed thrown no light on the nature of the usually benign idiopathic celiac disease, but pathological studies have been responsible for a revival of intense clinical interest in the entire group of disorders bearing the celiac imprint. They have resulted, furthermore, in the discovery and characterization of clinical entities associated with pancreatic insufficiency in early life, including a condition until recently confused with idiopathic celiac disease. This condition, in contrast to what Parsons found in celiac disease, is characterized by important and easily demonstrable pathologic changes and is associated with pancreatic achylia produced by obstruction to the outflow of pancreatic juice. The present review will be limited to a consideration of this disorder, which has been variously termed "pancreatic insufficiency," "pancreatic steatorrhea," "pancreatic fibrosis," and "cystic fibrosis of the pancreas." The term "pancreatic achylia" will be used to describe the physiologic consequences of this obstructive lesion in the pancreas. Reference to true or idiopathic celiac disease will be made only when necessary for clarification of the subject matter. Results of studies at the Children's and Infants' hospitals, including unpublished data, will be drawn

on throughout this account. The contributions of Parsons² and of Neale,³ the monographs of Lehn-dorff and Mautner⁴ and of Fanconi⁵ and the recent summary of therapeutic and physiologic studies by May, McCreary and Blackfan⁶ should be consulted by the reader interested in idiopathic celiac disease and the celiac syndrome.

The features that characterize the celiac syndrome include the typical wasting, more in the limbs than in the face; distention of the abdomen, which may be soft, doughy and inelastic or markedly distended and tight; bulky, foul-smelling, frothy stools that contain excess fat; and often retardation of growth. To these may be added clumping of barium in the small intestine, a flat glucose-tolerance curve and a low rise in the level of vitamin A in the blood during the vitamin A-absorption test.⁶ These symptoms may appear as a result of congenital malformations of the small intestine or its attachment, chronic infections, dysentery, megacolon or pancreatic insufficiency. True or idiopathic celiac disease is used to describe this group of symptoms and laboratory findings in patients in whom no underlying disease can be found and who are improved and usually cured by treatment consisting of good general care and any one of the well-established celiac diets. Some idea of the difficulty of understanding the celiac syndrome may be obtained by reference to the large number of names applied to members of this group of diseases. These include acholia, intestinal infantilism, chronic intestinal indigestion, Heubner-Herter disease, Gee-Herter disease, pancreatic infantilism, chronic idiopathic steatorrhea, familial pancreatic insufficiency, indigenous sprue and pancreatic steatorrhea.

Since the time of Gee, true celiac disease has been differentiated with difficulty from a chronic failure of nutrition caused by pancreatic disease, with symptoms resembling those in true celiac disease so closely that the two conditions were considered by most observers to be identical. The striking nature of the clinical features of the celiac syndrome explains the neglect of the respiratory and other non-nutritional aspects of the disease associated with pancreatic insufficiency. The paucity of complete post-mortem studies and competent

The articles in the medical progress series of 1941 have been published in book form (*Medical Progress Annual* Volume III 678 pp. Springfield, Illinois: Charles C. Thomas, 1942, \$5.00).

*Assistant professor of pathology, Harvard Medical School, pathologist, Infants' Hospital and Children's Hospital, Boston.

clinicopathological correlations is responsible for the late recognition of the fact that the celiac picture is only one of a group of what had been thought to be several unrelated diseases caused by or associated with an obstructive lesion in the pancreas that produces pancreatic achylia.

Beginning about thirty years ago, scattered post-mortem observations concerning the pancreas appeared in the literature on celiac disease. A marked increase in interlobular fibrous tissue of the pancreas, for example, was observed in 1914 by Poynton, Armstrong and Nabarro.⁷ Passini⁸ described actual pancreatic disease in an infant with nutritional failure. Some writers who found pancreatic lesions in patients with the celiac syndrome explained them as secondary to the failure of digestive secretion and function.⁹ The relation of pancreatic insufficiency to the celiac syndrome was brought into clear perspective in 1935 by a short clinicopathological communication by Parmelee,¹⁰ who referred to evidence gathered from the literature and reported 2 new cases of pancreatic disease. He suggested that what he called "congenital steatorrhea" differed from the usual picture of celiac disease in the early onset, the excessive amount of neutral fat in the stools and the uniformly fatal outcome. In these patients, at post-mortem examination there were found constant changes, including marked fibrosis and great diminution of secretory gland tissue in the pancreas, and bronchopneumonia, usually of a subacute type with purulent bronchitis and bronchiectasis. In 1935, Thaysen¹¹ grouped celiac disease, nontropical sprue and tropical sprue under the general heading of idiopathic steatorrhea. In the following year, Hanes and McBryde¹² stressed the identity of sprue and true celiac disease, and listed an impressive series of observations in favor of this conclusion. The logical analysis of Rauch, Litvak and Steiner¹³ paid particular attention to steatorrhea, which was classified as the idiopathic variety, which includes true celiac disease, and the pancreatogenous variety.

Several independent investigations published in 1938 and 1939 crystallized the problem and marked the beginning of the recent series of contributions to the present knowledge of the clinical characteristics of this pancreatic disease, the methods of diagnosis and treatment and the nature of the underlying disorder. Comprehensive reviews of the literature may be found in the papers of Andersen¹⁴ and of Rauch, Litvak and Steiner.¹³ In 1938, Andersen gave a detailed analysis of the clinical and pathological findings in 49 cases of pancreatic fibrosis, which included 20 from the post-mortem files of the Babies' Hospital, New York City. Her stud-

ies gave strong support to the validity of the separation of pancreatic fibrosis from true celiac disease and emphasized the logical use of pancreatic-enzyme analysis as a valuable diagnostic measure and of pancreatic substitution therapy. In the same year, Blackfan and May¹⁵ analyzed the clinical records of 35 cases selected from 2800 autopsies in the Department of Pathology of the Children's Hospital. These cases had been set apart as a pathologic entity because of the constant occurrence of an obstructive lesion of the pancreas, which was associated, however, with several different clinical pictures.

From the clinical analyses of Andersen and of Blackfan and May from a subsequent experience at the Children's Hospital,¹⁶ it appears that the infants in whom obstructive lesions of the pancreas are found at autopsy may be divided into three clinical groups: those who died either in the first week or first few weeks of life, usually from meconium ileus; those who died, usually in the first year of life, with a clinical history of nutritional disturbance often obscured by respiratory disease, usually called chronic pneumonia or bronchitis, or bronchiectasis; and those with symptoms recognizable as preceliac and celiac who died of respiratory disease.

Group 1. The term "meconium ileus" is used to describe intestinal obstruction in the newborn caused by the inability of the intestine to propel through its lumen a thick, mucilaginous meconium, the altered physical state of which is explained by the failure of pancreatic enzymes, particularly trypsin, to act on it during intra-uterine life.¹⁷ Death has occurred almost invariably in infants with this severe type of intestinal obstruction. Lesser degrees of obstruction may be produced by inspissated meconium unassociated with pancreatic achylia, as in stenosis of the ileocecal valve. Post-mortem examination of patients with true meconium ileus reveals pancreatic fibrosis with obstruction to the outflow of secretions proved in some cases to be caused by congenital atresia or stenosis of the main pancreatic ducts. Absence of tryptic activity in the pancreatic juice has been demonstrated in one patient with meconium ileus, and in the duodenal content obtained at autopsy shortly after death in another. Dilute solutions of pancreatin added to the grossly altered mucilaginous meconium bring this material to a watery consistence. Successful attempts have been made to relieve the intestinal obstruction in meconium ileus by introducing a 1 per cent solution of pancreatin directly into the duodenum so that it may act on the altered meconium.¹⁷ Recent reports of meconium ileus have been made by Hurwitt

and Arnheim¹⁸ and by Kaufmann and Chamberlin,¹⁹ who review the literature

Group 2. Andersen¹⁴ found that patients in this group usually died before six months of age, and that many of them presented feeding problems characterized by hunger, failure to gain weight and foul, bulky stools. A somewhat different summary was given by Blackfan and May,¹⁵ who recognized that the clinical manifestations in this group were limited in variety but were common to so many disorders in infancy that a sharply defined clinical picture could not be drawn. Usually, these infants developed symptoms referable either to the gastrointestinal tract or to the respiratory system. Vomiting and diarrhea with failure to gain weight or loss of weight preceded the onset of signs of infection of the respiratory system in some cases, but in others a severe and nonproductive cough was an early complaint, followed later by a productive cough and physical signs of partial or complete obstruction of different parts of the bronchial tree. Vomiting was usually not present. Diarrhea was occasionally severe and often lasted for prolonged periods. The stools contained no pus or blood and were definitely not fatty. The average duration of the illness of the patients who lived beyond the neonatal period was six months. The average age at death in this group was eight months. The pertussis-like cough impressed Rauch and his co-workers¹³ as a characteristic feature of this disease.

Group 3. About half the patients in Andersen's¹⁴ series fell into this group, and ranged in age from six months to fourteen and a half years. They all died of pulmonary infection. Only one fifth of the patients described by Blackfan and May¹⁵ were included with these cases, which possessed clinical features similar to those of true celiac disease, such as emaciation, distention of the abdomen and large, pale, putrefactive, fatty stools. All these patients died of pulmonary disease.

In our experience,¹⁰ Group 2 is by far the largest and the cases in it are the most difficult to recognize, and Group 3 in which the condition closely resembles that of true celiac disease, is the smallest. It appears that the patients in all groups are apt to die before there is developed a clinical picture that can be confused with true celiac disease. It is probable that, as further experience with the disease is gathered, the cases in Group 2, in which the respiratory symptoms dominate the picture, will be divided into more distinctive clinical branches.

The familial aspect of this disease has been recognized. A number of cases have been re-

corded of two or three siblings with the same disease, as proved either by post-mortem examination or by pancreatic-enzyme analysis. The early onset of symptoms has caused the disease to be regarded as congenital.

It is probable that this pancreatic disease is much commoner than may be concluded from the number of cases reported in the literature. Andersen¹⁴ found an incidence of 3 per cent in her post-mortem records. Blackfan and May¹⁵ reported an incidence of 13 per cent among infants and children examined at autopsy up to 1937 at the Children's Hospital. In the same laboratory during the following six years ending with 1942, 52 cases of marked pancreatic fibrosis (48 per cent) were found among 1089 autopsies on infants and children, with meconium ileus in 13; in 1942, autopsies were performed on 198 cases, of which 16 (12 per cent) showed pancreatic fibrosis.²⁰ Early cases of the lesion consisting in inspissation of secretions only in the acini are now being frequently found in routine post-mortem studies on infants and children.¹⁰

PATHOLOGICAL FINDINGS

The lesion in the pancreas seen most frequently in these patients is characterized by dilatation of ducts, inspissation of secretion, atrophy of acinar structures and replacement of connective tissue, leading to marked fibrosis of the organ.^{14, 18} Congenital stenosis or atresia of the pancreatic ducts may be found. In most cases, obstruction appears to begin in the acini. The islets of Langerhans are not involved. The lesion may be recognizable grossly or may be complete histologically and functionally without visible gross change. No matter what the cause of the lesion, the effect of obstruction within the acini themselves is equivalent to that produced by ligation of the main pancreatic ducts. From this histologic picture, interference with the production, liberation or passage of pancreatic enzymes leading to pancreatic achylia may be expected.

Hyperexpansion and atelectasis, usually in combination, are the commonest early findings in the lungs, and these are explained by obstruction caused by the tenacious mucopurulent material usually found in the upper respiratory tract. In the more advanced cases of the disease, widespread bronchiectatic and bronchiolestatic abscesses are found. *Staphylococcus aureus* is usually the offending organism. Thickening of the bronchiolar walls, replacement fibrosis in those areas of the lungs repaired after staphylococcal destruction and diffuse bilateral acute and chronic bronchopneumonia characterize the later stages of the disease. Fundamentally the process in the lung is one of upper respiratory obstruction caused by thickened,

tenacious mucus, with secondary infection by *Staph. aureus*.¹⁶

Three explanations for the pulmonary lesions have been offered. Decreased resistance in a chronically ill patient with nutritional failure is an obvious conclusion. Secondly, metaplasia of bronchial epithelium caused by vitamin A deficiency has been held responsible for the secondary infection that follows mechanical obstruction and loss of ciliated epithelium.¹⁴ This plays a role, but only in patients with evidence of vitamin A deficiency of important degree. The third explanation depends on the thick mucus produced in the tracheal and bronchial glands, which fails to lubricate properly the ciliated epithelium of the upper respiratory tract and so permits infection by a staphylococcus of low virulence.¹⁶ More important than the infection is the obstruction caused by the tenacious mucus, comparable in consistence to the viscid pancreatic juice found in the duodenal content. This obstruction is the cause of most of the early signs of respiratory disease and is responsible for the bronchiectasis and later the bronchiectatic abscesses.

The liver is usually increased in size and shows fat metamorphosis. In rare cases there is an unusual form of biliary cirrhosis characterized by a lesion resembling closely that in the pancreas.²⁰ Inspissation of secretions in the ducts and acini of the salivary glands and in the mucous glands of the trachea, bronchi, esophagus and gall bladder occurs with such frequency that it must be regarded as a characteristic feature of the disease.¹⁶ Other evidences of general, severe disturbances in nutrition and vitamin deficiency may be recognized elsewhere in the body—for example, in the skeleton, in the wasting, hypertrophy of muscles, in the disappearance of fat from the fat depots and in the general retardation of growth. Keratinizing metaplasia in the upper respiratory tract, pancreas, salivary glands or renal pelvis, characteristic of vitamin A deficiency, is occasionally but not regularly found.^{14, 16}

ETIOLOGY

Pancreatic achylia may be caused by congenital atresia or stenosis of the pancreatic ducts, or congenital malformation of the duodenum and head of the pancreas.^{14, 16} Congenital syphilis causing widespread fibrosis of the pancreas or intrauterine infection of unknown etiology producing obliteration to the duct system may well be responsible in some cases. In the majority of cases, however, the pancreatic achylia is unassociated with any such gross congenital anomalies or inflammatory lesions obstructing the outflow of pancreatic juice.¹⁶ To clarify the pathogenesis of the lesion producing pancreatic achylia in this large group of infants

and children, three causes have been suggested; namely, vitamin A deficiency, a filterable-virus infection and a fundamental alteration in the physical character of the acinar secretion.

A deficiency of vitamin A may be responsible for gross obstruction of the pancreatic ducts,¹⁴ but this is a rare event.¹⁶ Following metaplasia of the epithelium of the duct lining to a stratified squamous type, there may be complete filling of the ducts by masses of desquamated, keratinized epithelial cells. Some evidence of vitamin A deficiency on histologic examination of certain organs, not necessarily including the pancreas, was found by Andersen¹⁴ in 23 per cent of the cases studied or collected. In our own experience,¹⁶ evidences of vitamin A deficiency were less frequent than this. Although there is a defect in the absorption of vitamin A associated with this pancreatic disease, it must now be regarded as merely one of the complications of the disease process, not of primary importance in the pathogenesis of the pancreatic lesion but responsible for some of the symptoms and laboratory findings.¹⁶

The frequent occurrence of chronic bronchopneumonia in infants with pancreatic disease of this type and the finding of inclusion bodies in certain cases have justified further investigation of the possible role of a filterable virus in the etiology of this condition. Brody²¹ has recently reported the finding of inclusion bodies in 2 of 3 patients with pancreatic fibrosis. Experimental support for this suggestion is still lacking. A review carried out with the assistance of Dr. Edward Pratt²² of 50 post-mortem examinations of infants who suffered from a severe degree of this pancreatic disease disclosed intranuclear and cytoplasmic inclusions in the salivary glands, lungs, trachea or pancreas in 6 (12 per cent) of the series. This is no greater than the incidence of cytoplasmic and intranuclear inclusion bodies in the total number of autopsies in the same laboratory.²³ These studies, therefore, provide no support for the suggestion that a virus disease is of primary importance in the causation of this pancreatic lesion, although secondary effects from a possible superimposed virus infection cannot be excluded.

The prominence of the inspissated secretions in the pancreas in this disease suggested to Blackfan and Wolbach²⁴ in 1933 that this striking lesion could be attributed to the production of an abnormal pancreatic secretion. Study of 87 cases of the advanced lesion and about 350 cases of early stages of the process support the hypothesis that the basic lesion consists in a physically altered pancreatic secretion, which causes intrinsic obstruction in the acini and small ducts, finally leading to dilatation and obstruction in the larger ducts.^{16, 20} Atrophy

of the acinar structures follows, and condensation of the connective-tissue framework of the pancreas secondary to loss of parenchyma, combined with an ingrowth of new fibrosis tissue, gives the picture of diffuse fibrosis. Support for this theory comes from the observation that the fully developed clinical picture of the celiac syndrome may exist and the pancreatic enzymes in the duodenal contents may be markedly reduced at a time when the sole lesion in the pancreas consists of inspissation of secretion in the acini and small ducts, with no evidence of atrophy of the parenchyma, fibrosis or dilatation of the large ducts.²⁵ Further evidence of the abnormality of the pancreatic secretion is given by the gross appearance of the scanty, extremely thick and viscid pancreatic juice obtained when the duodenal contents are collected for enzyme analysis, as contrasted with the thin, watery pancreatic juice obtained from normal infants or from those suffering from true idiopathic celiac disease.²⁵

Inspissation of secretions and dilatation of glandular structures of the same general character as these alterations in the acini and small ducts of the pancreas are found at autopsy on these patients in the glands of the trachea, bronchi, esophagus, duodenum, gall bladder and intestinal tract. Inspissation of bile to a degree sufficient at times to cause intrahepatic biliary obstruction may also occur. These findings suggest that the inspissation of altered secretions in the pancreatic acini is only a part of a generalized disorder of secretory mechanisms involving many glandular structures but exerting its greatest effect on the pancreas.¹⁶ In experiments on kittens, suggested by this conception of the pathogenesis of the pancreatic lesion, it has been possible to produce, by the administration of parasympatheticomimetic drugs (pilocarpine and Mecholyl), the histologic picture of inspissation of secretions in the acini and small

ducts in the pancreas and the clinical picture of a severe chronic nutritional disturbance.¹⁸ The cause for this suggested disturbance of the secretory mechanism in the pancreatic acini of infants remains to be demonstrated.

(To be concluded)

EDITH E. PARRIS, *Assistant Editor*

CASE 29421

PRESENTATION OF CASE

A forty-one-year-old night watchman was admitted to the hospital because of intermittent gas pains of ten years' duration.

The patient was apparently well until about ten years prior to entry, when he developed intermittent attacks of indigestion in which he suffered from epigastric gas pains and the sensation that his stomach was "tied up in knots." The pain occurred approximately half an hour after eating, or when he had gone three or more hours without eating, and lasted for about an hour. It was relieved by anything that would "break the gas" and produce gaseous eructations, such as soda, milk or food. The attacks were sometimes precipitated by cabbage, pork and fried foods. Vomiting of undigested food, especially fried food, sometimes gave relief. The vomitus was never bloody, nor did it contain coffee-grounds material. The last attack of vomiting occurred six weeks before admission. Three years before admission, following x-ray examination at a community hospital, he was placed on a strict ulcer regime, with prompt symptomatic relief as well as gain in weight. The diet, however, was discontinued six months later and the symptoms recurred. Nine months prior to entry, while working in a dusty atmosphere, he had two or three attacks of vomiting and his symptoms increased in severity for two months, at which time he obtained another job, with some relief in his condition. In the three or four months before entry he experienced daily distress after almost every meal. There was anorexia and a weight loss of 15 pounds. He subsisted mainly on soups, milk and cream, crackers, tea and so forth. He became progressively weaker.

He had been constipated most of his life and had habitually taken various laxatives. There had been no back pain, heartburn, dizziness or fainting. He smoked one package of cigarettes daily and drank some beer and a little whisky. He had experienced considerable financial difficulties.

Physical examination showed a well-developed,

small, wiry, tense man, with evidence of recent weight loss. There was no pallor. He was edentulous. The tongue was reddened and coated with coarse papillae. The heart and lungs were normal. The abdomen was scaphoid and soft. There was no tenderness, spasm or palpable masses. Peristalsis was active. Rectal examination revealed a small, firm, nontender prostate. Considerable tenderness was elicited superiorly and on the left, where a questionable soft mass was palpated.

The blood pressure was 125 systolic, 80 diastolic. The temperature was 98.6°F., the pulse 76, and the respirations 20.

The blood showed a red-cell count of 4,300,000, with a hemoglobin of 14 gm. The white-cell count was 6800, with 63 per cent neutrophils. The urine was normal. The stools were guaiac negative on eight occasions but gave a +++ test on one occasion. The blood Hinton test was negative. The nonprotein nitrogen was 20 mg. per 100 cc. The blood protein was 5.6 gm. per 100 cc., the carbon dioxide combining power 21 millimols per liter, the chloride 95.9 milliequiv. per liter and the blood sugar 74 mg. per 100 cc. Gastric analysis showed no free acid before and half an hour after histamine injection; the values for total acidity were 5 and 18 units respectively. Both aspirations gave a ++ guaiac test.

X-ray examination showed a normal esophagus. Just below the cardia there was an ulcer crater measuring 1 by 1 cm., with a rigid, soft-tissue mass surrounding it. This filling defect measured 4 cm. in length. The remainder of the stomach and duodenum was normal.

The patient was placed on a gastric diet with tincture of belladonna, 15 drops, and phenobarbital, 2 gr., three times a day. His condition improved. Gastroscopic examination eight days after entry showed a normal antrum and pylorus and an increased reddening of the body of the stomach in the upper part, with a few streaks of bright-red blood. There was a marked verrucous, cobblestone appearance in the upper 4 or 5 cm. near the cardia; no ulcer crater could be demonstrated. Following gastroscopy, the epigastric symptoms recurred but were relieved by Creamalin, 45 cc. every two hours. A gastric analysis on the fifteenth day showed 25 units of free acid and a total acid of 35 units half an hour after histamine injection. X-ray examination after one month on the medical regime showed the ulcer crater to be smaller than it was formerly, but the crater was surrounded by what appeared to be a polypoid mass extending along the lesser curvature for about 8 cm. The lesser curvature was rigid in this area.

An abdominal exploration was performed six days later.

*On leave of absence.

DIFFERENTIAL DIAGNOSIS

DR. WILLIAM B. BREED: It seems to me that there are two possibilities to be considered. Either this lesion was a benign one throughout its course or it started as a peptic ulcer, then degenerated and became malignant. The history certainly is suggestive of the latter supposition. You will note that the early story is indicative of peptic ulcer with periodic pyloric obstruction and relief of symptoms on an ulcer regime, as well as recurrence of symptoms when the regime was discontinued.

The dusty atmosphere of his new job can be disregarded. I have no thoughts about that.

Two or three months prior to entry he began to have continual discomfort directly after eating, with anorexia and loss of weight but no typical symptoms of ulcer. Up to that point this could well have been a benign ulcer near the cardia that had degenerated and had become malignant. Gastroscoy possibly confirmed the nature of the process; the upper part of the stomach wall was verrucous and cobblestone in appearance.

DR. EDWARD B. BENEDICT: That does not mean malignant disease. That means gastritis.

DR. BREED: I am glad you are here, Dr. Benedict. The record states, "a marked verrucous, cobblestone appearance." There was no mass? Will you describe it as you remember it?

DR. BENEDICT: A verrucous and cobblestone appearance may mean chronic hypertrophic gastritis.

DR. BREED: In a localized area?

DR. BENEDICT: Sometimes localized, sometimes generalized. This was fairly well localized.

DR. BREED: You introduce the idea here at once that this lesion was benign. Let us go ahead and see whether we can put that together with the second examination by x-ray, which described a polypoid mass extending along the lesser curvature, with a rigid mucosa.

In passing, I should say that one has to consider lymphoma of the stomach in any condition like this. However, I am willing to conclude that if this was a polypoid mass it probably was not due to lymphoma. Do you ever see polyps in lymphoma, Dr. Benedict?

DR. BENEDICT: Not discrete polyps.

DR. BREED: You saw no polypoid mass?

DR. BENEDICT: No, but I could not see the ulcer. It was in a part of the stomach that is difficult to visualize.

DR. BREED: No polyp was seen on the first x-ray examination. We might see both sets of film.

DR. MILFORD SCHULZ: Here are the films made at the time of admission, and there is no gain saying the fact that there is an ulcer with what appears to be a mass of soft tissue about it. In

addition you can see an irregular soft-tissue mass extending into the cardia.

DR. BREED: What does that mean to you? Is this soft-tissue infiltration?

DR. SCHULZ: By all the rules it should be a carcinoma.

Here are the films made after a month of treatment. The ulcer is somewhat smaller. You still see all this thickened verrucous soft tissue extending into the air-filled and barium-filled portion of the stomach. It is true that there are quite prominent mucosal folds throughout the stomach; in a recent similar case, however, in which a diagnosis of cancer was made, the condition at operation proved to be gastritis and not carcinoma.

DR. BREED: This is not that case by any chance?

DR. SCHULZ: No.

DR. BREED: Kindly show me the polyp.

DR. SCHULZ: There is no true polyp, but there are numerous soft-tissue masses extending into the gas bubble of the stomach and displacing the barium. Here is the defect in the stomach in which the ulcer lay. By all the rules that should be a neoplasm.

DR. BREED: I am going to stick to the rules, because it is a fairly straightforward history and I see no reason for trying to be too smart. The patient had an ulcer for ten years and then developed a cancer at the site of the ulcer.

DR. BENJAMIN CASTLEMAN: Is there any other comment?

DR. J. H. MEANS: I think it could be a leiomyoma. I am not offering that as one of the possibilities, but it seems to me that I recall that they are apt to run a more or less benign course for some years and then become increasingly malignant.

DR. CASTLEMAN: They usually give a long history of bleeding and become larger extremely slowly. A few of them do become malignant, however.

DR. MEANS: What about other tumors of the stomach, such as fibroma?

DR. CASTLEMAN: I do not believe that an accurate differential diagnosis of the various intramural tumors—fibroma, neurofibroma and leiomyoma—can be made clinically or by x-ray, or even microscopically in some cases.

DR. MEANS: I discussed that point with Dr. George W. Holmes some years ago. He claimed that when they were smooth and round it was one thing, and when lobulated it was another. How about the significance of these differences? Does the lobulation mean anything?

DR. CASTLEMAN: A definite lobulation is perhaps more in favor of a neurofibroma, but all these

tumors tend to be well circumscribed and round. They often have a central ulceration.

DR. SCHULZ: An intramural tumor is usually quite characteristic in appearance roentgenologically. It displaces or smooths out the mucosa rather than showing soft-tissue masses extending into the lumen of the stomach.

DR. BREED: I shall have to add that he had gastritis as well as cancer.

DR. BENEDICT: I think the ten-year history is in favor of a benign lesion.

DR. BREED: Such as?

DR. BENEDICT: Benign ulcer. Of course that brings up the question, Do benign ulcers ever become malignant? A lot of people think that they never do.

DR. CASTLEMAN: I was about to take issue with Dr. Breed's statement.

DR. BREED: I have two against me.

DR. CASTLEMAN: We are certain that an ulcer remains an ulcer and does not degenerate into a carcinoma. I believe that there are a few cases with definite ulceration in the stomach, proved roentgenologically, that ten years later develop carcinoma in the same location—that is, in the ulcer. If one checks some of these histories of long-standing ulcer with carcinomatous degeneration one often discovers that the ulcer was in the duodenum and not in the stomach, and things of that sort. It is true that carcinoma can remain in the precancerous state,—carcinoma in situ,—limited to the mucosa, without invasion over a long period of time. We have seen several examples of this condition.* Furthermore, precancerous lesions have been known to exist for six or seven years in the cervix. These carcinomas in situ may ulcerate; they are, however, ulcerating carcinomas, rather than carcinomas developing in benign ulcers.

DR. BREED: Along that line, it did occur to me when I was studying this case that the patient might have had a duodenal ulcer and that this was a new malignant lesion. I am willing to go back to that idea. Since the pathologist insists that ulcers do not degenerate, I shall probably have to agree; but I still think that the lesion was malignant.

DR. MEANS: The picture could fit with carcinoma in situ, could it not?

DR. CASTLEMAN: It could, although ten years is a long time for carcinoma in situ; most of them are under five years in duration.

DR. RONALD C. SNIFFEN: This area of the stomach is rather unusual for carcinoma in situ, is it not?

*Mallory, T. B. Carcinoma in situ of stomach and its bearing on histogenesis of malignant ulcers. *Arch. Path.* 30:348-362, 1940.

DR. CASTLEMAN: Yes; most of the lesions have been in the prepyloric region.

DR. BREED: The patient may have had a duodenal ulcer for ten years and then developed cancer of the stomach in the cardia. I am willing to accept that.

CLINICAL DIAGNOSIS

Carcinoma of stomach.

DR. BREED'S DIAGNOSES

Carcinoma of stomach.

Duodenal ulcer?

Chronic gastritis.

ANATOMICAL DIAGNOSIS

Acute and chronic phlegmonous gastritis, with gastric erosions and ulcerations.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The surgeon's operative notes state that he was able to feel two ulcers, one close to the cardia and one 5 or 6 cm. below that. He thought that the lesion was probably benign, but since he was not absolutely sure, and since the ulcers were high in the cardia, he believed that the patient would do better by having a resection.

When the stomach was opened, we found innumerable ulcers. Some were old, measuring 2 or 3 mm. in diameter, with a greenish-fibrinoid base, the result of necrosis. Between the ulcers the mucosa was markedly edematous and red and the rugae were prominent. This appearance reminded me of that of ulcerative colitis, with bridges between the ulcers. It might be called a phlegmonous gastritis.

Microscopic sections showed an acute and chronic inflammatory reaction throughout the whole wall, with necrosis of the mucosa and the formation of erosions and deep ulcers. We were unable to find a chronic ulcer that the patient might have had for ten years. It may have been in the duodenum, or the more recent disease may have covered it.

DR. BENEDICT: Were they true peptic ulcers, or erosions?

DR. CASTLEMAN: Both were present.

DR. BENEDICT: How do you distinguish between them?

DR. CASTLEMAN: One speaks of an erosion if the destruction extends to the muscularis mucosa; if it goes beyond that, it is an ulcer. The etiology is the same.

There was no evidence of malignant disease.

CASE 29422

PRESENTATION OF CASE

A fifty-four-year-old press operator entered the hospital because of uterine prolapse.

The patient had been in good health all her life. She had had four pregnancies, only two of which terminated successfully. About eight years before admission she was told by her physician that she had prolapse. About the same time she developed increased frequency and occasional slight incontinence. There was no nocturia. About one year before entry she noted protrusion of a mass between her legs. At first the mass appeared after prolonged standing and on coughing or exertion. The prolapse increased in amount and she developed low abdominal pain, slightly increased urinary frequency and occasional slight incontinence. There was nocturia (one to three times). She had lost 30 pounds during the year before entry.

Physical examination showed an obese woman in no distress. The fundic vessels were tortuous, and there was moderate arteriovenous nicking. The lungs were clear. The heart was normal. The sounds were regular and of good quality. The liver edge was palpated two fingerbreadths below the costal margin. There was an "enormous" rectocele, with an ulcer on the posterior vaginal wall near the cervix and another on the cervix. A large cystocele was also present. The fundus of the uterus was not particularly enlarged; it was palpated almost at the level of the introitus.

The blood pressure was 184 systolic, 110 diastolic. The temperature was 99.2°F, the pulse 88 and the respirations 20.

Examination of the blood showed a hemoglobin of 90 per cent and a white-cell count of 12,250. Urinalysis revealed a ++ test for albumin; the sediment contained 3 white cells per high-power field. The blood Hinton test was negative. A urine culture was negative. A vaginal culture showed colon bacilli, *Staphylococcus aureus* and beta-hemolytic streptococci.

On the third hospital day a vaginal hysterectomy and perineorrhaphy were performed under ether and nitrous oxide anesthesia. During the course of the operation, which lasted three hours, the blood pressure fell to 80 systolic, 40 diastolic, with a rise of pulse to 100. With intravenous fluids, however, the pressure gradually rose to 100 systolic, 70 diastolic, at which level it remained the last hour of the operation. At the end of the operation she was given 500 cc. each of plasma and blood, with a subsequent rise of systolic blood pressure to 220.

Following operation, the patient failed to regain consciousness or even respond to painful stimuli.

Examination revealed absence of motion in any part of the body. The neck was not stiff. The abdomen and heart were not "too remarkable." There was no upward motion of the eyes, which remained fixed, looking straight ahead. The pupils were dilated, measuring 4 mm. in diameter. They were round and regular but failed to react to light. The face was flat, flabby, symmetrical and motionless. The tongue moved when stimulated. The muscles of the extremities were symmetrical. A slight increased resistance to passive stretch was noted in the right leg. There were no adventitious movements. No reaction to pinpricks could be elicited. The biceps, triceps, radial, knee and ankle reflexes were "very lively," with increased knee jerks on the right. Bilateral ankle clonus and Babinski reflexes were present, and there was an increased Hoffmann sign on the right. The non-protein nitrogen was 18 mg. per cent, and the chloride 100.3 milliequiv. per liter.

The patient remained unconscious, and died twenty hours after operation.

DIFFERENTIAL DIAGNOSIS

DR. JULIA G. ARROWOOD: This discussion should answer two questions: By what accident or mechanism did this catastrophe occur? Was it possible to foresee and prevent it? Since at these meetings we desire to arrive at the final diagnosis as a sort of climax, let us first examine the somewhat meager information we have in search of an answer to the second question.

The patient was obese, arteriosclerotic and hypertensive. The cardiac examination is disposed of in two sentences. "The heart was normal. The sounds were regular and of good quality." With a diastolic pressure of 110, I should be inclined to expect some cardiac enlargement and hypertrophy. It is stated that she had nocturia. How did the quantity of day and night urine compare?

DR. BENJAMIN CASTLEMAN: There is no further statement in the record.

DR. ARROWOOD: Was there a cardiac consultation or an electrocardiogram?

DR. CASTLEMAN: No.

DR. ARROWOOD: The temperature of 99.2°F. and the white-cell count of 12,250 can be explained by the ulcerated condition of the large cystocele and rectocele. It would be interesting, however, to know if she had a daily elevation of temperature during the preoperative hospital stay.

DR. CASTLEMAN: The temperature on admission was 99.2°F. It fell to normal the following day and remained so during the entire preoperative period.

DR. ARROWOOD: Whether or not this death could have been foreseen and prevented, one can

only say that patients of this type are notoriously poor risks, and that their cardiac status should be carefully investigated before surgery is undertaken.

It is obvious that during the operative period this woman must have had an episode of cerebral anoxia, which resulted in complete functional decerebration. The persistent coma, with absent superficial reflexes, hyperactive deep reflexes and the presence of bilateral ankle clonus and Babinski reflexes, indicates widespread cerebral damage. It seems likely that this may have occurred in one of three ways: from asphyxia following overdosage of the anesthetic agent, from respiratory obstruction or from a cerebrovascular accident during the operation.

There is no mention of any untoward happening, but I would like some additional information about the course of anesthesia. Was the induction satisfactory? Was there cyanosis, obstruction or respiratory difficulty at any time? What was the anesthetist's estimate of the anesthesia and of the patient's condition at its close? I assume, however, that there was no period of acute respiratory failure to account for the patient's condition.

The second possibility is that the cerebral damage was produced by hypoxia lasting over a considerable period of time. The lithotomy position in an obese patient causes considerable embarrassment to respiration by pressure of the abdominal contents against the diaphragm. The operation lasted three hours, and the blood pressure fell to 80 systolic, 40 diastolic. In this connection, I should like to know what the initial blood-pressure reading on the anesthesia sheet is, and when the fall occurred. It is stated, "The pressure gradually rose to 100 systolic, 70 diastolic, at which level it remained the last hour of the operation." What was the blood pressure on the patient's return to the ward, and how long was it before it reached a more nearly normal level—say 130 systolic, 80 diastolic? My point is that hypoxia from respiratory embarrassment due to position, combined with a blood pressure that was very low for this patient, whose blood-pressure reading on the ward was 184 systolic, 110 diastolic, might have been sufficient to produce the fatal brain damage.

The third possibility is that the patient had a cerebrovascular accident during the time of anesthesia and operation. This could have been a massive hemorrhage with continued bleeding, reaching proportions sufficient to cause the extensive damage that occurred. It is quite conceivable that there had been previous coronary disease with cardiac infarction and mural thrombosis and such a cardiac thrombus could have been the origin of a cerebral embolus, which in turn formed the basis

for a growing thrombus. Finally it is possible that during the long period of hypotension in this arteriosclerotic patient, a thrombus could have originated in a cerebral vessel, the early signs being masked by the anesthesia.

To be specific concerning my diagnosis, I do not believe that the patient had any episode of acute anoxia to account for her death, but that she had a cerebrovascular accident, either thrombosis, hemorrhage or embolus. I do not believe it is possible to differentiate these with the evidence we have, but my guess is in the order named.

DR. CASTLEMAN: Dr. Brenizer, you saw this patient during operation. Will you tell us about the case?

DR. A. G. BRENIZER: The patient had good color throughout the operation. There was no cyanosis or anything like that, just a drop in blood pressure uncontrolled by intravenous fluids.

DR. RICHLARD H. SWEET: Was the intravenous solution running before or after the fall in blood pressure had occurred?

DR. BRENIZER: It was started as soon as we were notified that the blood pressure was falling. The 5 per cent dextrose and physiologic saline solution was changed over to plasma as soon as possible.

DR. SWEET: Was there much loss of blood?

DR. BRENIZER: I should say moderate.

DR. SWEET: There is apt to be with that type of operation.

DR. CHARLES S. KUBIK: Was there anything else to indicate that something had happened suddenly? Was the drop in blood pressure rapid?

DR. BRENIZER: The drop in blood pressure was rather sudden.

DR. FREDERIC B. MAYO: In answer to Dr. Arrowood's question concerning neurologic opinion, three diagnoses were considered: thrombosis at the time that the blood pressure dropped; hemorrhage when the blood pressure rose so high; and cerebral anoxia, which was subsequently ruled out by information that anesthesia was uneventful.

DR. SWEET: One of the conditions that I fear most in practicing surgery is the marked drop in pressure from ether or nitrous oxide anesthesia in a person who has or may have cardiovascular disease, especially those with hypertension. This patient probably had hypertension, and the fall to the level that she reached is, in itself, enough to explain the things that happened to her. The possibility that such an accident may occur is one reason why many of us do not use spinal anesthesia in patients of that sort.

DR. JACOB LERMAN: Sudden rise in systolic blood pressure from a low level to 220 suggests a rapid increase in intracranial pressure. That would per-

haps fit more with subarachnoid than with cerebral hemorrhage.

CLINICAL DIAGNOSIS

Cerebral anoxia.

DR. ARROWOOD'S DIAGNOSIS

Cerebrovascular accident (thrombosis, hemorrhage or embolus).

ANATOMICAL DIAGNOSES

Cerebral embolus, left middle cerebral artery.
Cerebral infarction with temporal pressure cone
Subacute bacterial endocarditis, mitral valve
Chronic rheumatic endocarditis, with stenosis of mitral valve.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: At autopsy this patient showed a cerebral embolus, which Dr. Kubik will describe. The heart was moderately enlarged, weighing 370

gm. There was a marked degree of mitral stenosis, on which was superimposed a subacute bacterial endocarditis that must have been present long before operation. A thrombus had undoubtedly broken off and entered the brain.

DR. CHARLES S. KUBIK: The embolus was in the left middle cerebral artery, and infarction of a large portion of the left cerebral hemisphere corresponding to the distribution of the occluded artery had occurred. An unusual feature was marked swelling of the left hemisphere, with herniation of the hippocampal gyrus into the notch of the tentorium and resulting compression of the midbrain. The aqueduct was flattened, and there were small hemorrhages in the midbrain. The herniation, or temporal pressure cone, through its effect on the midbrain unquestionably accounted for the dilated fixed pupils and for the bilateral extensor plantar responses and was probably responsible to a large degree for the deep state of coma and eventual fatal outcome

FOREIGN RELIEF AND REHABILITATION

WAR can leave little but disaster in its wake, and it is to offset its miseries so far as possible and as quickly as possible that the Office of Foreign Relief and Rehabilitation Operations was organized. This organization, under the directorship of former Governor Lehman, of New York, has recently reported on activities of the medical personnel attached to its North African mission, and described its preparations for medical and sanitary measures in future relief theaters.

In North Africa, public-health officers assigned

to OFRRO by the U. S. Public Health Service have been working with the North African relief and rehabilitation mission for the past six months, gaining valuable experience in medical relief. They have been attached by General Eisenhower to the military command, in charge of activities affecting civilian health, and they work through the French civil authorities, utilizing existing health and governmental services and professional personnel.

Acting in a military capacity, members of the OFRRO serve practically as public-health officers of the Army. Thus, medical personnel of the mission entered Tunis within twenty-four hours after the city's fall, establishing sanitary controls for the region, and the same was done in the Panteliera and Lampedusa campaigns.

Among the varied duties of the medical personnel of OFRRO have been assisting the French authorities in obtaining lend-lease medical supplies, helping to restore normal health service in cities and rural districts, advising in the creation of modern health departments, as was done at Oran, establishing de-lousing stations to check the spread of typhus, and disinsecticizing airplanes to prevent the spread of insect-borne disease.

Meanwhile, in order that future relief programs in distant theaters may be expeditiously carried out, different types of standard packaged units of medical supplies are being assembled in the United States for immediate shipment to any area. Thus, one basic unit containing the minimal medical supplies required for the control of the more frequent diseases of world-wide occurrence is designed to meet the needs of a group of 100,000 people for a one-month period, and includes some one hundred and fifty items. A larger unit, containing approximately fifteen hundred items, is planned to care for a group of 1,000,000 people for a three-month period. Supplemental packages are designed to combat epidemic disease, or conditions peculiar to certain regions.

In addition, standard hospital units have been prepared. One includes the essential equipment

for a 50-bed hospital, and another that for a 150-bed hospital. Laboratory units contain equipment for an epidemic-control laboratory, an emergency field laboratory, a laboratory for a 50-bed or a 150-bed hospital, a central pathological laboratory and a laboratory supply center. A few public-health teams are also being recruited, a typical team being made up of a health officer, a sanitary engineer, a pediatrician, a medical nutritionist, a medical supply officer, a nursing specialist, a malarialogist, if necessary, and a hospital nutritionist.

Our nation, more power to it, has always been eager to spread its good works abroad. In the excitement of rebuilding the Eastern Hemisphere, however, we must not lose sight of our own problems that are just causes for anxiety and concern. In eventually putting our own house in order we must accept the challenge of a rising venereal-disease rate; we must cope with an influx of tropical diseases; we must face, far more intelligently and humanely than we have yet done, the problem of rehabilitation of many thousands of young men rejected by their draft boards or discharged from the army as unfit for further military service; and, last but not least, we must provide some means, other than that proposed by Senators Wagner and Murray, for improving the health of the people of the Nation.

SHOCK THERAPY

The brilliant results obtained by the use of plasma and plasma substitutes in shock are well known and occupy an important place in modern war surgery. But investigators have not limited their observations to this one therapeutic method.

The question whether to warm or cool the patient in shock has recently received considerable attention. First-aid courses continue to teach that the application of external heat is a cardinal principle in the treatment of shock—indeed it is practically the only method of therapy (except leaving the patient alone) that may be practiced by the first-aid worker; and it is often assumed that a patient cannot be overheated so long as his

skin is not burned by hot applications. Yet all current reports that bear on the subject clearly indicate that the overzealous application of heat is harmful in shock. This is equally true whether it is due to burns,¹ trauma or hemorrhage.² Indeed, a little thought along physiologic lines makes this obvious. Shock is a state in which the circulating blood volume is inadequate, with resulting anoxia. The local application of heat produces cutaneous vasodilatation, and this, in turn, causes the blood volume to become even more inadequate, owing to the greater vascular bed; furthermore, an increase in tissue metabolism resulting from warming the whole body increases the anoxia, and sweating augments dehydration. It therefore seems unwise to use hot-water bottles, heating pads and other sources of external heat to such an extent that the internal temperature of the body is raised above normal levels. As a matter of fact, induced hyperthermia may reproduce the shock syndrome.

As a corollary, it might be supposed that cooling of the body would be beneficial. However, two experimental studies^{1,2} have shown that this may also be inadvisable, although not quite so dangerous as overheating. In experimental burns in rats, the optimal environmental temperature range for survival seems to lie between 75 and 95°F.¹ Local refrigeration of an injured extremity may, on the other hand, be beneficial if ice is applied to the extremity during a prolonged crush³ or during the prolonged application of a tourniquet.⁴ It is obvious that more studies are required to determine the true value of local refrigeration in traumatic shock.

Stem,⁵ from Russia, offers evidence that secondary shock is benefited by the intracisternal injection of a solution of potassium phosphate. She claims that the potassium stimulates the sympathetic centers and that the phosphate by reducing the concentration of ionized calcium, depresses parasympathetic tone. Since sympathomimetic drugs are generally understood to be ineffective or harmful in shock, confirmation of this observation, especially with reference to the ultimate rates of survival, is desirable.

MEDICAL EPONYM

HEERFORDT'S SYNDROME

In an article entitled "Über eine 'Febris uveoparotidea subchronica,' an der Glandula parotis und der Uvea des Auges lokalisiert und häufig mit Paresen cerebrosptinaler Nerven kompliziert [Febris Uveoparotidea Subchronica, Localized in the Parotid Gland and the Uvea of the Eye, and Frequently Complicated by Pareses of the Cerebrospinal Nerves]," in Albrecht von Graefes *Archiv für Ophthalmologie* (70:254-273, 1909), Dr. C. F. Heerfordt reports three cases. A portion of the translation follows:

The cases reported by me, together with that of Daireaux-Pechin and von Collomb's case constitute a clinically well-defined disease group with such peculiar characteristics that it would seem quite proper to establish them—for the present—as a special disease entity—a "febris uveoparotidea subchronica"—that is different from acute epidemic parotid fever.

We consider the following to be characteristic of this febris uveoparotidea subchronica: the protracted course of the illness, the prolonged low-grade fever, the localizations in the parotid gland and the uvea of the eye and, in addition, the frequent occurrence of complicating pareses of the cerebrospinal nerves. Finally, in my observation, this disease entity seems to be only mildly infectious.

DEATH

ATWOOD—CHARLES A. ATWOOD, M.D., of Taunton, died October 10. He was in his eighty-third year.

Dr. Atwood received his degree from Harvard Medical School in 1883. He was a member of the staff of the Morton Hospital and a consultant of the Taunton State Hospital. He had been medical examiner in the First Bristol District many years. He was a member of the Massachusetts Medical Society and the American Medical Association.

A brother survives.

CORRESPONDENCE

DEPRIVATION OF LICENSE

To the Editor: At a meeting of the Board of Registration in Medicine held October 6, the Board voted to revoke the license of Dr. Theodore Rosen, 9A Summit Avenue, Brookline, because of gross misconduct in the practice of his profession as shown by his conviction in court.

BOOK REVIEW

Transurethral Prostatectomy. By Reed M. Nesbit, M.D. 4°, cloth, 192 pp., with 62 plates. Springfield, Illinois: Charles C Thomas, 1943. \$7.50.

This monograph is timely, and fills the need for an orderly description of transurethral resection. The material is arranged in four sections.

The first consists of ten chapters, which present the mechanics and principles of prostatic resection and comprise the most significant contribution of this monograph. Practical clinical information can be obtained from these clearly and well-written chapters. The excellent drawings by Mr. Didusch simplify and co-ordinate the various steps in the procedure.

The New England urologist will be interested in the second section (Chapter XI), which is an enthusiastic appraisal of the author's management of prostatism by transurethral surgery. The conservative resectionist who limits and selects his patients for transurethral surgery will note that this is a method not only for prostatic resection but also for transurethral prostatectomy, since the author does not hesitate to operate on glands yielding 100 to 150 gm. of tissue. He will read with envy and amazement that the technic offers the following advantages—freedom from postoperative discomfort and sepsis, bed confinement only for the day of operation, no postoperative strictures or urinary incontinence and a mortality rate as low as 1.2 per cent. Over a decade has passed since the introduction of the present methods of transurethral resection. With the comparative safety of modern surgery, the morbidity of a technic is almost as important as the mortality. This chapter occupies but 10 pages and, in the opinion of the reviewer, is entirely inadequate. It would be more convincing if a detailed and faithful follow-up study, including postoperative urologic and roentgenologic examinations, were a part of this chapter. Many urologists have subsequently operated on patients who had had transurethral surgery done by prominent resectionists, and it is surprising that such failures do not appear in the end-result statistics. It seems as though it were time for a definite evaluation of this procedure to be made.

The third section (Chapter XII) deals with the history of transurethral prostatic resection. It makes interesting reading and is well illustrated. The fourth is composed of a well-selected bibliography, grouped alphabetically according to the authors' names and also classified according to pertinent subdivisions.

This monograph is instructive but the reviewer does not believe that it will be instrumental in converting the conservative urologist to the author's point of view.

CIVILIAN MEDICAL DEFENSE AND ITS ADAPTATION TO PEACETIME CIVIL LIFE*

A. WILLIAM REGGIO, Senior Surgeon (R), U.S.P.H.S.†

BOSTON

OUR normal way of living has been greatly upset, and we have gradually been adjusting ourselves to new conditions forced on us as a nation and as individuals as the result of a war not of our own choosing. We have been forced into a war by enemies who were quite sure that we, as a nation, could not get together in time to avoid defeat. They considered us selfish, stupid and soft because we lived at peace with our neighbors, respected the rights of others, and were unprepared to meet and repel their sneaking attack upon us. Perhaps we were a bit blind to the dangers threatening us, but somehow it is not in our make-up to attribute to any human being such low qualities as we have found our enemies to possess!

Be that as it may, we have swung into line in a manner characteristic of our way of doing things. Once we began, nothing was allowed to stand in the way of accomplishing the end toward which all our efforts were directed. That end is quite some way off as yet, but all of us and all our allies know that the ultimate end is victory for us. And—our enemies of the Axis know it, but do not as yet admit it—our loud!

The thought comes to mind, however, in all this hard struggle and increasing sacrifice, of what is going to happen when the final victory is won and we once again return to our peaceful manner of living. Shall we again lapse into our former error of assuming that all nations can be trusted to carry out their signed covenants? Are we going to forget the lessons we have learned the hard way? Are we going to allow the work done in setting up the medical organization of the Office of Civilian Defense to go to seed and fail to profit by it in the future just because peace has returned? I do not believe so—any

more than we should disband our police force just because no murder had been committed recently or there had been no riots for some time.

Before the Office of Civilian Defense was created, the only adequately organized disaster setup was the American Red Cross, but even it would have considerable difficulty in handling any sudden large-scale enemy action against us. This threat is spurring us on to get ready for the time when enemy action will strike this country, and should continue to drive us to perfect our civilian defenses. The threat has by no means been removed as yet, and may be even more imminent and nearer than we think. As the enemy becomes more desperate and despairing of the victory that they assumed to be certain for themselves, they may readily resort to action against our shores in an attempt to intimidate us and bolster their own failing morale. The work to perfect our civilian defense has been no small task, and the magnitude of it can be somewhat appreciated when one realizes that practically every community in the country has organized itself to ensure, in so far as possible, the care of injured people. Property when destroyed can be restored and rebuilt. Life cannot. Death is permanent.

In the Boston night-club disaster of some six months ago, it takes but little imagination to visualize what might have happened regarding loss of life if the civilian-defense organization had not been prepared to function. Although the deaths reached the distressing number of 491, it is safe to say that this number would have been larger but for the functioning of the Emergency Medical Service. Ambulances; doctors, nurses and hospitals were available and ready to handle the injured immediately after the disaster occurred. One thing above all stands out as instrumental in saving lives—the lack of it would quite definitely have created a most serious problem, but owing to the Emergency Medical Service it was instantly avail-

*Presented at the annual meeting of the New Hampshire Medical Society, Manchester, May 12, 1943.

†Regional medical officer, Office of Civilian Defense, instructor in surgery, Harvard Medical School, visiting surgeon, Massachusetts General Hospital.

able in abundance and to spare. I refer of course to blood plasma. At the time of the disaster over 2700 units of plasma set aside for the Emergency Medical Service were instantly available in the city itself, and a total of 3564 units in the State. It is doubtful whether such a supply would have been so quickly available under peacetime conditions. This plasma was on hand largely because of the tireless efforts of those whose job it was to think and plan for a catastrophe that might strike any community. This work is being carried on, and as of April 1 of this year, sixty hospitals in New England reported a total of 23,121 plasma units in storage and immediately available.

This is just one example of why we must not allow ourselves to relapse into blissful inertia when war conditions are no longer present and a general letdown would threaten the safety of any large number of people. How much plasma would have been available in the hospitals under the old conditions is, of course, a matter of speculation; but it is doubtful whether anywhere near an adequate number of units for a disaster of this magnitude would have been on hand, although a small number of units might have been obtainable from commercial sources.

What about the hospitals and the emergency organizations they have set up? Handicapped as these hospitals are by their greatly reduced staffs and personnel, they are, nevertheless, ready to function at a moment's notice should large numbers of casualties suddenly be brought to their doors. This has been no small task of organization in the face of continually dwindling medical and nursing staffs, as well as of the other personnel so necessary for the adequate functioning of any hospital. Being forced to run a hospital with about half its usual peacetime personnel is no easy job, to say nothing of the additional difficulties in trying to maintain and replace supplies of all kinds when they are becoming more and more difficult to obtain; and yet hospital administrators and superintendents are doing just these things.

The peacetime civilian hospital organized on an emergency wartime basis has already proved itself in a serious disaster not presumably of enemy origin. This same emergency that proved the worth and wisdom of a large store of plasma also showed the value of such civilian defense efforts in hospital organization.

It may not be generally known that during the Coconut Grove disaster 80 per cent of the casualties were brought into the emergency wards of two hospitals at the rate of one case in every eleven seconds. One hospital received 325 casualties, another 114. It needs no great stretch of the imagination to visualize what confusion might easily have resulted had not the Emergency Medical

Service been established, and through practice drills each person's role been set down and everyone made familiar with his specific duties. Short-handed as these hospitals were, there was no confusion; and it is quite certain that because of the well-devised plan and the well-drilled organization, not a single life was needlessly sacrificed or even jeopardized.

The reserve pool of nurses that had been organized for some time was called on, and the response on the part of these retired nurses to fill in for the emergency was more than adequate for the need. They came immediately and served without question, uncomplainingly and gladly. Many worked overtime for as long as there was any need for them. The Red Cross volunteer nurses' aides swung into line, responding in large numbers to fill any position requested. The entire Red Cross setup of ambulances and canteens worked steadily, in some instances day and night—long hours for many of them.

Why do I dwell at length on this particular disaster? It is for the purpose of bringing out the point that had it not been for the Emergency Medical Service the mortality would unquestionably have been much higher.

We are learning during these strenuous times how to function adequately with greatly reduced resources. We are building up a medical organization that will function on the instant, without becoming overwhelmed by a sudden wave of casualties in spite of fewer people to handle the situation. Through practice sessions the weak points are brought out, and these can be remedied at the next field exercise. We are learning to accomplish more, in spite of having less with which to work. We are learning the true value of many things to which we have in the past given but little thought because there was always plenty more where they came from. In plain language, we are learning the hard way to be less wasteful and more appreciative and conserving of what we have. We can already make less go farther, and much to our surprise find that it works rather well.

Another factor developed by the present threatening conditions is the arrangement for mutual aid between communities and states. It is quite possible that a state could be so seriously hit by disaster that it was beyond its own resources to cope with the conditions. The resources of neighboring states are now available and ready for such an eventuality, and they can send assistance quickly with little confusion, since their own emergency resources are well known and immediately available.

The work that has gone into the development and organization of medical resources should not

be lightly cast aside when peace returns. These services, possibly in a modified form, are a valuable adjunct in the event of any catastrophe involving human lives.

The question of an adequate number of nurses for the staffing of hospitals and for the taking care of patients in their homes is a serious one. "Luxury nursing," as it may be termed, is practically a thing of the past, and there is considerable difficulty in obtaining even essential and necessary nursing care. The replacement of nurses who have entered the armed forces is becoming increasingly difficult, since the number of new applicants for training for the nursing profession is not keeping up with the number of trained nurses being withdrawn. The reasons for this are many and readily understandable, but the solution of the problem is difficult.*

The establishment of pools from which nurses can be obtained when urgently needed is of much value. Many retired nurses are willing and glad to return to work, giving as many hours as they can. A number of these same nurses are taking refresher courses in nearby hospitals to brush up on such advances in nursing as have taken place since last they were in active practice.

Physicians, retired for some time, are back at work—especially in the hospitals—and having the time of their lives at it. The term "retiring age" under the present emergency conditions is no longer a compliment. Much valuable work is being done by the older men who so gladly return to work filling the vacancies caused by the younger ones who have gone into the service. All this wartime activity stimulates us to look ahead and to prepare our medical resources so that they will be ready to function when enemy action hits us and the care of casualties is imperative.

Why run the risk of throwing away all this tremendous effort just because the threat of enemy action against us will have been removed with the return of peace? Floods, hurricanes, conflagrations and catastrophes of one kind or another will continue at intervals even in peacetime. It would be little short of criminal to allow the preparations we have made for mutual aid in caring for those whom disaster will strike under war conditions to be dissipated and forgotten when peace returns. The effort necessary to keep a civilian-defense organization going in peacetime would of course be minimal, and the knowledge, coupled with a feeling of safety, that we were prepared to meet disaster in any form would more than repay the efforts of those people farsighted enough to hold such an organization together even if only on a small scale.

This trained and disciplined group would act with greater efficiency in aiding the already existing peacetime organizations than would people hurriedly gathered together, and would provide a reservoir of manpower that could be drawn on, with the knowledge that the needs of any particular situation could be met. By being ready they could make their work more effective. The practice gained will be invaluable if the enemy strikes, and inversely, experiences gained from enemy attacks will prove profitable in peacetime disasters. Co-operation and not regimentation has always been the American way. Mutual aid as exemplified by the civilian-defense organization is a typically American way of aiding our neighbors who are in distress. This may be in a local community, within a state or in another state—it makes no difference. The war has caused us to develop and perfect an organization for mutual aid unparalleled in our history. Without the Emergency Medical Service, untold numbers would needlessly suffer and die.

The value of all this is not conjectural. We have proof, not only in England but also in our own country, in the time when civilian-defense forces have aided materially in natural disasters caused by fire and flood. The aid rendered has been so valuable that it seems neither reasonable nor possible that a thinking people would be willing to give it all up when the present emergency is over.

My closing thought and appeal is to ask you all to consider seriously the possibility that the emergency medical services in your own communities will carry on and will preserve a type of organization that could be called up at any time to save life and property and alleviate the human misery that goes hand in hand with any disaster. An emergency, anticipated and prepared for, ceases to be an emergency. It is up to us to see to it that the lessons learned from the Emergency Medical Service are not thrown away.

17 Court Street

DISCUSSION

DR. C. H. PARSONS, Concord: Dr. Reggio's description of the value after the war of the services furnished by the Office of Civilian Defense is much to the point. However, they can be of value then only as they are adequately organized at the present time. The majority of our communities are extremely well organized. That has been proved in the several highly successful drills that have been held. The drills, however, have shown certain deficiencies, which have been due primarily to lack of attention to the details of organization and to inadequate practice.

During the summer, an attempt will be made by the state committee to aid each community in reorganizing

*At the time this paper was presented, the United States Cadet Nurse Corps program was not under way.

its medical services according to a plan that has been made necessary by the present types of bombing and by the new methods of medical care following thermal burns. This reorganization has been shown necessary by the events taking place during and after the Coconut Grove fire.

I am sure that the emergency medical services in the communities of New Hampshire will be adequately trained and organized to take care of any incident, should such an unhappy state of affairs occur.

DR. W. J. P. DYE, Wolfeboro: The question of civilian defense has been adequately and inspiringly covered by Dr. Reggio. A great many of us, particularly those in the smaller communities such as that from which I come, have a tendency to be optimistic about the situation. It looks as though things were rolling fairly well, and that the chances of any incidents in this country are quite small, so far as actual bombing or things of that sort are concerned; nevertheless, Dr. Reggio has men-

tioned that there is a possibility of nuisance bombing or some attempt to destroy civilian morale.

The entire civilian setup is, on the whole, so far as I can judge from my own and the neighboring communities, fairly well organized. A typical incident occurred in Wolfeboro not so long ago, when a large dairy farm suddenly caught fire in the early morning hours. It was in the middle of the winter, when the temperature was subzero, and the firemen worked under considerable difficulties. The motor corps and various other units were on the scene practically as soon as the firemen were, and they furnished hot coffee and gave first-aid care promptly and with a great deal of interest.

That was a small casualty in a small community. But if it is multiplied by many such casualties in large communities, such as are likely to happen in peacetime, and if we have, as Dr. Reggio has said, continued interest and continued practice in civilian-defense methods and in organization, then all these emergencies can be better met and we shall have achieved quite an advance in community and national service.

THE TREATMENT OF ANGINA PECTORIS*

A Summary of Ten Years' Objective Study

JOSEPH E. F. RISEMAN, M.D.†

BOSTON

IT IS well recognized that patients differ in their response to therapy, yet in evaluating the efficacy of treatment in angina pectoris this fact has not been taken into consideration. It is also self evident that various methods of therapy must differ considerably in value, yet there is little in the published reports or in the claims of the pharmaceutical houses to permit comparison.

Objective studies of the value of treatment in angina pectoris have been carried out in a special clinic of the Beth Israel Hospital since 1933. To date, sixty-eight different methods of chemical, physical and surgical therapy have been studied by clinical and objective procedures that permit unbiased comparison of effectiveness. Some of the results have been reported.¹⁻⁷ The detailed data of these and the unreported results are too voluminous to be presented in detail here, and will be the subject of a forthcoming monograph.

The purpose of this paper is to present a summary of these results, with special reference to variations in the response to therapy and to a practical plan of treatment with the methods most likely to be of value.

METHODS OF STUDY

The objective studies that have been carried out have been based on the following self-evident premises. First, since angina pectoris occurs only

in human beings, the value of therapy must be measured in terms of patients. Secondly, since exercise is the commonest precipitating cause of attacks, any treatment to be of value must enable the patient subsequently to do more work before experiencing pain. Observations during the last ten years have shown that the value of any form of treatment can be determined objectively by measuring the amount of work that can be done before angina is induced, provided that the measurements are made under conditions closely simulating those responsible for the majority of attacks in daily life, and that they are standardized in such a manner that the response to therapy is the only variable factor that can influence the exercise tolerance.

The standardized exercise-tolerance test. Previous studies¹ have shown that several factors materially influence the amount of work that can be done by patients with angina pectoris before pain is induced (Fig. 1‡). These factors have usually been overlooked by investigators studying the exercise tolerance of such patients. The importance of exercise in the cold must be emphasized, for if patients exercise at ordinary room temperatures, approximately one third fail to develop an attack,^{1, 8, 9} whereas in others the exercise tolerance varies independently of therapy. If these conditions are properly standardized, as shown in Fig.

ure 2, the amount of work necessary to induce angina becomes remarkably constant (usually

sions of the clinical response to therapy were recorded, and also the number of attacks experienced

FIGURE 1.

around 10 per cent of the average exercise tolerance).

Method of administering medication for evaluating the response to therapy. The variable course of angina pectoris makes it necessary to evaluate

since the last visit. In addition, the standardized exercise tolerance was determined one or two hours after the last dose of medication.

Several months of observation were necessary to determine the usual frequency of attacks in daily

FIGURE 2.

the effect of therapy at frequent intervals. Patients were seen in a special clinic weekly. At each visit the patient's and the physician's impres-

life and the usual exercise tolerance. When these had been ascertained, medication was given three or four times daily for at least a week. If there

was no evidence of improvement, another therapeutic measure was tried. If there appeared to be a therapeutic response, a placebo resembling the drug being evaluated was given for one or two weeks or until the apparent therapeutic response disappeared. Later the studies were repeated or

Correlation between the results of the standardized exercise-tolerance test and the clinical response to therapy. The standardized exercise-tolerance test makes it possible to differentiate real improvement due to therapy and apparent improvement unrelated to it. Patients who show an in-

at least two occasions, the medication being given in disguised form—painted with tincture of cudbear, sugar coated or enclosed in a capsule.

Electrocardiographic studies gave further objective evidence that the response to therapy was not psychologic or fortuitous but was due to a positive effect on the heart. In most patients with angina pectoris, exercise causes characteristic changes in the electrocardiogram that are commonest and most striking in the precordial lead.¹⁰ They consist of a deviation—usually a depression—of the initial portion of the RS-T segment. This begins shortly after the onset of exercise, reaches a maximum when the patient is forced to stop because of pain, and thereafter either subsides rapidly—frequently within fifteen seconds—or shows further progression, especially the height of the T waves. Because of the progressive and transient nature of the changes, the tracings must be obtained immediately after exercise, and only one lead can be observed during any one attack. The time necessary to adjust the electrodes and machine makes it impossible to obtain comparable tracings by any other technic.

Most therapeutic measures that decrease myocardial anoxia and thereby enable the patient to do more work without pain prevent or minimize the electrocardiographic changes that accompany exercise (Fig. 3).^{6,7} The degree to which these changes are prevented is an index of the therapeutic effect or potency of the medication and of the patient's response to it.

crease in exercise tolerance of 100 per cent or more following treatment usually have complete or almost complete freedom from attacks in daily life. An increase of 30 to 75 per cent is usually associated with a moderate diminution, but not complete disappearance of these attacks. An increase of 20 per cent or less is usually unassociated with any clinical improvement.

The converse is not true. Most patients with angina pectoris feel better after visiting the physician, regardless of the therapy prescribed. Furthermore, some of those with infrequent attacks have periods of relative comfort. Without an objective test, neither patient nor physician can say whether these periods of relief are the specific result of treatment or are merely coincidental with therapy.

Shortcomings of other methods used to evaluate therapy. The inadequacy of studying the efficacy of therapy by clinical evaluation alone is apparent from the above discussion. It is not surprising that the majority of published reports indicate that a wide variety of therapeutic agents—including many that are obviously inert—are apparently of value in treating patients with angina pectoris. It must be remembered that the clinical evaluation of the benefit of therapy is, in fact, the physician's impression of the patient's opinion of the response to treatment. Objective measurements are essential.

Attempts at having the patient report the response to therapy in terms of ability to perform

such customary tasks as walking and climbing stairs are similarly misleading. Few patients in variably experience pain in daily life after a given amount of work. Such factors as environmental temperature, food, emotion, physical activity and the relation to previous attacks cannot be readily

the results in 75 patients, chosen because they had been observed for long periods of time and because their response to many different forms of medication had been measured. All patients had Heberden's angina¹⁵ due to coronary-artery disease of arteriosclerotic origin. From 10 to 35 patients

FIGURE 4.

This diagram shows the average of results in 3 patients in each of Groups 1, 2 and 3 who received nitroglycerin (nitrites), theobromine sodium acetate (purines), quinidine sulfate (quinidine), codeine sulfate (sedatives), atropine sulfate (autonomic drugs), enteric-coated potassium iodide (iodides) and locally applied heat (miscellaneous).

controlled or observed by the patient. Furthermore, such studies fail to reveal remissions in the course of the disease unrelated to therapy.

The electrocardiographic response to anoxia¹¹⁻¹³ is a valuable objective means of measuring the response to therapy, but has no close or clear-cut correlation to the clinical response. For example, nitroglycerin, the most potent drug available for the treatment of angina pectoris, does not yield such good results as does intravenous amino phyllin when measured by this method.¹² This is probably because the response to nitroglycerin occurs two or three minutes after its administration⁴ and may have ceased by the time that anoxia induces changes in the electrocardiogram. The response to cobra venom is an additional illustration of the inadequacy of using the electrocardiograph in evaluating clinical response. Since this drug causes no vasodilatation, the marked clinical improvement that may occur is not associated with any electrocardiographic improvement during exercise or induced anoxia.¹⁴

Subjects used in the present studies. For the purpose of this summary, an analysis was made of

were studied in evaluating most methods of therapy. The study of larger numbers was impractical, for the evaluation of any form of therapy requires weeks or months of study, and the clinical course of patients with angina pectoris is variable and is frequently interrupted by cardiovascular accidents and the like that are unrelated to therapy. These patients' clinical course and response to therapy were known so well, however, that an accurate biologic assay was possible. In the cases in which the therapeutic procedure was hazardous—surgery—or time consuming and expensive—bed rest, x-ray therapy and so forth—fewer patients were studied. In these cases the patients selected included one or two who were known to respond favorably to several simple methods of treatment, and also one or two who were known to respond to practically no method of treatment.

RESULTS

Variations in Therapeutic Response

It is possible to divide patients with angina pectoris into three groups on the basis of their

response to most therapeutic measures. Some patients, termed "marked reactors," show a striking response to practically all effective methods of therapy. Others, termed "moderate reactors," show a moderate response to the same therapeutic measures, and still others, termed "nonreactors," show little or no response to most available methods of therapy (Fig. 4).

The response to nitroglycerin can be used to determine the likelihood of response to other forms

of attacks in daily life. The average control deviation of the RS-T segment during pain was 2.43 mm., with a range of 1.5 to 3.5 mm., and after the same amount of work following nitroglycerin was 1.1 mm., with a range of 0.0 to 2.5 mm.

Group 3 (nonreactors). The remaining 40 per cent of patients showed no response to nitroglycerin and little response to most other methods of treatment. They showed the same elec-

of treatment and serves to divide patients into the three groups described, as shown in Table 1.

Group 1 (marked reactors). In this series 27 per cent of all patients fell in the first group. Two minutes after the sublingual administration of 1/100 gr. of nitroglycerin, these patients were able to perform approximately 100 per cent or more work than had been possible without medication. When given other drugs, they showed a definite increase in exercise tolerance—usually 50 to 100 per cent—and practically complete disappearance of attacks in daily life. The electrocardiogram before treatment and immediately following exercise sufficient to produce pain showed an average depression of the RS-T segment of 2.03 mm., with a range of 1.0 to 2.7 mm. Following the administration of nitroglycerin or other effective vasodilating measures, the average of the RS-T deviations after the same amount of work was 0.2 mm., with a range of 0.0 to 0.5 mm.

Group 2 (moderate reactors). Thirty-three per cent of all patients comprised the second group. They could do approximately 50 per cent more work after receiving nitroglycerin than before. When given other effective medication, most of them showed a moderate increase in exercise tolerance (25 to 50 per cent) and a definite decrease but not complete disappearance

of attacks in daily life. The average control deviation of the RS-T segment during pain was 2.43 mm., with a range of 1.5 to 3.5 mm., and after the same amount of work following nitroglycerin was 1.1 mm., with a range of 0.0 to 2.5 mm.

Group 3 (nonreactors). The remaining 40 per cent of patients showed no response to nitroglycerin and little response to most other methods of treatment. They showed the same electrocardiographic changes during exercise whether therapy had been given or omitted.

Group 3 contained a high percentage of women and a low percentage of thin persons and of patients whose illness began before the age of fifty. Hypertension was somewhat commoner in Group 3 than in Group 1, and there was a high percentage of patients with low exercise-tolerance tests. Striking exceptions were frequent, however, and in any given case no characteristics other than the response to therapy served to differentiate the groups. In particular, the frequency and severity of attacks and the frequency of cardiac hypertrophy or abnormalities of the electrocardiogram at rest were approximately the same in all three groups.

There was a striking difference in the mortality of the groups (Fig. 5). During the period of observation, death occurred in 15 per cent of the patients in Group 1, 28 per cent in Group 2 and 43 per cent in Group 3. Conversely, after ten years of illness, 30 per cent of the patients in Group 1 were still living as compared with 16 per cent in Group 2 and 3 per cent in Group 3. Viewed in the light of the pathological studies of Schlesinger, Blumgart and their associates,¹⁶⁻¹⁸ this suggests that the patients in Group 3 represent those in whom the collateral circulation has compensated to the maximum extent. The coronary circulation

of such patients has little reserve, so that neither an increase in blood flow due to the use of vasodilators nor the development of additional anastomotic channels following additional coronary

crease in the standardized exercise tolerance and a corresponding decrease in the frequency of attacks in daily life usually occur, especially in Group 1 patients. This clinical improvement is

FIGURE 5. Mortality in Patients with Angina Pectoris.

occlusion is possible. Patients such as those in Group 1, on the other hand, have developed a well-functioning system of anastomotic channels with considerable reserve, so that an increase in blood flow occurs with vasodilating drugs and additional collaterals develop following coronary occlusion.

During the course of observation, several patients showed a change in ability to respond to therapy. Five patients who originally responded strikingly (Group 1) later responded to a lesser degree (Group 2). A sixth became completely unresponsive to medication for several months (Group 3) and died. Similarly, 2 patients originally in Group 2 suddenly failed to respond (Group 3), and 1 died within a few months after this change. On the other hand, 4 patients originally in Group 3 improved during the period of observation; 2 were ultimately classified in Group 1 and the other 2 in Group 2. In at least 2 of these patients, the improvement occurred after recovery from an episode of myocardial infarction.

Comparative Value of Therapeutic Measures

The comparative value of sixty-eight different therapeutic agents can be separated into three groups—those of marked value, those of moderate value and those of no value—on the basis of clinical effectiveness, low toxicity and low cost (Table 2).

Clinical effectiveness. When a therapeutic agent is given in adequate doses, a definite in-

crease in the standardized exercise tolerance and a corresponding decrease in the frequency of attacks in daily life usually occur, especially in Group 1 patients. This clinical improvement is

usually accompanied by a decrease in the electrocardiographic changes following exercise.

Low toxicity. This includes not only freedom from untoward reactions but also ease and practicability of administration in clinical practice.

Low cost. The importance of cost to the patient lies in the fact that angina pectoris and its underlying coronary arteriosclerosis are chronic conditions and that treatment must be continued over a long period, usually for life. To be of practical value, therefore, therapy must be sufficiently inexpensive so that the patient will be able to continue treatment for as long as necessary. The marked difference in cost of various commercial preparations without regard to their clinical effectiveness has been illustrated.⁸

The therapeutic agents of marked value were of three types as measured by results. The majority of agents resulted in an increase in exercise tolerance of 30 to 100 per cent or more in at least half the patients in Group 1. A few agents—the sedatives, atropine and potassium iodide in large doses—were not of such striking value, but were of appreciable benefit to some patients in Group 3 for whom few other satisfactory agents were available. The surgical procedures—total thyroidectomy and alcohol injection—were included because although costly, difficult to perform and not infrequently accompanied by untoward effects.

TABLE 2 *Comparative Value of Methods of Treatment.*

they were nevertheless of striking value in a few patients not helped by other and simpler means.

The therapeutic agents of *moderate value* were those the administration of which was followed by some improvement but not of sufficient degree or frequency to recommend them for routine use, — especially since more valuable methods of thera-

py are somewhat less valuable and is also more expensive. In using the enteric-coated preparations, it must be understood that several hours will elapse before they become effective (Fig. 7). It is important, therefore, to administer medication before the patient retires, for it is this dose that is effective on the following morning. In many cases it

FIGURE 6.

py were available, — and those, such as oxygen therapy, that were clinically effective but were impractical for clinical use.

The therapeutic agents of *no value* resulted in no appreciable increase in standardized exercise tolerance. Any clinical improvement that followed their use could be ascribed to psychologic influence.

ROUTINE TREATMENT

Treatment should be individualized. Careful questioning and prolonged observation may reveal specific precipitating factors — such as walking uphill or after meals, going out into the cold or emotional disturbances — that can be guarded against or eliminated. A change in habits, the use of sedatives or the prophylactic use of nitroglycerin at appropriate times is frequently of value in such cases. In a few cases (less than 1 per cent) hyperthyroidism, anemia, polycythemia or arrhythmias responsible for attacks may be discovered and corrected.

Medication is usually necessary. The purines are most likely to be of value (Fig. 6). Theobromine and sodium acetate, enteric-coated (7½ gr., four times daily), is the drug of choice. Theophylline and sodium acetate (3 gr.) and theophylline and calcium salicylate (8 gr.) are equally helpful but more costly. Aminophylline (3 gr.)

is advisable to give in addition a single dose of nonenteric-coated medication on the patient's arising. The purines were of benefit in 43 per cent of all patients (88 per cent in Group 1, 50 per cent in Group 2 and 12 per cent in Group 3).

In addition, especially during the first few weeks of therapy or if the symptoms are severe, it may be advisable to give 1/400 gr. of nitroglycerin under the tongue every hour when the patient is awake. Sedatives may be given as an adjunct. Although the latter may not increase the exercise tolerance to a striking degree, they help to stabilize the patient emotionally and make the pain easier to bear.

If this regime is of value, it will be evidenced within a week by the complete or almost complete disappearance of attacks in daily life. Any improvement short of this is probably not due to the medication used.

If no satisfactory response is obtained, it is advisable to substitute quinidine sulfate (5 gr. three or four times daily) as the drug next most likely to bestow benefit. Quinidine is about as effective as the purines, and the toxicity in patients with angina pectoris and normal cardiac rhythm is low. Sixty-one per cent of all patients were benefited by the purines or quinidine (all those in Group 1, 50 per cent in Group 2 and 24 per cent in Group 3).

The treatment of the remaining two fifths (39 per cent) of patients, especially those in Group 3, is a difficult problem, and future research should be directed toward the care of this group. Atro-

If the symptoms reappear when the patient returns to normal activity, cobra venom is worthy of a trial.^{14, 20} This drug diminishes attacks without affecting the underlying cardiac mechanism

FIGURE 7. Comparative Effect of Nitroglycerin and Theobromine Sodium Acetate, Both Uncoated and Enteric-Coated, in Patient S. W. (Group 2).

pine sulfate (1/120 gr., four times a day) was of some value in approximately 10 per cent of such patients in Group 2 and 6 per cent in Group 3. Potassium iodide in comparatively large doses (1.0 gr. in an enteric-coated tablet, three or four times daily)¹⁰ was of value in an additional 12 per cent in Group 3. The sedatives, especially codeine sulfate, helped another 20 per cent in Group 3. There remain about 20 per cent of all patients (two thirds of whom were in Group 3) who responded to none of these medications.

TREATMENT OF SEVERE ANGINA PECTORIS

In many cases, especially in patients with severe angina pectoris who fail to respond to this regime, it is advisable to use a combination of therapeutic agents. While admittedly a "shotgun" method, the results obtained in such patients and the absence of other simple effective therapeutic measures justify its use.

Such patients should have a period of complete bed rest combined with adequate sedatives and small hourly doses of nitroglycerin. In some cases it is advisable to give in addition adequate doses of an active purine and, if necessary, quinidine sulfate. This regime usually results in the complete disappearance of pain within a week, unless there has been a recent coronary occlusion or unless a strong emotional element is present.

responsible for the pain. It must be given by injection, daily for at least a week and two or three times weekly thereafter.¹⁴ Despite these drawbacks, cobra venom, in certain cases, obviates the necessity for surgery.

Only if these measures fail to give relief should surgery be considered. Few patients, however, come to surgery (Fig. 8). At the Beth Israel Hospital, in 46 per cent of the patients with angina pectoris the disease was so mild even without therapy that surgery was unnecessary. In an additional 24 per cent, the response to medicinal therapy (exclusive of cobra venom) made surgery unnecessary. Of the remaining 30 per cent, approximately half were unsuitable surgical risks, and half the remainder refused operation when the risk and the likelihood of benefit were explained. As a result, surgery was performed in approximately 7 per cent of patients with angina pectoris.

In our experience, total thyroidectomy^{21, 22} has given more striking results than has any other form of therapy (Fig. 9). It is the surgical procedure of choice in patients with normal basal metabolic rates, prolonged but nonprogressive symptoms and a fair life expectancy who are adequate surgical risks. Suitable cases are admittedly few, but thyroidectomy may be a valuable means of alleviating symptoms and restoring physical ac-

tivity in those few to whom there is little else to offer.

Some form of surgery of the sympathetic nervous system may be employed in patients not suit-

Experience has shown that the above plan goes a long way toward prevention of attacks of angina pectoris. It has enabled many patients to increase their physical activity and in some cases to return

able for total thyroidectomy. Alcohol injection is at present considered to be the method of choice, but it rarely results in any increase in ex-

ercise tolerance and may be followed by a neuritis.²³⁻²⁶ The comparative freedom from pain that occurs in some patients, however, justifies the use of this method in the few selected patients who may require such relief.

to gainful occupation. Information concerning prolongation of life is difficult to obtain, but it is logical to reason that freedom from attacks in-

FIGURE 9.

ercise tolerance and may be followed by a neuritis.²³⁻²⁶ The comparative freedom from pain that occurs in some patients, however, justifies the use of this method in the few selected patients who may require such relief.

indicates comparative freedom from the physiologic mechanism responsible for some of the complications.

SUMMARY

An objective evaluation of the efficacy of treat-

ment of angina pectoris carried out over a ten-year period shows that 27 per cent of patients respond strikingly to practically all available forms of therapy, 33 per cent respond to a moderate degree, and 40 per cent usually fail to respond appreciably. This variation in therapeutic response should be taken into account in any study of the efficacy of treatment of angina pectoris.

The clinical evaluation of the efficacy of therapy is extremely difficult and unreliable. Nothing short of complete or almost complete disappearance of attacks can be considered as a favorable response, and it must be remembered that such periods may be spontaneous and not related to treatment.

Of the sixty-eight methods of therapy evaluated, twenty were found to be of considerable value, twenty-two were of slight value, and twenty-six were of psychologic value only.

In prescribing medicinal therapy, the drugs of choice are nitroglycerin (1/400 gr. every hour), theobromine and sodium acetate (7½ gr., four times daily), quinidine sulfate (3 to 5 gr., four times daily), atropine sulfate (1/150 gr., four times daily), enteric-coated potassium iodide (1.0 gm., four times daily), cobra venom (given intramuscularly) and the sedatives. The plan of treatment outlined was of value in approximately 80 per cent of all patients.

Few patients require surgery. Total thyroidectomy is of considerable value for selected patients. The paravertebral injection of alcohol gives symptomatic relief to others.

CLINICAL NOTE

LARYNGOPYOCELE

REPORT OF A CASE

OLIVER A. LOTHROP, M.D.*

BOSTON

A LARYNGOCELE or aerocele is supposed to be a congenital sac due to a prolongation of the ventricle of Morgagni. It is normal in certain groups of monkeys and is then bilateral. It is

tracheal rings seemed normal. The right cord was red and indistinct and was partly obscured by a red and protruding false cord. There was some limitation of motion on the right side, as well as marked fullness on the outside of the neck just to the right of the larynx. The roentgenologist (Dr. A. S. MacMillan) reported an aerocele of the right ventricle (Fig. 1).

At operation, an oval sac measuring 2 by 3 cm. was located at the right of the thyroid cartilage, extending up to the cornu of the hyoid bone and reaching posteriorly and laterally to the region of the superior laryngeal nerve. Its wall was thin and slightly adherent at the fundus. The other end of the sac took the form of a neck that penetrated the thyrohyoid membrane and curved over the superior border of the thyroid cartilage, passing down its inner surface and under the right false cord to its

FIGURE 1. X-Ray Films Taken in the Lateral and Anteroposterior Positions.

sometimes referred to as a "monkey pouch." The literature contains reports of about 80 cases in human beings, by far the greatest proportion being found at autopsy or in dissecting rooms. The presence of pus in the laryngocoele is rare, and in the case reported below may have taken place at the time of the patient's extremely "sore throat" a year and a half previous to examination.

CASE REPORT

A 45-year-old woman, referred by Dr. W. W. Marston of Newton, had complained of hoarseness intermittently for 1½ years. She had received a satisfactory tonsillectomy 25 years previously. She had had a very sore throat 1½ years previously.

Examination of the larynx showed that the left cord was normal in color and motion. The epiglottis and

origin in the ventricle of Morgagni. The sac was removed after suturing and severing the neck. It was filled with a fluid pus, thus making it a pyoceles and not an aerocele. A stained smear of the pus showed gram-positive bacilli, and a culture was negative for beta-hemolytic streptococci. The pathologist's report was as follows: "The specimen consists of a small oval cystic structure opened at one end and measuring 3.5 by 2.0 by 1.0 cm. Its outer surface is roughened from resection. The wall is fibrous and less than 1 mm. in thickness. The lumen is empty, and the lining is smooth and pinkish gray. Microscopically, the cyst-like cavity is lined by ciliated columnar epithelium, supported by stroma that is rich in lymphocytes and at one point shows a nest of mucous glands. Diagnosis: laryngocoele?"

The patient made an uninterrupted convalescence. After 2 weeks the wound was healed, the hoarseness had disappeared, and the appearance and motion of the larynx had become normal.

Those seeking further information on this rare condition are referred to an excellent article by

*Chief, Otolaryngological Service, Newton Hospital.

Freedman,¹ published in 1938. He outlines the history of the discovery of the laryngeal ventricles, sometimes called the ventricles of Morgagni because of the latter's detailed description given in 1741. Freedman refers to the fine dissections made of this space by Hilton² in 1837 and to the discovery of the sacculus laryngis, which contains many mucous glands; he ventures the theory that these glands furnish the fluid to lubricate the vocal cords. He then elaborates on the physiology of this function of the sacculus, and on the consequences of its failure. The sacculus or its extension, he says, represents the air sac of the anthropoid apes. Freedman expounds the theory that apes and other climbing mammals are at times forced to cease breathing temporarily, and that these air sacs are filled with oxygen on inspiration but with carbon dioxide during expiration, and therefore act as mixing chambers. He reports a case of pyocele in a fifty-four-year-old

man and describes his operative technic. He also cites a case of prolapse of the sacculus and a laryngocele in a nine-week-old boy. His article ends with references to ten other articles.

Jackson and Jackson,³ in their textbook published in 1937, state that laryngocele is a very rare disease and that they have seen only 2 cases. In both these cases the sac protruded into the lumen of the larynx and not into the neck, and contained air and not pus as in the case here reported.

SUMMARY

A case of laryngopyocele is reported, and the pertinent literature is discussed.

MEDICAL PROGRESS

PANCREATIC INSUFFICIENCY AND THE CELIAC SYNDROME (Concluded)

SIDNEY FARBER, M.D.*

BOSTON

PANCREATIC-ENZYME ANALYSIS

THE frequent familial history, the apparently congenital nature of the process, the early onset of symptoms and the presence sooner or later of pulmonary infection assist in the clinical differentiation of pancreatic insufficiency from idiopathic celiac disease. Measurement of the activity of pancreatic enzymes in the duodenal content, however, appears to be the most valuable single laboratory aid in making this differentiation and in establishing the diagnosis in the absence of symptoms of the celiac syndrome. Two recent extensive studies of pancreatic-enzyme activity in infants and children, with particular reference to the celiac syndrome, have been made. Andersen²⁶ included data on such activity in the duodenal content of 15 patients who had a clinical history consistent with the diagnosis of pancreatic fibrosis, in a report of enzyme studies on 98 infants and children including some with chronic diarrhea, others with extreme marasmus and some with a classic picture of true celiac disease. Farber, Maddock and Shwach-

man²⁵ presented data on the pancreatic-enzyme activity of 150 infants and children including normal patients with chronic nutritional failure, 11 with true celiac disease and 22 with pancreatic fibrosis. The results of these studies, in agreement with all similar observations, such as those by Sive,²⁷ Benoit,²⁸ Tiling²⁹ and others³⁰ who have studied pancreatic enzyme activity in the celiac syndrome in small numbers of patients, demonstrated that markedly diminished or absent activity of pancreatic enzymes in the duodenal content, particularly that of trypsin and lipase, characterizes all cases of pancreatic fibrosis, in contrast to the essentially normal values found in patients with true celiac disease and other types of chronic failure of nutrition. An important pancreatic lesion was found at autopsy in every patient in whom pancreatic achylia had been demonstrated during life. Farber, Maddock and Shwachman state that patients with sprue, idiopathic steatorrhea or that form of the celiac syndrome associated with malrotation of the bowel have normal pancreatic enzyme activity and do not differ in this respect from patients with true celiac disease. The duodenal content in patients with pancreatic fibrosis is frequently so striking in its scantiness and viscid-

The articles in the medical-progress series of 1941 have been published in book form (*Medical Progress Annual*, Volume III, 678 pp. Springfield, Illinois: Charles C Thomas, 1942. \$5.00).

*Assistant professor of pathology, Harvard Medical School; pathologist, Infants' Hospital and Children's Hospital, Boston.

ty that diagnosis may be made with considerable accuracy on gross inspection alone. All patients with chronic nutritional failure may be divided provisionally into two large groups on the basis of pancreatic enzyme analysis: those with normal activity and those with markedly reduced or absent activity. From this temporary classification further subdivision may be carried out in the group with normal enzyme activity. The generalization has been made that the diagnosis of true celiac disease, idiopathic steatorrhea, nontropical sprue, pancreatic fibrosis or other similar conditions should not be considered as established until the pancreatic-enzyme activity in the duodenal drainage has been measured.

Andersen²⁶ has recognized two groups of patients who may be separated from those with celiac disease and with pancreatic fibrosis on the basis of enzyme analysis. She found some patients with what she called "near-celiac" disease who showed intolerance to starch in the diet, a low level of amylase in the duodenal juice, and starch in the stools but no excessive stool fat. Such patients have a relatively mild, though prolonged, clinical course. In the second group she placed those with idiopathic steatorrhea, intolerance to fat, a high concentration of stool fat, normal amounts of pancreatic enzymes and a severe and protracted clinical course. She suggests that in these patients the difficulty lies in the absorption rather than in the digestion of fat. In 3 patients with severe marasmus she found depression of activity of trypsin, amylase and lipase, with a return to normal after clinical improvement. Farber, Maddock and Shwachman²⁵ encountered patients with failure of nutrition in whom selective lipase deficiency was demonstrable in the presence of normal amounts of trypsin and amylase. They reported also the demonstration of absence of trypsin activity in an infant with meconium ileus.

Andersen²⁶ has suggested that the assay of trypsin alone is a reliable means of diagnosis of pancreatic deficiency. In general, she states that few errors in the diagnosis of pancreatic fibrosis will be made if amylase and lipase are not measured. Rare exceptions may be encountered, such as a case of selective trypsin deficiency in a boy with chronic nutritional failure that did not resemble the celiac syndrome; in the duodenal content normal amylolytic and lipolytic activity was demonstrated.²⁵ Particularly during the first few months of life, the assay of amylase yields little information of value, since this enzyme is present in such low concentration in normal infants.²¹ In many older infants and young children with chronic diarrhea amylolytic activity in the duodenal content may be reduced.²⁶

It appears probable that further anomalies of pancreatic exocrine function will be discovered when studies of pancreatic activity are carried out on large series of infants and children. In patients with pancreatic fibrosis Maddock, Farber and Shwachman²² found that stimulation of the pancreas by secretion had little effect on the duodenal content and was not essential for the correct interpretation of the enzyme activity in the pancreatic juice. Stimulation by secretion, however, causes a moderate increase in amylolytic activity in patients with true celiac disease and a marked rise in those with chronic nutritional disturbances of the nonceliac type.²²

Pancreatic achylia appears to be a permanent finding unaffected by pancreatic substitution therapy or any other form of treatment, since six determinations of enzyme activity in the duodenal content of a patient made between the ages of five and twenty-five months showed no appreciable change in the level of enzyme activity, although the patient's general condition appeared to improve.²⁵

Detailed descriptions of methods of pancreatic-enzyme analysis for use on infants and children have been given.^{20, 23, 24} It appears clear that this field of investigation, opened by the pioneer work of Hess²⁵ on infants in 1912, will have much value. The use of Mecholyl and secretin in studies of pancreatic function should yield data of great interest.³⁰

METABOLIC STUDIES

Shohl, May and Shwachman²⁷ found the weight of the feces of patients with pancreatic fibrosis to be greater than that in any other condition in childhood. In a series of metabolic studies designed to furnish data concerning altered nitrogen metabolism in pancreatic fibrosis under controlled conditions, when native protein was removed from the diet, there was no difference in the weight of the feces. When both protein and fat were omitted, however, and nutriment was given parenterally, the residue of the feces was small. Pancreatic substitution therapy was followed by reduction in the weight of the feces, but not to the normal level. Those writers concluded that the amounts of nitrogen in the feces of patients with pancreatic fibrosis may exceed that in the urine and reach three or four times that in the feces of normal infants. Excessive nitrogen in the feces is the cause of a negative nitrogen balance and is partly responsible for the loss of weight and the deterioration of patients with this disease. With respect to high fat in the stools, excessive excretion of nitrogen in the feces and marked increase in the weight of the stools, children with pancreatic

fibrosis behave as do dogs in which the pancreatic juices have been excluded from the intestines. Shohl et al. were able to reduce the amount of fecal excretion and nitrogen excretion in the feces to normal limits when a fat-free ration, consisting of casein hydrolysate and glucose, was administered.

It may be of interest to mention the similar results of metabolic studies in 4 adults with pancreatic achylia reported by Beazell, Schmidt and Ivy.³⁸ Although the etiologic factors were unknown, the diagnosis was made on the basis of an absence of pancreatic enzymes in the duodenal drainage, an increase in the quantity of nitrogen and fat in the feces and a reduction in the wastage of both nitrogen and fat with substitution therapy. The patients were placed on a standard balanced diet supplying 64 gm. of protein and 112 gm. of fat daily for a period of six days. Beginning with breakfast on the fourth day, the patients were given with each meal 8 gm. of pancreatin in the form of enteric-coated tablets. A total of 24 gm. was given daily, one half immediately before and one half immediately after the meal. The 24 gm. corresponds to approximately 240 cc. of pancreatic juice, which represents only 15 per cent of the quantity normally estimated to be secreted by adults within twenty-four hours. After one month on this dose, the daily dose was progressively reduced until only 2 or 3 gm. was given with each meal. Response was noted by observing the subjective reaction, the character of the stools, the reduction in the frequency of stools, the gain in weight and the increased strength. These authors state that they have never seen pancreatic achylia, either clinically or in an experimental animal, that failed to respond to adequate enzyme therapy. Conversely, in the absence of demonstrable pancreatic insufficiency enzyme therapy never effected reduction in the nitrogen or fat of the stool.

Although steatorrhea has been stressed as one of the most characteristic findings in both pancreatic fibrosis and celiac disease, to the extent of including the word in the name of the disease,¹³ wide variations in the amount and kind of fat in the stool may be encountered. It should be recalled that the fat content of stool specimens of normal infants and children varies from 10 to 80 per cent of the dried feces.³⁹ Andersen⁴⁰ found that it increased to 30 to 80 per cent of the dry weight when the patient was given a whole-milk formula or an average mixed diet. Only 7 of the 35 patients with pancreatic fibrosis proved at autopsy studied by Blackfan and May¹⁵ had stools that were described as fatty. Examination of the stools of patients with pancreatic fibrosis for the ratio of neutral fat to hydrolyzed fat⁴¹ has not

served to differentiate this disease from celiac disease, since fat may normally be split by intestinal lipase in the absence of pancreatic lipase.⁴²

In the entire group of celiac diseases, absorption of fat is disturbed, although the mechanism may differ from case to case. Measurement of the absorption of vitamin A from the intestines was proposed by Breese and McCoord⁴³ as a test to aid in the diagnosis of celiac disease. The studies of May and McCreary⁴⁴ show that a low rise in the vitamin A absorption test is found in both celiac disease and pancreatic fibrosis. Differences in the degree of decreased absorption of vitamin A are detectable, but are not great enough to be of aid in differentiating these two conditions in a given patient. May and McCreary found no improvement in true celiac disease in the absorption of vitamin A when the vitamin was introduced intraduodenally and active intestinal peristalsis was maintained with Mecholyl.

An observation of considerable importance concerning the increased absorption of vitamin A in pancreatic fibrosis when the motility of the bowel is increased has been described by Flax, Barnes and Reichert.³⁰ Proceeding on the assumption that the inefficient absorption of vitamin A as well as of glucose is probably associated with the lack of tone and abnormal motility of the intestinal tract, they administered Prostigmine parenterally to a patient with pancreatic fibrosis and observed an almost immediate rise in the blood level of vitamin A. They chose this drug because of its success in restoring muscle tone in postoperative ileus.⁴⁵ After a period of five months, during which Prostigmine Bromide was given in amounts of 75 mg. three times a day, the absorption of vitamin A showed a normal curve. A rise in the total blood-cholesterol level was also observed, which suggested an increased lipid absorption. Of considerable interest was a diminution in the cough with decreased evidence of lung infection on roentgen-ray examination, a change that these writers attribute to better absorption of vitamin A brought about by increased motility of the bowel.

A low blood-sugar curve in the glucose-tolerance test is found in true celiac disease.² Andersen⁴⁰ has pointed out that the glucose-tolerance curve in pancreatic fibrosis, although usually flat, may show an initial sharp rise and a rapid fall, as in the hunger curves described by Harris. Normal values are encountered. The low rise of the curve in celiac disease was at first interpreted as a change secondary to diminished gastrointestinal motility. May, McCreary and Blackfan⁶ found, however, that when a solution of 3 per cent glucose containing as much glucose as was given ordinarily in a 10 per cent concentration was introduced intraduode-

nally in patients with celiac disease, the level of glucose in the blood did not rise more than 40 mg. per 100 cc. even if active intestinal motions were maintained by means of Mecholy. When patients recovered from celiac disease, however, a normal rise in the blood sugar occurred following the simple intraduodenal administration of glucose in a 3 per cent concentration. Although intestinal motility plays an important role in intestinal absorption, there must be in addition in celiac disease an impairment of absorption of glucose by the intestinal mucosa. No adequate explanation has been offered for the poor absorption of glucose when it does occur in patients with pancreatic fibrosis.

ROENTGENOLOGIC STUDIES

In both pancreatic fibrosis and celiac disease clumping of the barium meal in roentgenograms of the small bowel similar to that observed by Snell and Camp⁴⁶ in adults with steatorrhea and in vitamin B deficiency states⁴⁷ was found with regularity by Blackfan and Vogt,⁴⁸ and was explained by May and McCreary⁴⁹ by the impairment of peristalsis and tone and by segmentation of the bowel. Alternate segments showing spasm and dilatation with loss of the normal pattern of the valvulae conniventes characterize the roentgenologic picture. This abnormality in the motility of the bowel may be temporarily corrected by Mecholy.⁴⁴

Attwood and Sargent⁴⁹ have described the roentgen-ray appearance of the pulmonary lesions that are so consistently a part of the disease at any time after the first few weeks to months of age. They reported an increase in the density of hilar shadows, with loss of definition and prolongation outward into a surrounding mottling that gradually diminishes toward the periphery of the lung. The changes are bilateral and are symmetrically distributed about the roots of the lungs and the adjacent parenchyma. The changes in the upper lung fields are quite as marked as those at the bases. These writers warn against the danger of making an erroneous diagnosis of tuberculosis in patients in whom the illness is prolonged, because of the marked chronicity of the pulmonary lesions. Neuhauser⁵⁰ has divided the lung changes into two stages corresponding to the pathologic picture. The first is characterized mainly by emphysema and atelectasis dependent on the partial or complete obstruction of bronchi and bronchioles by the tenacious mucus or mucopurulent exudate. Atelectasis is at times difficult to recognize, since the small shadows of increased density resemble areas of pneumonic consolidation. Obstructive emphysema is identified with less difficulty by the decreased density, the bulging spaces and the

widening of the intercostal spaces. In the later or second stage, the roentgenologic changes become more marked, with patchy areas of peribronchial infiltration and areas of bronchiectasis. The process is marked toward the hilum, and the bronchovascular and interstitial markings radiating from each hilum are increased. The end stage is that of pneumonic infiltration, bronchiectasis and bronchiectatic abscesses, with varying degrees of atelectasis and obstructive emphysema. It should be stressed that these x-ray manifestations of pulmonary disease are by no means limited to patients with pancreatic achylia. They occur so frequently, however, in patients with this disorder that studies designed to confirm or exclude this diagnosis, such as analysis of pancreatic-enzyme activity, should be carried out whenever such changes are encountered.

TREATMENT

The outstanding disturbances produced in this disease, either by the pancreatic insufficiency or by the alterations elsewhere in the body, include absent or greatly reduced pancreatic-enzyme activity, particularly of trypsin and lipase; malabsorption of vitamin A; loss of nitrogen in stools; and upper respiratory obstruction and infection leading to bronchiectasis and bronchopneumonia. Treatment may be directed logically along these four channels. Pancreatic substitution therapy is indicated by the pathologic picture and the demonstration of pancreatic hypochylia or achylia. It has been found of value in infants and children and in adults with pancreatic insufficiency.^{27, 38, 40} The greatly diminished absorption of vitamin A that has been demonstrated by the vitamin A absorption test,^{43, 44} as well as by the occasional finding of histologic evidence of vitamin A deficiency,¹⁴ may be corrected either by enteral or parenteral administration of vitamin A.^{30, 40} Intramuscular injection of preparations of vitamin A in large doses has been recommended.³⁰ The marked loss of nitrogen in the stools may be corrected in part by pancreatic substitution therapy and in part by a direct replacement of lost nitrogen in the form of casein hydrolysate.³⁷ Infection in the lungs is an almost invariable accompaniment of the disturbance in nutrition. Since the most frequently found organism is *Staph. aureus*, and since it is one of apparently low virulence, chemotherapy is indicated, although difficulty is encountered in finding a completely effective form of specific therapy.

Flax, Barnes and Reichert²⁰ have recommended the parenteral administration of Prostigmine to improve the muscle tone in the intestinal tract and so permit enhancement of nutrition in general

and absorption of vitamin A in particular. They summarize their therapeutic regimen as follows: a high-calorie, high-protein, moderately low-fat and low-starch diet; pancreatin granules, 1.5 gm. daily; vitamin A, 50,000 international units daily, in divided doses; adequate amounts of vitamins B, C and D; and Prostigmine Bromide, 3.75 to 7.50 mg. three times daily. Andersen⁵¹ recommends a diet essentially similar to that used in celiac disease, with two important differences: hexose and sucrose, which can be utilized, are given instead of starch, and if pancreatin is administered a moderate amount of fat can be utilized. She used a diet high in protein, moderately low in fat and free from starch but not from sugar, and emphasizes the value of a caloric intake 30 to 50 per cent greater than that calculated for the given age to compensate for the loss of food in the stools. Although the parenteral injection of vitamin A concentrate or carotene was logical in theory, it was disappointing in practice. Much better results were obtained by the oral administration of large doses (15 drops) of percomorph or haliver oil three times a day.

At the Children's Hospital, Smith⁵² emphasizes the importance of good hygienic surroundings, with special reference to prevention of upper respiratory infection, and recommends the immediate and intensive treatment of all infections with some chemotherapeutic agent. In some infants a small maintenance dosage is continued for longer periods. The disturbed nitrogen metabolism is cared for most satisfactorily by the use of casein hydrolysate preparations, as described by Shohl and his co-workers.³⁷ Pancreatic substitution therapy is given in the form of minute granules each of which is enteric coated (Panteric Capsules, Parke Davis). The granules are sprinkled on the food and are given in amounts of 2 to 5 gm. daily in divided doses. Special attention is paid to a high vitamin intake with especially large doses of vitamin A. Glucose is added to the diet to increase the caloric content. Intravenous and parenteral fluids are given according to indications in the given case.

Until recently all patients with proved pancreatic fibrosis have died, as has been clearly shown in recent studies.⁵³⁻⁵⁸ Before pancreatic-enzyme studies were used, it was impossible to be certain of the diagnosis in patients said to have recovered from this disease. Recently a number of infants have been kept alive longer than was previously possible and some have improved markedly under a form of treatment similar to those discussed above.^{51, 52} The great power of regeneration possessed by the exocrine portion of the pancreas⁵⁹ gives hope for resumption of pancreatic function if the cause of the obstruction can be removed.

The form of treatment recognized for this removal, however, remains to be found.

In most cases the pulmonary lesions are responsible for death. Avoidance of infection is only one, albeit an extremely important, aspect of the problem. The markedly thickened mucus, responsible for the partial obstruction of the respiratory tract and the consequences thereof and for the pertussis-like cough, is one of the most important variable factors influencing the prognosis. It is representative of what may be present in other secretions in the body, if the disease is a systemic one, as pathological studies indicate.¹⁶

CONCLUSIONS

Adequate pancreatic substitution therapy, replacement of the large amounts of nitrogen lost in the stools and the administration of vitamin A and other therapeutic measures designed to correct the consequences of pancreatic achylia and the supposed error in fat absorption will do much to care for the pancreatic aspects of the problem. The disease is unfortunately much more than a lesion of the pancreas, and indeed, the great amount of attention paid to the pancreas in the recent literature, and even in this discussion, may serve to increase the neglect of the respiratory and other changes that emphasize the systemic nature of the process. Further studies are required to clarify and delimit the clinical disturbances associated with this disorder. Pathological studies⁵⁰ indicate that there exist combinations of organ involvement in this systemic disease the clinical counterparts of which have not yet been defined. The most frequently encountered combination is that of pancreatic and pulmonary disease, as emphasized above. In some cases the pancreas, lung and liver all show significant lesions, with biliary cirrhosis the most striking pathologic finding. Finally, involvement of the lungs and the liver, with no disease in the pancreas, and therefore absence from the clinical picture of those symptoms referable to pancreatic insufficiency, provides further evidence for the systemic nature of the underlying disease process, and places the lesion in the pancreas in its proper setting.

The studies that were undertaken to terminate the confusion of idiopathic celiac disease with pancreatic steatorrhea have satisfactorily accomplished their purpose. And they have done more. Several dissimilar clinical disorders—meconium ileus, chronic bronchopneumonia and pancreatic insufficiency and a celiac-like disease associated with chronic pulmonary disease—have all been found associated with the same obstructive pancreatic lesion, and valuable metabolic and thera-

peutic studies, suggested by the nature of this lesion, have been successfully accomplished. Finally, this apparently unrelated group of clinical disorders has been shown to possess logical interrelations by the demonstration that the pancreatic and pulmonary lesions are manifestations of a common disorder involving many secretion-forming structures in the body in a systemic disease. The definition of further clinical disturbances produced by this systemic disease and the clarification of the nature of the underlying process are tasks that remain to be accomplished. A satisfactory nomenclature, which has so far evaded the workers in this field, would do much, if not to hasten progress, at least to facilitate a discussion of this subject.

EDITH E. PARRIS, *Assistant Editor*

CASE 29431

PRESENTATION OF CASE

A seven-and-a-half-week-old male infant was admitted to the hospital because of diarrhea.

The infant was delivered following eighteen hours of labor, but breathed and cried normally and weighed 8 pounds, 14 ounces. A formula containing Similac was used and the child seemed to tolerate it well. He continued, however, to pass meconium in small, frequent stools for the first six days, and he was given two doses of castor oil, following which he passed small yellow formed stools for one week. He left the maternity hospital on the tenth day, weighing 7 pounds, 14 ounces, on a formula consisting of 8 ounces of evaporated milk, 1 ounce of Karo and 16 ounces of water, with six feedings a day. He failed to gain weight and was admitted to a community hospital, where he remained for two and a half weeks. His stools at first were watery but later became formed and of normal color. He vomited considerably. The day following discharge, the stools became watery again, associated with vomiting but no fever. His physician tried Biolac without success. On evaporated milk and Karo, however, the stools became semi-soft, copious, excessively foul smelling and yellow, rapidly changing to gray. During the week before admission there were six to eight bowel movements a day. The baby's appetite was said to have always been good, but he was irritable. He had received 50 mg. of vitamin C daily, as well as capsules of vitamins A and D. There had been no hematemesis, melena, bloody stools or jaundice. No history of recent infection could be elicited.

A twenty-month-old sister had recently died of "pancreatic fibrosis" in the same local hospital. Another sister had died of peritonitis at one week of age in another local hospital.

Physical examination showed a thin, pale, undernourished, moderately dehydrated, underdeveloped, screaming infant, weighing 7 pounds, 4 ounces. The eyes, ears, nose and throat were normal. The lungs were clear. The heart was nor-

mal. The abdomen was moderately distended. There was moderately active peristalsis. The skin over the extremities and chest was loose. Examination was otherwise normal.

The temperature was 97°F.

The blood showed a red-cell count of 4,210,000, with 14.5 gm. of hemoglobin. The white-cell count was 17,400, with 37 per cent neutrophils, 53 per cent small lymphocytes, 9 per cent large lymphocytes and 1 per cent monocytes. The urine gave a + test for albumin, and the sediment contained 15 to 20 white cells and occasional red cells per high-power field. The stools were light gray, hard, formed, guaiac negative and positive for fat. A stool culture was negative for pathogenic bacteria. The blood protein was 4.2 gm. per 100 cc., the cholesterol 122 mg. per 100 cc., the chloride 101.7 milliequiv. per liter, and the sodium 130 milliequiv. per liter.

X-ray films of the chest were negative, and films of the skull showed a somewhat anteroposteriorly drawn-out skull, with relative overdevelopment of the posterior fossa. The sutures and fontanelles were open.

The baby was placed on a formula of evaporated milk 7 ounces, Karo 1 ounce and water 12 ounces. His appetite was good. During the first week the stools were yellow, soft to formed and only occasionally watery. They numbered two to four daily. There was a slight increase in weight. At the end of the first week, the formula was changed to evaporated milk 9 ounces, Karo 1 ounce and water 11 ounces, in six feedings. The stools became copious, gray and foul smelling, and the baby began to vomit. Duodenal-enzyme analysis showed absent trypsin. At that time a discharge summary received from the community hospital where he had been treated, stated that a diagnosis of idiopathic pancreatic fibrosis had been made and that he had been discharged on pancreatic extract, 2 capsules daily. The fasting carotenoid level was noted to have been 1.8 units per 100 cc., and the vitamin A level 7.5 units.

On the eighth hospital day, the baby was placed on pancreatic extract, 1 granule three times a day, 15 drops of Navitol, a teaspoonful of vitamin B complex and 25 mg. of cevitic acid. He did not pick up, and an attempt was made to mix Nutramigen and pancreatin with whole boiled milk, supplementing these by vitamin K and liver extract intramuscularly twice weekly. The red count was 2,970,000, with 11 gm. of hemoglobin, and the white-cell count was 10,000. The stools were formed, green to yellow, almost fat free but guaiac positive. The total blood protein was 3.9 gm. per 100 cc. The weight was 7 pounds. He refused about half his feedings or vomited most of those he took. At the end of the second week he

*On leave of absence.

was placed on a formula consisting of 18 ounces of 2 per cent milk and 1 ounce of Karo supplemented by 5 gr. of pancreatin, which was steadily increased until he was getting 5 gm. of pancreatin. Vitamin D was furnished by ultraviolet irradiation. He was given repeated small transfusions of whole blood, which raised the red-cell count to 5,900,000, with 17 gm. of hemoglobin, on the eighteenth hospital day. He had two transfusions of plasma. The baby's condition seemed to improve considerably. The weight was 7 pounds, 8 ounces, on the twenty-fifth day, at which time he was having four small bowel movements daily.

On the thirtieth hospital day the temperature rose to 101°F. and the white-cell count to 19,000 and the baby was noted to have a weak cough. Physical examination and x-ray films of the chest were negative. He was, however, placed on sulfadiazine. The following day he developed vomiting and diarrhea, was taken off fluids by mouth and placed on intravenous and subcutaneous fluids. On the thirty-second hospital day the temperature rose to 103°F. The eardrums appeared inflamed but paracentesis yielded no exudate. Lumbar puncture was negative. Blood cultures gave no growth. He developed increasing respiratory distress, but the x-ray films of the chest remained negative. The respirations dropped to 8, and the heart became weak. The veins were collapsed, and the blood dark. Whole-blood transfusion and intranasal oxygen brought no improvement, and the baby died on the thirty-fourth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. RALPH A. ROSS: The fact that this baby passed meconium stools for six days is significant, because ordinarily at the end of the third day meconium stools have ceased, and with an infant taking a reasonable formula, one expects to see beginning milk-curd stools. Apparently this was a matter of concern to the physicians in charge because the child was given two doses of castor oil.

The administration of castor oil in some circles has been used, I think, in an attempt to affect what is called meconium ileus, a rather rare instance of sticky meconium that cannot be passed on by the normal peristaltic movements of the bowel. In some hospitals the giving of castor oil has been made more or less routine on the third day, if there is any question about the stools. I believe, however, that castor oil is a drug that should never be used—perhaps I should say “hardly ever”—in the newborn period. If the expected effect of giving castor oil is to release the sticky meconium, it seems completely impossible that that can be accomplished by the administration of a violent irritant to the bowel. It is more likely that the meconium will completely obstruct

the bowel and that the hyperactivity of the gastrointestinal tract will lead to a disastrous outcome.

The loss of weight of 1 pound is more than should occur in a normal child at the age of ten days.

The foul-smelling gray stools point to the presence of excess amounts of fat.

One can only question whether the sister who died at the age of one week suffered from meconium ileus and had a rupture of the intestine with peritonitis.

On admission the infant's weight was 1 pound, 10 ounces, lower than at birth. He was only moderately dehydrated and was screaming, and was therefore not in collapse or shock from dehydration. A moderately distended abdomen in an emaciated child is an abnormal finding and points to some severe difficulty.

“The temperature was 97°F.” This low reading may have been due to exposure, but in an infant in such a debilitated state the low temperature may very well have been a sign of severe infection. The blood counts for a newborn infant were within normal limits. The white and red cells in the urine possibly point to some infection in the urinary tract.

The sodium was definitely low, which indicates loss of excessive amounts of sodium, probably through the gastrointestinal tract.

There is no indication that a gastrointestinal series was done. Is that correct?

DR. BENJAMIN CASTLEMAN: Yes.

DR. ROSS: “Duodenal-enzyme analysis showed absent trypsin.” That is a significant finding and almost pathognomonic. There is no note about presence of a lowered level of lipase in the duodenal enzyme. The level of amylase at this age is so low that it can barely be read.

The fasting carotenoid level was noted to have been 1.8 units and the vitamin A 7.5 units. These so-called “blue units” that are used to express the level of blood carotenoids and vitamin A are purely arbitrary. In this age group the normal range for carotenoids is between 7 and 10 units and for vitamin A around 15. Thus there was a marked reduction in these two fat-soluble vitamins or previtamins. The diagnosis of idiopathic pancreatic fibrosis would naturally lead to an attempt at substitution therapy, using one of the pancreatic extracts. Nutramigen is one of the casein hydrolysates, providing a mixture of protein break-down products, largely amino acids.

The stools became “almost fat free.” That may have been due to the fact that the diet was low in fat content. The lowering of the red-cell count, of the hemoglobin and of the total protein points to poor protein absorption. Vitamin D

was furnished by ultraviolet irradiation on the assumption that fat soluble vitamins would not be absorbed from the gastrointestinal tract.

The differential diagnosis in an infant of this age, with the long, complete story that we have, does not allow many possibilities. The obvious diarrhea, the inability to tolerate fat, the failure to gain and the enlarged abdomen, all point to some difficulty with intestinal absorption.

Celiac disease would be rather unusual at such an early age. It is a condition seen in infants and young children, usually appearing late in the first year of life, with the typical symptoms not often being seen until the beginning of the second year. The disease is not associated with any change in duodenal enzymes. There is another type of disease associated with intolerance of starch, in which fat may be properly absorbed but starch inadequately taken care of; in such cases the amylase content of the duodenal fluid is low. That again appears in an apparently normal child after six months of life and has a strong tendency to be familial. Syphilis has been reported to have produced fibrosis in the pancreas and the condition outlined here; however, although no specific statement is made, I should guess that this was not syphilis.

DR. CASTLEMAN: The blood Hinton test was negative.

DR. ROSS: Sprue, the vitamin B deficiency disease, certainly has never been proved at this early age. Mechanical obstruction to absorption in the gastrointestinal tract and short circuiting, as in gastroduodenal fistula, are possibilities, but there is no evidence for them.

Congenital stenosis of the gastrointestinal tract, with impairment of absorption, as seen in tuberculous peritonitis with obstruction to the return of lymph from the intestinal tract, would not appear in an infant this young. The books say that heavy-metal poisoning may cause obstruction to absorption. There is no evidence in this child that such poisoning had occurred.

I am forced to the diagnosis that the other hospital made — namely, idiopathic fibrosis of the pancreas. In support of this diagnosis we have the family history of one other child with pancreatic fibrosis and the second one with a suspicion of the same disease. There were absent trypsin and increasing anemia and hypoproteinemia despite the administration of large amounts of blood; in other words the child was unable to manufacture its own protein. These signs are associated mainly with the disease that we know as idiopathic fibrosis of the pancreas. The low fat absorption, as evidenced by the rather

low cholesterol, carotenoids and vitamin A, certainly fits in with this picture. The variation in fluid metabolism that would result from large amounts of fluid in the loops of bowel that had been distended and were edematous may explain the low sodium. The one thing that is missing is the presence of respiratory infection. However, this child was so young that he possibly did not have time to develop the type of infection so classically seen in fibrosis of the pancreas after the first three or four months of life. Such infection can possibly be explained on the basis of inability to absorb fat-soluble vitamins, with the development of vitamin A deficiency, metaplasia of the epithelium of the respiratory tract and areas of infection. In this infant, however, there is no evidence that infection was the cause of death; quite possibly, even though physical examination and x-ray examination did not show it, Dr. Castleman may be able to point out evidence of pulmonary infection. The diagnosis of rickets, due to vitamin D deficiency, in a child this young and with so little growth is unlikely.

CLINICAL DIAGNOSES

Pancreatic fibrosis.
Otitis media.

DR. ROSS'S DIAGNOSES

Idiopathic pancreatic fibrosis.
Vitamin A deficiency.

ANATOMICAL DIAGNOSES

Idiopathic pancreatic fibrosis.
Pulmonary atelectasis, focal.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: This child did have idiopathic pancreatic fibrosis. At autopsy the child was quite emaciated but well developed. The only gross finding that was easily visible was focal atelectasis of the lung, but no real areas of consolidation. The pancreas appeared somewhat smaller than normal and was extremely firm. Microscopically there was marked interlobular and interacinar fibrosis throughout the pancreas, and many of the acini and ducts were dilated and filled with mucus (Fig. 1). Some showed definite cyst formation. I know very little about the pathology of this condition and have invited Dr. Farber to come down from the Children's Hospital to tell us more about it.

DR. SIDNEY FARBER: I was able to study the organs of the sibling mentioned in the record who died at the community hospital. The patient, who had much the picture that Dr. Castleman has just

described, was a girl twenty months of age with symptoms that began shortly after birth. The pancreas showed a more extreme degree of atrophy, dilatation of the acini and ducts and fibrosis than the one under discussion here. But the one here I regard as a fairly marked example of the disease. In addition, the sibling had a widespread bronchopneumonia caused by *Staphylococcus aureus*, and there was rather marked obstruction in the

structures, coalescence of the fibrous-tissue stroma and the formation of new fibrous tissue. The thick inspissated material is what one sees when one looks at the duodenal contents, which are thickened and sticky.

If the disease has run some months, the trachea and bronchi and the upper respiratory tract may be literally blocked by this very thick mucus, to which is usually added staphylococcal infection.

FIGURE 1. Photomicrograph of a Section of the Pancreas.

upper respiratory tract caused by inspissated mucus and purulent material.

I shall describe some of the changes we saw in this and other cases of pancreatic fibrosis. The pancreas may be normal in appearance or it may show the picture of marked atrophy. The normal portions of the pancreas stand out above the level of the diseased lobules, which are depressed, representing areas of atrophy and fibrous-tissue replacement. The clinical picture, however, may be produced by a pancreas that grossly appears normal. On microscopic examination the obstruction will be found in the small acini, and such obstruction causes pancreatic achylia in as great a degree as that produced by ligation of the main pancreatic ducts.

The term "cystic fibrosis" has been used, but there are no true cysts. Obstruction develops in the acini and is caused by inspissated pancreatic secretion, which is propelled with difficulty into the ducts. This, in turn, causes atrophy of the acinar

In this case, however, the main picture in the lung is not one of infection but rather one of obstruction. The major bronchi and the bronchioles are filled with inspissated material, and these infants may actually die of suffocation. The x-ray picture goes with these findings. Thus the same mechanism responsible for the pancreatic change appears to be responsible for the changes in the respiratory tract. Changes due to vitamin A deficiency are present in some but not all cases of this disease. Vitamin A deficiency, I believe, is not responsible for the occurrence of pulmonary infection.

The explanation for the obstruction, as well as the superimposed staphylococcal infection so often present, is found in the alteration of the character of the mucus produced by the glands of the trachea and bronchi. It is similar to the alteration found in pancreatic secretions in the pancreas. The material in the bronchial gland is thick and sticky and does not lubricate properly the mucosal surface of the trachea and bronchi. The organism

is not of great virulence as seen by the fact that little damage pathologically can be demonstrated even after the *Staph. aureus* is proved to have been present in the lung for one or two years. Similar changes may be found in the sublingual gland, duodenum, gall bladder, esophagus and bowel. One of the rare complications of the disease, which has occurred six times in our experience in recent years, is involvement of the liver in a form of cirrhosis that I have not encountered or seen described elsewhere. It is an essentially obstructive biliary cirrhosis. The bile capillaries are greatly distended and are filled with inspissated eosinophilic-staining material similar to the substance in the pancreatic acini and ducts. The obstruction causes atrophy of the liver drained by these bile capillaries and replacement fibrosis.

I have been forced to the conclusion that this disease is not a disease limited to the pancreas. The pancreas is merely one of many organs in the body affected by a general pathologic process involving secretory structures in many parts of the body. Wherever secretory structures are affected the fundamental change appears to be the same—the material secreted is more viscid, flows less readily than normal and, by mechanical action, causes obstruction to the duct system or gland system with an eventual fibrous-tissue replacement distal to the point of obstruction. There is sufficient evidence to say that vitamin A deficiency is a complication of the disease, not the cause of it. The exact cause is still unknown.

DR. CASTLEMAN: I might add that in our case there was no evidence of vitamin A deficiency. There was a small amount of mucus in the trachea and large bronchi and a very small amount in the bronchioles, which might have accounted for the focal atelectasis. There was no evidence of pneumonia. Examination of other mucous glands, such as the submaxillary gland and the duodenum, showed an early change, but nothing striking, probably because the child was so young.

CASE 29432

PRESENTATION OF CASE

A sixty-year-old woman entered the hospital because of persistent nausea and vomiting.

Eight days prior to admission the patient suffered with gaseous fullness and crampy lower abdominal pain. She passed large amounts of gas rectally, with some relief. Two days later she felt nauseated and vomited small amounts of bitter, yellow, nonbloody fluid. The nausea and intermittent vomiting continued to the day of admission, and she had been unable to retain anything except small amounts of broth. Bowel movements

had been regular and normal during the illness; the patient, however, took a laxative each day. The stools were not observed to be tarry, bloody or acholic. She had not been jaundiced, nor had she suffered with fever or chills.

The patient had been admitted to the hospital seventeen months previously, at which time the left breast was radically resected because of carcinoma. The axillary lymph nodes were reported to have been uninvolved. The family history was noncontributory.

Physical examination disclosed a well-developed and well-nourished woman. There was a well-healed scar over the left chest extending into the axilla. No nodules were felt in the scar line, right breast or axillas. The heart and lungs were normal. The abdomen was distended and quite tympanitic. No tenderness was elicited, and no masses were felt. Marked peristaltic rushes were audible over the entire abdomen. Questionable dullness was percussed on the left side of the abdomen.

The blood pressure was 132 systolic, 72 diastolic. The temperature, pulse and respirations were normal.

The white-cell count was 8500. The urine was normal, and the stool guaiac negative. A Hinton test was negative. A roentgenogram of the abdomen demonstrated several loops of slightly dilated small bowel in the left midabdomen. A barium enema passed to the junction of the descending colon and sigmoid, where it met a point of practically complete obstruction. During the fluoroscopic examination no barium was seen to pass beyond the obstruction. On the films, there was a small amount of barium proximal to the lesion. There were numerous diverticula of the sigmoid, one of which was close to the point of obstruction. On one film there appeared to be a cavity in which there was a small amount of dilute barium. There was evidence of a small pressure defect in the sigmoid just distal to the lesion. Several loops of slightly dilated small bowel were observed, and there was a large amount of gas in the cecum. The right side of the pelvis showed evidence of Paget's disease.

On the day after admission a cecostomy was established, and ten days later the barium enema was repeated. This was again unsatisfactory, since the barium did not pass the point of obstruction.

An operation was performed on the seventeenth day after admission.

DIFFERENTIAL DIAGNOSIS

DR. CLIFFORD C. FRANSEEN: It is interesting to point out that this patient had bowel movements up to the time the barium enema was done, but it was not possible to pass barium beyond the

stricture. Of course that is a frequent occurrence, —that is, barium goes easily in one direction but not in the other in this type of lesion. The x-ray pictures will undoubtedly be of great assistance, and we should see them before proceeding.

DR. GEORGE W. HOLMES: This ought to be *the* case in which the findings are due to diverticulitis.

The film of the chest is negative. Those of the abdomen show the characteristic signs of obstruction, with accumulations of gas in the small bowel. So far as the x-ray is concerned there is no positive evidence of free fluid. The diverticula are quite large and are scattered throughout the lower sigmoid. Evidently the patient had some difficulty in retaining the enema. A retaining catheter was used, and apparently complete obstruction was demonstrated. I might add that the picture at the point of obstruction looks a little like tumor.

DR. FRANSEEN: Dr. Holmes says that this should be *the* case with diverticulitis, undoubtedly because we have recently discussed two cases with similar findings in which a diagnosis of diverticulitis was made only to have them both turn out to have been due to carcinoma. We shall have to review the findings to look for some evidence, other than the presence of diverticula, for making the diagnosis of diverticulitis.

The first thing in sequence that seems to be of significance is the breast carcinoma that was operated on seventeen months previously. That is the only point in the history up to eight days before entry that gives any lead to a possible cause. The lymph nodes were uninvolved at the time of the breast operation; hence the likelihood of distant metastases is diminished, but certainly not excluded. On general principles, the first thing we ought to consider is a metastatic lesion. To my mind, a metastatic lesion that could produce this picture would be a little unusual because the obstruction to the large bowel was complete. A metastatic lesion is usually extrinsic, and would have to be extensive to produce complete obstruction by pressure on the large bowel. One could assume that there was some obstruction to the small bowel because of the dilated loops, and it is also conceivable that a metastatic lesion could have a loop of small bowel affixed to it, thus producing enough obstruction to the sigmoid to give this picture. It would be unusual, however, to have a single isolated metastasis like this from a carcinoma of the breast without other evidence of metastatic lesions.

Other things of extrinsic origin could have produced the picture—such as endometriosis. There is no way of proving any of these diagnoses,

however, and the case narrows itself down in large part, if one uses the statistical method of diagnosis, to a primary lesion in the bowel.

The two most likely diagnoses are carcinoma and diverticulitis, or both. Numerically, carcinoma is, of course, the most frequent. One thing that is against carcinoma is the lack of previous trouble. On the other hand, the short history is in favor of an inflammatory lesion in an area of diverticulosis. The absence of bleeding, although favoring diverticulitis, does not entirely exclude carcinoma. It is unusual, however, for a carcinoma to produce obstruction without previous symptoms or without bleeding. It is also unusual, at least in my experience, to have the obstruction of a carcinoma so complete without previous symptoms. There was really no lumen to the bowel at the point of tumor, since the barium enema showed complete obstruction. The evidence in favor of diverticulitis, on the other hand, is the presence of numerous diverticula. Perhaps a carcinoma was present that mechanically obstructed a diverticulum and set up a diverticulitis. The presence of a small cavity is certainly evidence in favor of an inflammatory lesion—presumably an abscess draining into the bowel, since it was shown by barium enema. If one is going to bring the small bowel into the picture I cannot escape the impression that the x-ray findings there were entirely due to backing up of gas in the small bowel. The obstruction could also have been due to secondary ileus from an inflammatory lesion. Adhesion of a loop of small bowel to the sigmoid does occur, and it is more likely to occur in an inflammatory lesion than in carcinoma. In the late stages of carcinoma of the sigmoid, of course, it frequently happens. Another thing against an inflammatory lesion is that no tenderness was elicited on examination. One would expect some tenderness in a case of diverticulitis so severe that the bowel is obstructed; but this patient was sixty years old and we know that old people can have severe inflammatory lesions in the bowel with no tenderness or spasm to account for them. The temperature, pulse and respirations were also normal, which argues to some extent against an inflammatory process, but not entirely. The white-cell count was also normal.

I end up with an uncertain picture for either carcinoma or diverticulitis. It might, of course, be both, but on the basis of the evidence presented by the x-ray findings, by the history and by the other points that I have discussed, I believe that one should go on the basis of probabilities and put diverticulitis first, with strong reservation so far as carcinoma is concerned.

DR. FLETCHER H. COLBY: Does the fact that ten days after cecostomy complete obstruction was still present favor an inflammatory lesion?

DR. FRANSEEN: Not entirely. I am sure Dr. Smithwick will agree that after cecostomy is done for an obstructing carcinoma in the lower bowel the patient frequently has spontaneous bowel movements, the lumen opening up again. To my mind, your point argues in favor of diverticulitis.

DR. REGINALD H. SMITHWICK: In my personal experience it is rather unusual for diverticulitis to produce total and persistent complete obstruction. In the 65 patients on whom we have operated in this hospital in fifteen years, there are only 4 or 5 that really had complete obstruction by barium enema when they entered the hospital. In these the obstruction cleared up completely within two weeks after proximal decompression, so that my feeling is that if obstruction fails to let up it is more in favor of cancer than it is of diverticulitis.

DR. FRANSEEN: The one strong point in favor of carcinoma is the suggestion of protrusion of a mass into the lumen of the bowel.

DR. SMITHWICK: Another point is the location of the lesion in a case such as this. It is quite difficult to say by barium enema where the descending colon ends and where the sigmoid begins, but it is rare to have any surgical complication of diverticulitis above the upper end of the sigmoid. In this particular case it is probable that the point of obstruction was in the descending colon rather

than in the sigmoid. That also is in favor of cancer.

At the time of operation we were unable to tell whether this woman had diverticulitis or cancer, or both. She did have an inflammatory process and obvious diverticulums. The involved area was resected.

CLINICAL DIAGNOSIS

Carcinoma of sigmoid?
Diverticulitis with obstruction?

DR. FRANSEEN'S DIAGNOSIS

Diverticulitis of sigmoid?
Carcinoma of sigmoid?

ANATOMICAL DIAGNOSES

Adenocarcinoma of descending colon.
Diverticulosis coli.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: The lesion in this case was a completely annular, constricting carcinoma, as well as multiple diverticulums. The diverticulums were distal to the cancer. I should say that the cancer was in the lower end of the descending colon rather than in the sigmoid.

DR. SMITHWICK: I cannot conceive how this patient could have gone up to a few days of the time of her hospital entry without any symptoms.

MEDICAL ADVERTISING

In an editorial "Council Standards and Medical Advertising," which appeared in the October 9 issue of the *Journal of the American Medical Association*, it is stated that the business managers of various state medical journals are urging the breakdown of standards set by the Council on Pharmacy and Chemistry of the American Medical Association. Since the *Journal* is one of the periodicals mentioned by name, refutation of the accusation seems justifiable.

For many years the *Journal* has obtained the majority of its contracts covering nationally advertised products from the Cooperative Medical

Advertising Bureau, which was created in 1913 by the Board of Trustees of the American Medical Association. All accounts are handled through the office of the Bureau in Chicago, and this service is paid for on a commission basis. Since the Bureau is a nonprofit organization, a generous refund is made to the *Journal* at the end of each fiscal year. As part of the agreement, the *Journal* agrees to limit advertising to pharmaceutical products that have been accepted by the Council on Pharmacy and Chemistry of the American Medical Association, and failure to abide by this clause has provoked the serious accusation referred to above.

The *Journal*, at the moment, has advertising contracts with two local firms that manufacture nonaccepted products. In each instance, the drugs had never been submitted to the Council for approval, and careful investigation revealed that they were being used and recommended by authoritative physicians; furthermore, no unwarranted claims have been made in the advertising copy. All this has been done with the full knowledge of the Cooperative Medical Advertising Bureau, which, incidentally, has failed to reply to a letter dated August 11, 1943, in which it was stated that the *Journal* intended to continue with the advertising of this type unless specifically told not to do so by the Advisory Committee of the Bureau.

Another difficulty often leading inadvertently to the advertising of nonapproved drugs arises from the fact that Bureau-sponsored firms often submit copy covering such products directly to the medical journal. Unless the business manager is alert, such copy is likely to be accepted routinely.

By and large, there appears to be no concerted effort to break down, or even weaken, the standards of the Council on Pharmacy and Chemistry. Certainly there is little excuse for the statement, "The time should long since have passed when leaders of medical organizations consent to permit the exploiters of unestablished proprietary remedies to pay the bulk of printing and publishing bills of the medical journals that are supposed to

represent scientific medicine," or for the exhortation, "Let us keep the good name unsullied; its value is far above that of jewels or gold." The editorial and business staffs of the majority of state medical journals fully appreciate the good that has been accomplished by the efforts of the Council on Pharmacy and Chemistry and have no intention of "upsetting the apple cart." On the other hand, it should be appreciated that federal regulations regarding new drugs and labeling are much stricter and much more rigidly enforced than they were thirty-five years ago; that approval by the Council of effective and valuable drugs that are widely used is often unduly delayed or withheld because of minor infringement; and that the chief revenue of the majority of state medical journals is that derived from medical advertising. Previously, only one of the three members of the Advisory Committee of the Co-operative Medical Advertising Bureau had been connected with a state medical journal. Quite recently, however, the Board of Trustees of the American Medical Association, owing to pressure brought to bear by representatives of the state journals, has appointed two additional members, both of whom are editors. It is hoped that some arrangement regarding medical advertising that is advantageous both to "scientific medicine" and to the state journals will be forthcoming.

MISSILE WOUNDS OF THE SKULL AND ITS CONTENTS

It is earnestly recommended that all physicians take the trouble to read the leading article in the August 21 issue of the *Lancet*. Entitled "Treatment of Head Wounds Due to Missiles," it is an analysis of 500 cases treated during nearly two years by a mobile neurosurgical unit of the Royal Army Medical Corps in the Middle East. The author, Major P. B. Ascroft, visited Boston last May, at which time he gave a memorable talk on the same subject before a joint open meeting of the Boston Surgical Society and the Boston Society for Neurology and Psychiatry. Those fortunate

enough to have been present can scarcely forget the modesty with which he cited the extraordinary results he and his team had attained. The paper contains all that he said at that time, as well as certain other data. It is obvious that any organization that can deal with over four hundred missile wounds of the skull and its contents with a mortality of only 10.6 per cent and in addition return 71 per cent of the survivors to duty in an army geared to total war speaks with authority about its specialty.

The author and head of the unit was a trained neurosurgeon whose reputation had already been established in England before undertaking this particular assignment. Assisting him were a neurologist, Major Kremer, an anesthetist, Major Cope, and two assistant surgeons, Major Hooper and Captain Northcroft. All their reported methods and conclusions have civilian as well as military application, but certain of their points bear repetition, particularly those regarding compound fractures of the skull not sustained in battle. By categorically stating that it is better not to operate in forward areas provided the patient can reach a fully equipped base hospital within forty-eight to seventy-two hours of injury, by emphasizing the importance of a mechanical sucker and by failing to mention irrigation as a therapeutic agent in dealing with these wounds, as well as in other details of resuscitation, anesthesia, lumbar puncture and so forth, they confirm under battle conditions the opinion of a group of American neurosurgeons about the value of certain procedures relative to the time and method of dealing with civilian compound fractures of the skull, and settle a debate that has exercised this specialty for some years.

It is interesting to note also that Major Ascroft recommends the use of a plaster-of-Paris bandage as a means of securing the first dressing applied at the front, as well as to protect the patient's head. This is in line with the Russian experience as detailed by Vladimir Lebedenko, surgeon and professor at the First Moscow Medical Institute, at the meeting of the American Neurological Society

in New York last May. So far as is known, this work, equally as authoritative as that reported in the English paper, has not as yet been published. Lebedenko, however, considered this therapy of sufficient importance to bring samples of such plaster casques with him from Russia. In addition, Major Ascroft's suggestion that the plaster be also used to carry a sketch of the wound should not be lost sight of. Lebedenko's reported conclusions relative to transportation, preferable locale for operative interference and proper time of operation after injury correspond closely to those reached by Major Ascroft.

It is axiomatic that the English report should be made required reading by every member of the medical departments of the Army and Navy, even should it prove necessary to reproduce it in its entirety by photostating, mimeographing or any other suitable method. In particular, copies should be made available at once to the front-line hospitals and personnel, because the conclusions differ so fundamentally from those previously authorized for publication by the War Department, which were largely reached shortly after World War I and which have been influenced little, if at all, by advances made in traumatic civilian neurosurgery in the intervening years.

All civilian surgeons should read this paper as well. Familiarity with its contents will, among other things, do much to destroy outworn shibboleths and help the overworked local doctor speak with conviction when he advocates moving the civilian prototypes of such patients to the large medical centers. Responsibilities he neither wants nor is equipped to carry on his own shoulders will be thus shifted to surgeons with better facilities and more appropriate training—with consequent benefit to the patient, the community, the doctor and the war effort.

MEDICAL EPONYM

HINES-BROWN TEST

This test is described by Drs. Edgar A. Hines, Jr. (b. 1906) and George E. Brown (1885-1935)

in an account entitled "A Standard Stimulus for Measuring Vasomotor Reactions: Its application in the study of hypertension," which appeared in the *Proceedings of the Staff Meetings of the Mayo Clinic* (7: 332-335, 1932). A portion of the article follows:

The subject is placed at rest for twenty minutes and the blood pressure is taken every five minutes until a constant level is obtained. Then one hand is immersed above the wrist in ice water for twenty to thirty seconds. The temperature of the water varies from 4° to 5°C. The systolic and diastolic blood pressures immediately rise, and then return to the basal level in from one to two minutes. . . .

It was found that among subjects . . . with organic forms of hypertension, the average increase of systolic and diastolic pressures was greatest for all the subjects studied. . . .

A later report on the results of this test in 571 normal and hypertensive subjects appears in the *American Heart Journal* (11: 1-9, 1936).

OBITUARY

HALBERT GREENLEAF STETSON

1868-1943

On September 15, 1943, Dr. Halbert G. Stetson, of Greenfield, president of the Massachusetts Medical Society in 1931 and 1932, died at his home after more than a year of failing health, occasioned by a decompensated heart. Born in Greenfield on May 8, 1868, he was educated in the public schools of Orange and at New Salem Academy, acquiring his medical education at the College of Physicians and Surgeons of Baltimore, from which he graduated in 1895. He immediately began practice in Greenfield, which he continued to within a few months of his death, although he had done little surgery for several years.

In 1899 he formed a partnership with Drs. George P. Twitchell and Charles F. Canedy, which continued until the death of Dr. Twitchell in 1930, Dr. Canedy having died in 1925.

In 1897 he married Frances A. Gildart, of Salisbury, New Brunswick, who died in 1920. They had one son, Maurice H., now living in Kalamazoo, Michigan. In 1923 he married Anna B. MacKenzie, then head nurse at the Franklin County Hospital, who survives him.

His medical affiliations included membership in the American Medical Association, Massachusetts Medical Society, American College of Surgeons, Connecticut River Valley Medical Association, and New England and New York Association of Railway Surgeons.

Although surgeon for the Boston and Maine Railroad since 1903 and medical examiner of Franklin County since 1921, his chief interest was in the Franklin County Hospital, of which he was chairman of the Board of Trustees. He had much to do with the building and development of the present hospital, which was completed in 1910, and in 1938 donated a library in honor of his former partners, Drs. Twitchell and Canedy. This was named "The Stetson Library," by the hospital staff and a bronze plaque was placed on the wall in his honor. In addition he had served in several civic capacities, including president of the Greenfield Chamber of Commerce and chairman of the School Committee.

His chief hobbies, aside from the hospital, comprised books and postcards and attendance at medical meetings.

Dr. Stetson was a man of strong character and had the respect of all who knew him.

*Pfeiffer-bacillus meningitis only other form reportable previous to 1941.

COMMENT

The increase in poliomyelitis cases commented on in the August report has been considerably accelerated during September. The number of cases for this month was approximately nine times the seven-year median. This figure, nevertheless, is not high if judged by previous standards, and this year's outbreak on the whole will probably rank as a relatively minor one.

Meningococcal meningitis is still at a high level, nearly thirteen times the seven-year median, and there was a moderate rise over last month's figure. This may indicate

that the high prevalence may continue into the next season.

Diphtheria shows a slight increase this month, owing to 8 cases in a small town that has done little immunizing for the past few years.

Scarlet fever did not drop to the usual low seasonal level. This is the twenty-fourth consecutive month in which the number of cases exceeded the number reported the same month the previous year.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anterior poliomyelitis was reported from: Attleboro, 2; Bedford, 1; Belmont, 3; Berkley, 1; Beverly, 23; Boston, 7; Braintree, 3; Brockton, 2; Cambridge, 1; Fall River, 6; Framingham, 1; Hinsdale, 2; Holliston, 1; Holyoke, 1; Hopkinton, 1; Lee, 2; Lynn, 11; Malden, 1; Mansfield, 1; Marblehead, 1; Maynard, 1; Medford, 1; Melrose, 1; Milton, 1; Natick, 1; Newton, 1; North Attleboro, 1; North Brookfield, 1; Norton, 1; Norwood, 2; Peabody, 2; Pittsfield, 3; Quincy, 2; Reading, 1; Revere, 1; Salem, 8; South Hadley, 1; Somerville, 1; Southbridge, 3; Springfield, 1; Swampscott, 1; Truro, 1; Wakefield, 2; Waltham, 4; Watertown, 3; Wenham, 2; Weston, 1; Weymouth, 1; Wilbraham, 1; Worcester, 1; total, 122.

Diphtheria was reported from: Arlington, 1; Blackstone, 1; Boston, 1; Boxboro, 8; Easthampton, 1; Taunton, 1; Weymouth, 1; Woburn, 1; total, 15.

Dysentery, bacillary, was reported from: Becket, 2; Boston, 2; Lawrence, 1; Malden, 1; Holyoke, 4; Melrose, 2; Northampton, 4; Wellesley, 1; Wilbraham, 1; Woburn, 5; total, 23.

Encephalitis, infectious, was reported from: Amherst, 1; Lynn, 1; Malden, 1; Stoughton, 1; total, 4.

Malaria was reported from: Amherst, 1; Camp Edwards, 1; Chelsea, 1; Fort Banks, 8; Leominster, 1; Revere, 1; Springfield, 1; total, 14.

Meningitis, meningococcal, was reported from: Acushnet, 1; Barnstable, 3; Boston, 14; Brookline, 1; Camp Edwards, 1; Chelsea Naval Hospital, 2; Dudley, 1; Fall River, 2; Fort Devens, 3; Hanover, 1; Holyoke, 1; Lowell, 3; Lynn, 1; Malden, 1; Northbridge, 1; Norfolk, 1; Revere, 1; Somerset, 1; Somerville, 2; Southbridge, 1; Wareham, 1; Westfield, 1; Weymouth, 1; Winthrop, 1; Worcester, 5; total, 51.

Meningitis, other forms, was reported from: Fall River, 1; Lawrence, 1; Lynn, 1; New Bedford, 1; Springfield, 1; Wilbraham, 1; Worcester, 1; total, 7.

Meningitis, undetermined, was reported from: Gloucester, 1; Medford, 1; Worcester, 1; total, 3.

Salmonella infections were reported from: Becket, 1; Beverly, 1; Brockton, 1; Cambridge, 2; Haverhill, 8; Lexington, 1; Lowell, 1; Pittsfield, 1; Somerville, 1; Templeton, 11; Wakefield, 1; Waltham, 1; total, 30.

Septic sore throat was reported from: Boston, 1; Marion, 4; Milton, 1; West Springfield, 1; total, 7.

Tetanus was reported from: Billerica, 1; Boston, 1; Haverhill, 1; Lowell, 1; Peabody, 1; total, 5.

Trachoma was reported from Hudson, 1; total, 1.

Trichinosis was reported from: Boston, 1; Westwood, 1; total, 2.

Typhoid fever was reported from: Gardner, 1; Malden, 1; total, 2.

Undulant fever was reported from: Adams, 1; North Brookfield, 1; total, 2.

WAR ACTIVITIES

CIVILIAN DEFENSE

The following notice was recently released by Dr. George Baehr, chief medical officer of the Office of Civilian Defense, Washington, D. C.

Rumors that civilian defense is no longer necessary have recently been spread by irresponsible persons. These rumors are thoughtless or calculatingly subversive, for they are not supported by Army authorities responsible for our coastal defenses or by the present military situation.

Fortunately, the success of our armed forces overseas has saved us thus far from experiencing the horrors of enemy bombing to which the cities of our allies are being subjected. In the opinion of the best military authorities our coastal areas and industrial centers will not be free of the danger of enemy attack from the air or of widespread sabotage until the last day of the war.

Civilian defense is needed also as one of the essential measures for safeguarding internal security. This is especially true of the Emergency Medical Service. If we had not created a nationwide organization for civilian defense two years ago, we would be obliged to organize one today for home security. Disasters of all kinds have increased because of the tremendous speeding up of our great industries, the overburdening of our railroads and the inexperience of hundreds of thousands of new war workers. Our police and fire departments, our public works and utility services and our hospitals, on which we depend for protection, are being increasingly depleted of trained personnel. We must therefore strengthen our voluntary protective services throughout the land. Along the Pacific and the Atlantic coasts these services must be especially strong in volunteer personnel and equipment to guard us against the hazards of enemy attack and sabotage until that day when the Army advises us that the danger is ended.

MISCELLANY

FIFTIETH ANNIVERSARY OF TUFTS COLLEGE MEDICAL SCHOOL

The grand assembly of the Fiftieth Anniversary of Tufts College Medical School was held on October 6 in Boston and was attended by 940 medical alumni and students. Among the speakers were Harold E. Sweet,

president of the Board of Trustees of Tufts College, Dr. Alonzo K. Paine, professor of obstetrics, Dr. Karl T. Compton, president of the Massachusetts Institute of Technology, Captain A. Warren Stearns (MC), USNR, dean-on-leave, Dr. Louis E. Phaneuf, professor of gynecology, Commander Bartholomew W. Hogan (MC), USN, and Dr. Leonard Carmichael, president of Tufts College.

President Carmichael read a letter that he had received from President Roosevelt, in which the accomplishments of the medical school during the fifty years subsequent to its founding were praised and well wishes for the coming years were given. He announced that \$746,000 has been raised toward the \$850,000 Building Fund goal. He also acknowledged a contribution of \$125,000 by Edward Cohen toward the Building Fund. The total was exclusive of contributions that were made for various other specific purposes in connection with the medical school.

The Fiftieth Anniversary Committee consisted of Dr. Phaneuf, chairman, Dr. Carmichael, Capt. Stearns, Dr. Dwight O'Hara, acting dean, and Dr. Harry Blotner, secretary-treasurer of the Tufts Medical Alumni Association.

RENEWAL OF AWARD TO SHARP AND DOHME

Sharp and Dohme, originators of the process by which dried blood plasma is made, and sole manufacturers of the first nine months' supply of this vital material for the armed services, was awarded the Production Army-Navy E for the second time on Saturday, October 16. In a letter to the workers at the Philadelphia plant and the Glenolden laboratories of Sharp and Dohme, Robert P. Patterson, Under-Secretary of War, stated: "You have continued to maintain the high standards that you set for yourselves six months ago. The White Star, which the renewal adds to your Army-Navy Production Award flag, is the symbol of appreciation from our armed forces for your continued and determined effort and patriotism." Sharp and Dohme's pioneer work in developing the methods and equipment necessary for the production of dried plasma is one of the most important contributions of the biological industry and has already resulted in great saving of life through transfusion of plasma at the scene of battle.

NOTES

Dr. Joe V. Meigs has recently been appointed surgeon in charge of gynecology at the Palmer Memorial Unit of the New England Deaconess Hospital. The Gynecologic Tumor Clinic of the Out Patient Department, which for many years had been under the direction of the late Dr. G. A. Ireland, Jr., will be under the guidance of Dr. Meigs.

Dr. Charles F. McKhann has recently accepted the position as assistant to the president of Parke, Davis and Company and will devote his entire time to the scientific activities of the company. From 1936 to 1940, Dr. McKhann was associate professor of pediatrics and communicable diseases at the Harvard Medical School and a member of the staff of the Children's Hospital; he then

joined the faculty of the University of Michigan, serving as professor of pediatrics and communicable diseases at the Medical School and as professor of maternal and child health at the School of Public Health.

CORRESPONDENCE

PLUMMER-VINSON SYNDROME

To the Editor: In your leader on the Plummer-Vinson Syndrome in your issue for July 22 you suggest that Kelly's name should be added to that of Paterson in discussing the upper-dysphagia-with-anemia syndrome. My reason for not mentioning Kelly is the same as my reason for no longer mentioning Plummer and Vinson. Paterson's first description of the condition was published in the *British Medical Journal* in 1906 (2:355) — thirteen years before his fuller description mentioned by you and before Kelly's. The priority is therefore quite clearly Paterson's and not Kelly's.

BOOK REVIEWS

Athletic Injuries: Prevention, diagnosis and treatment. By Augustus Thorndike, M.D. Second edition. 8°, cloth, 216 pp., with 105 illustrations. Philadelphia: Lea and Febiger, 1942. \$3.00.

The second edition of this book has been thoroughly revised in the light of recent advances in the physiology of physical fitness, and the chapter on physical therapy has been rewritten with the assistance of Dr. Arthur L. Watkins. The manual should be popular with all those having to do with sports and physical culture. It is well printed, with a good type, and is of handy size.

The Clinical Application of the Rorschach Test. By Ruth Bochner, M.A., and Florence Halpern, M.A. With an introduction by Karl M. Bowman, M.D. 8°, cloth, 216 pp., with 3 graphs. New York: Grune and Stratton, 1942. \$3.00.

This comparatively new test is now widely used by psychiatrists. The test itself is simple in that the subject reports his interpretation of ten standardized ink blocks, pointing out everything that is revealed in or suggested by the outline of the figures. The results are then interpreted, a fairly complicated procedure only to be comprehended after considerable study under expert guidance. The aim of the test is to study the personality traits in the individual. This can, naturally, be done by prolonged personal investigation, but the time will be greatly shortened if the Rorschach test proves to be valuable. At pres-

ent the test should be left in the hands of those most competent to carry it out, since it is not something that can be widely applied by unskilled workers. This book will help anyone to understand the test as it is done by the authors, both of them qualified psychologists formerly associated with the Bellevue Psychiatric Hospital.

The test itself cannot be regarded as infallible and there are still many controversial points about its value. It has, however, established itself, probably permanently, in the psychiatric clinics as an important test for personality. This book, giving the known facts regarding the test and its interpretation, is an important addition to the current literature. A number of typographical errors need correction.

Synopsis of Materia Medica, Toxicology and Pharmacology. By Forrest R. Davison, M.Sc., Ph.D., M.B. Second edition. 12°, cloth, 695 pp., with 45 illustrations. St. Louis: The C. V. Mosby Company, 1942. \$5.75.

The first edition of this work was published in 1940, and it has now been found necessary to publish a second edition, which has been revised to include information on a large number of new drugs. The general plan of the work has not been changed, but in nearly every section important additions and deletions have been made. The revision conforms to the latest edition of the *National Formulary*, the twelfth edition of the *Pharmacopoeia of the United States* and the *British Pharmacopoeia*. The chapter on sulfonamide drugs has, of necessity, been enlarged.

An attempt has been made to keep the volume moderate in size, and this has led, unfortunately, to the use of a rather small type. The book also has been printed on coated stock, which makes it rather heavy for its size; a lighter paper would have made the volume easier to handle.

Memorable Days in Medicine: A calendar of biology and medicine. By Paul F. Clark, Ph.D., and Alice S. Clark. 12°, cloth, 305 pp., with 29 illustrations. Madison, Wisconsin: The University of Wisconsin Press, 1942. \$2.00.

This calendar of birth and death dates of noted men in the field of biology and medicine is a useful compilation, especially for those who have to plan regular exhibits for public display. The selection is purely a personal one of the authors and therefore will not meet the ideas of all those interested in the history of medicine. It seems incongruous to include the birthdays of the Virgin Mary and Leif Ericson.

One inaccurate entry is of considerable local interest. Under date of November 27, 1782, it is stated that the Harvard Medical School was established by the Corporation of Harvard College and that three professorships were then voted to John Warren, Benjamin Waterhouse and Aaron Dexter. The records of the Corporation show that on September 19, 1782, a report embodying a plan for the formation of a medical school was adopted, and that on November 22 one professor was appointed, namely, John Warren, who managed all branches of the new school. Benjamin Waterhouse was elected on December 24, 1782, and Aaron Dexter was not voted in until May 22, 1783. It was not until October 7, 1783, that Warren and Waterhouse were inducted into office with much ceremony.

STUDIES ON THE DESTRUCTION OF RED BLOOD CELLS*

III. Mechanism and Complications of Hemoglobinuria in Patients with Thermal Burns: Spherocytosis and Increased Osmotic Fragility of Red Blood Cells

SHU CHU SHEN, M.D.,† THOMAS HALE HAM, M.D.‡
WITH THE ASSISTANCE OF ELEANOR M. FLEMING, A.B.§

BOSTON

HEMOGLOBINURIA, the excretion of extra cellular hemoglobin in the urine, is recognized as an early complication of severe thermal burns. It is a sign of rapid destruction of red blood cells producing, in the plasma, free hemoglobin, which is usually excreted promptly by the kidney.¹⁻³ In this paper observations are reported on the changes in the blood and in the urine and on the kidney complications occurring in 14 patients with moderate or severe thermal burns 10 of whom showed hemoglobinuria. Experimental studies on the effect of heating human red cells and on the effect of injection into the dog of heated canine red cells will be outlined briefly and reported in more complete form elsewhere.

In the literature on thermal burns, hemoglobinuria has infrequently been reported as a complication of severe third degree burns involving usually half or more of the body surface.⁴⁻⁶ Cope and Rhinelander⁷ reported 9 cases of hemoglobinuria in patients burned in the Coconut Grove disaster. Hemoglobinuria, according to Wilms⁶ was not a constant finding in severe burns. It lasted for only one or two days and the amount of blood destroyed was not sufficient to endanger the patient's life. Ohguri and albuminuria however, were the usual consequences of severe second degree or third degree burns, whether or not hemoglobinuria was present. Albuminuria lasted five days or longer. Marchand⁸ in a critical re-

view of the pathology of thermal burns found that the renal lesion of so called "burn nephritis" is similar to that produced by hemoglobinuria due to other causes. Experimentally, hemoglobinuria has been demonstrated in animals burned by scalding.⁹⁻¹⁰ The heating of blood to 52 to 65°C in vitro⁹⁻¹⁵ and the apparent heating of blood in vivo in burned animals¹⁶⁻¹⁸⁻¹⁹ have both produced progressive fragmentation of the red cells, with the formation of spherocytes and microspherocytes. Pfeiffer¹⁹ found that destruction of erythrocytes by heat was evidenced by the immediate occurrence of hemoglobin in the plasma of anesthetized animals burned by scalding, with a rise in subcutaneous temperature as high as 63°C. Von Lesser¹⁰ observed hemoglobinemia and hemoglobinuria in burned animals, in normal animals transfused with blood from a burned animal, and in normal animals injected with homologous blood heated to 60 or 62°C in vitro. The red cells with abnormal morphology were rapidly removed from the animal's circulation and presumably destroyed. Spiegler¹² and Isaac Brock and Minor¹ confirmed the morphologic changes occurring in heated blood and observed that red cells heated to above 50°C were increased in osmotic fragility. No hemolysins or agglutinins were found in the plasma or serum of burned animals by Burkhardt.¹³ Spiegler noted the lack of toxic manifestations when heated blood was injected into dog.

METHODS OF INVESTIGATION

Following the Coconut Grove disaster samples of urine showing hemoglobinuria were obtained for analysis. It was impossible in many cases to secure complete urine specimens during the first forty-eight hours because of incontinence and because of the complex nurs-

*From the Thonike Memorial Laboratory, Section of Medical Science (H. and B.) Boston City Hospital and the Department of Medicine, Harvard Medical School. This investigation was aided in part by a grant from the National Research Council.

CASE No.	URINALYSIS	HEMOGLOBINURIA	
		DEGREE IN URINE	KIDNEY FINDINGS AT AUTOPSY
1	10 hr.: red. 18 hr.: brown; hemoglobin,* 90 mg. per 100 cc.; pH 5.4; 130 cc.; specific gravity, 1.012; sediment—precipitate of hemoglobin, hemoglobin casts, trace of hemosiderin.	Severe	No autopsy
2	24 hr. (catheterized): dark brown; scanty amount; protein, +++; sediment—no red cells.	Severe	No autopsy
3	16 hr.: brown; pH 5.5; specific gravity, 1.022; protein, ++; sediment—innumerable hemoglobin casts, no red cells.	Moderate	No autopsy
4	16 hr.: dark red; hemoglobin,* 520 mg. per 100 cc.; pH 5.5; 265 cc.; specific gravity, 1.016; protein, +++; sediment—precipitate of hemoglobin, hemoglobin casts, hemosiderin ++. 46 hr.: light brown; hemoglobin,* 80 mg. per 100 cc.; pH 7.5; 40 cc.; specific gravity, 1.011; protein, +++; sediment—precipitate of hemoglobin, hemoglobin casts, hemosiderin ++.	Severe	Extensive hemoglobinuria; nephrosis.
5	17 hr.: dark red. 20 hr.: brown. 42 hr.: yellow; no hemoglobin; pH 5.8; 70 cc.; specific gravity, 1.014; protein +; sediment—no hemoglobin casts, hemosiderin +.	Moderate	Slight hemoglobinuria
6	24 hr.: black. 40 hr.: amber; no hemoglobin; pH 4.5; protein, ++; sediment—hemoglobin casts, hemosiderin ++.	Severe	Hemoglobinuria; interstitial nephritis; healing tubular nephritis.
7	16 hr.: dark brown; hemoglobin,* 80 mg. per 100 cc.; pH 5.1; 190 cc.; specific gravity, 1.010; protein, ++; sediment—precipitate of hemoglobin, hemoglobin casts, hemosiderin ++.	Severe	Slight hemoglobinuria; late tubular nephritis; slight interstitial nephritis.
8	13 hr.: dark red. 34 hr.: amber; trace of hemoglobin*; pH 5.8; protein, +; sediment—hemoglobin casts, hemosiderin +.	Severe	
9	2 hr. (catheterized): orange; trace of hemoglobin*; pH 5.5; 15 cc.; sediment—negative for hemoglobin casts, trace of hemosiderin, no red cells.	Slight	Slight hemoglobinuria
10	24 hr.: dark amber; trace of hemoglobin*; pH 7.0; 95 cc.; specific gravity, 1.010; protein, +++; sediment—no hemoglobin casts or hemosiderin. 44 hr.: orange, faint trace of hemoglobin*; pH 7.0; specific gravity, 1.008; protein, ++.	Slight	Hemoglobinuria; slight nephrosis and interstitial nephritis.
11	6 hr.: orange; questionable trace of hemoglobin; pH 7.0†; protein, +; sediment—no hemoglobin casts, no hemosiderin. 11 hr.: amber; negative for hemoglobin; pH 7.0; protein, ++; sediment—no hemoglobin casts, hemosiderin +.	None	No hemoglobinuria or renal abnormality
12	8 hr. (catheterized): yellow; no hemoglobin; pH 8.0†; 6 cc. 10 hr. (catheterized): amber; trace of hemoglobin; pH 7.0, 190 cc.; specific gravity, 1.015; protein, +++; sediment—no hemoglobin casts, no hemosiderin, many red cells.	None	No hemoglobinuria or renal abnormality
13	24 hr.: yellow; no hemoglobin; acid; 440 cc.; specific gravity, 1.020; protein, +; sediment—no casts. 48 hr.: red brown; acid; specific gravity, 1.022; 1020 cc.; sediment—many red cells and sulfadiazine crystals.	None	No hemoglobinuria or renal abnormality
14	4 hr.: yellow, no hemoglobin; acid†; 65 cc.; protein, +; sediment—no hemoglobin casts, hemosiderin +, few red cells (menstruation). 13 hr.: amber; trace of hemoglobin; slightly acid; protein, +++; sediment—no hemoglobin casts, hemosiderin ++, few red cells.	None	

*Positive reaction to benzidine; no red cells in sediment.

†Received intravenous sodium lactate or sodium bicarbonate solution on both an admission and for 24 and 48 hours.

ing problem presented by the many gravely ill patients. The urine data for Cases 1-8 in Table 1 are therefore necessarily incomplete concerning the total output of urine and the analysis of all specimens. In these cases one or more urine samples voided within sixteen to forty-two hours after the burn were examined critically. The pH and hemoglobin content were determined within a day after obtaining the specimen. Careful study of the sediment was not done until five days after collection of the early specimens, which were preserved in an icebox and remained acid and remarkably free from bacterial contamination. In the patients not injured at Cocoanut Grove (Cases 9-14), the collection and examination of urine was prompt and was more complete than in the Cocoanut Grove cases. Samples of venous blood were always examined within two hours after collection. The hematologic and chemical methods employed in this investigation have been described in detail in a previous paper.²⁰

Quantitative estimation of the *hemoglobin* in plasma and in urine was performed by the benzidine method of Bing and Baker.^{21, 22} Examination of *pigments* in plasma, serum or urine was made with the Hardy recording spectrophotometer.²³ The *pH* of urine was measured with a glass electrode. The *total protein* in urine, including hemoglobin and other proteins, was roughly estimated by observing the precipitate in a sample boiled after acidification with acetic acid. *Hemosiderin* was detected microscopically as black-staining particles in a drop of sediment from centrifuged urine observed after the addition of a drop of ammonium sulfide solution.²⁴ Blood samples were taken from the antecubital vein or femoral vein, using as anticoagulant a mixture of dry ammonium and potassium oxalate, 200 mg. per 100 cc. of blood.²⁵ The *hemoglobin* was determined by a photoelectric-cell colorimeter calibrated so that 100 per cent hemoglobin was equivalent to 15.6 gm. per 100 cc. The erythrocytic volume per cent or *hematocrit* was determined by the Wintrobe²⁶ method.

The number of unusually *spherical cells* present in the red-cell population was estimated from fixed smears of blood stained with Wright's stain. A cell was considered to be a spherocyte if it was small in diameter compared to the other red cells and was homogeneous and intensely stained. Using these crude criteria, several observers agreed within 0.5 to 1.0 per cent on the number of spherocytes in 1000 red cells counted if the number was 3 per cent or above. In smears from 16 normal subjects the number of red cells classified as spherocytes varied from zero to 0.4 per cent, with an average value of 0.2 per cent.

The *osmotic fragility* of red cells was determined from freshly drawn venous blood. Accurately measured 0.1-cc. samples of blood were pipetted into a series of tubes containing 1.0-cc. amounts of the following solutions: hypertonic sodium chloride (2.0, 1.5 and 1.0 per cent), isotonic sodium chloride (0.85 per cent), hypotonic sodium chloride (0.80 to 0.10 per cent) and distilled water. These reagents were maintained as stock solutions kept at room temperature. The samples were mixed and centrifuged, the supernatant fluid was poured into a separate set of clean tubes, and 0.5-cc. samples of the supernatant solutions were diluted to 10 cc. with distilled water in Evelyn colorimeter tubes. One drop of ammonium hydroxide was added to each tube, the sample mixed, and the hemoglobin determined in an Evelyn colorimeter

using filter No. 540. The colorimetric values observed in the hypertonic salt mixtures were averaged as the "blank" and subtracted from each value obtained in the hypotonic range to give a corrected figure for hemolysis. The percentage hemolysis at each salt concentration was then calculated by dividing the corrected figure for hemolysis by the similarly corrected figure for complete hemolysis produced in distilled water. The curve of osmotic fragility was next plotted, using the hemolysis in per cent on the ordinate and the corrected tonicity of the hypotonic mixture on the abscissa. Since the hypotonic mixtures contained 1.0 cc. of salt solution of known but different tonicities and 0.1 cc. of whole blood, the plasma contributed by the blood sample altered the final tonicity. Accordingly, the final tonicity of the hypotonic mixture was corrected assuming arbitrarily that the amount of plasma in each case was 55 per cent of the blood sample and that the plasma was osmotically equivalent to an 0.85 per

cent solution of sodium chloride. Table 2 shows the osmotic-fragility values for 30 normal subjects with hemoglobin levels of 80 to 105 per cent, comprising 13 males and 17 females between the ages of seventeen and sixty-one. There was no significant difference between males and females.

Autoagglutinins (cold agglutinins)²⁷ and *hemolysins*²⁸ were tested for in the serum from clotted venous blood samples. The serums were diluted serially with physiologic salt solution and to each dilution was added an equal volume of 2 per cent suspension of Group O erythrocytes. As a source of complement for the hemolysis tests fresh human serum was then added in quantities equal to the patient's serum. These mixtures were observed for agglutination or hemolysis after being chilled for one hour at 0°C. and again after subsequent incubation at 37.5°C for one hour.

HEMOGLOBINURIA

Observations were made on 40 patients with combined second-degree and third-degree thermal burns involving from 15 to 65 per cent of the body area. Eleven of these patients showed hemoglobinuria. The series includes 34 patients burned in the Cocoanut Grove disaster and 6 others. Detailed studies on 10 of the 11 patients showing hemoglobinuria (Cases 1-10) and on 4 patients showing no hemoglobinuria (Cases 11-14) are shown in Table 1. One patient with gross hemoglobinuria following a 65-per-cent burn sustained at Cocoanut Grove was omitted from the table because no determinations on the blood were made before death, which occurred in six hours. Gross hemoglobinuria was observed in 9 of 12 patients from Cocoanut Grove who showed combined second-degree and third-degree burns involving

*Observations made at the Massachusetts Institute of Technology

Histologic Examination of Kidneys

The kidneys were studied histologically in 9 patients.³⁵ In 3 patients (Cases 11, 12 and 13) who showed no hemoglobinuria there was no significant abnormality in the kidneys. In 6 patients (Cases 4, 5, 6, 7, 9 and 10) who showed hemoglobinuria the histology of the kidneys was consistent with that of hemoglobinuria, as evidenced by the finding of hemoglobin casts in the tubules in each case.

In general the histologic picture was as described below, with variations for particular patients, as indicated in Table 1. The casts in the tubules varied in number and appearance from typical hemoglobin casts to coarsely and finely granular, brownish or reddish casts. Some tubules also contained dense blue, hyaline material, occasionally polymorphonuclear leukocytes and mononuclear cells and, rarely, red cells. In some cases the epithelium of the tubules containing the hemoglobin casts showed evidence of degeneration and necrosis. The tubular epithelium was occasionally more granular than normal; in other cases there was evidence of regeneration of the epithelium of the tubules. In several cases the interstitial tissue showed areas of infiltration with lymphocytes, plasma cells and, rarely, eosinophils. In general the glomeruli and blood vessels were normal.

CHANGES IN RED CELLS

The osmotic fragility of the red cells was significantly increased above normal in 7 patients. Of these, 5 patients (Cases 1, 2, 4, 5 and 9) had hemoglobinuria and 2 patients (Cases 12 and 14) had no hemoglobinuria. No significant increase in osmotic fragility of the red cells was observed in 5 patients with hemoglobinuria (Cases 3, 6, 7, 8 and 10) and in 2 patients with no hemoglobinuria (Cases 11 and 13). It should be emphasized, however, that in 10 patients the earliest observation of the osmotic fragility was from seventeen to forty-four hours after the burn; the red cells in 6 of these 10 patients showed no significant elevation of the osmotic fragility. This interval was usually beyond the period of maximum hemoglobinuria and presumably, therefore, past the period of maximum blood destruction. The interval after the burn in which the initial observation was made of the osmotic fragility is shown in Figure 1. In 4 patients not from Coconut Grove, the osmotic fragility of erythrocytes was determined promptly, within a period of a half to three hours after the burn. The fragility was normal in only 1 of these patients (Case 11), whose burn involved 20 per cent of the body area. In the other 3 patients, the osmotic fragility was increased as follows: slightly in Case 12, burned 65 per cent; moderately in Case

14, burned 15 per cent; and extremely in Case 9, burned 30 per cent. In the last case, hemoglobinuria was observed at a time when the osmotic

The maximum range of osmotic fragility (from 1 to 95 per cent hemolysis) is shown for each of the 14 cases.

fragility test (Table 1 and Figure 2) indicated that 1 per cent of the patient's red cells were hemolyzed in isotonic (0.85 per cent) sodium chloride

FIGURE 2. Curve of the Osmotic Fragility of the Red Cells from Case 9.

The cells were obtained two hours after a burn involving 30 per cent of the body, and three hours before the patient's death.

solution and thus, presumably, were susceptible to osmotic hemolysis in the patient's own isotonic blood plasma. The progressive disappearance and probable destruction of the red cells with abnormally increased osmotic fragility are shown for Cases 4 and 14 in Figures 3 and 4, respectively.

Blood smears from certain of the burned patients showed fragmentation, budding, spherocytes and microspherocytes of the red cells. Maximum fragmentation of red cells was seen only in the smears taken promptly after the burn, as in Case 14, shown in Figure 5. Deeply staining spherocytes,

FIGURE 3. Serial Curves of the Osmotic Fragility of the Red Cells from Case 4.

This shows a progressive loss of abnormal cells up to sixty hours after the burn.

cytes, however, were detectable in significant numbers in Case 4 sixty hours after the burn, as shown in Figure 5. The spherocytes were observed to be significantly increased in number, being 3 per cent or above, in Cases 3, 4, 13 and 14, with simultaneous increases in osmotic fragility occurring in Cases 3, 4 and 14. In Case 13 the fragility was normal when determined thirty-eight hours after the burn, and accordingly the observation one hour after the burn of 3 per cent spherocytes in the blood smear constituted the only abnormality detected in the red cells. The disappearance of spherocytes from the blood smear coincident with the disappearance of red cells with increased osmotic fragility is shown in Figure 4.

Since autoagglutinins or autohemolysins might have arisen from the thermal burn and might have influenced the red cells, these antibodies were sought for in samples of blood serum obtained from Cases 1-8 seventeen to thirty-seven hours after the burn. No "cold" or "warm" agglutinins or hemolysins were detected in these samples taken at a time when increased osmotic fragility was observed in Cases 1, 2, 4 and 5.

EXPERIMENTAL STUDIES ON HEATED BLOOD

The experimental studies on human blood heated *in vitro* and on dog's blood heated *in vitro* and injected into the same animal are summarized briefly below and will be reported fully elsewhere

When samples of normal human defibrinated blood were heated in glass test tubes in a constant-temperature water bath to temperatures as high as 46°C. and the temperature was maintained constant for a period of one hour, no changes were observed in the erythrocytes. At temperatures of 47 to 50°C., abnormal changes in the red cells occurred depending on the duration of heating, which was extended to one hour as a maximum. Within a "critical zone" of temperatures (51 to 65°C.), abnormal changes always occurred even when blood samples were heated rapidly—in one

FIGURE 4. Progressive Loss of Spherocytes and of Red Cells of Increased Osmotic Fragility in Case 14.

and a half minutes—to a given temperature and immediately cooled to 37°C.

These abnormal or "thermal" changes in the red cells occurred in a regular and reproducible manner. The first detectable alteration was the formation of increasing numbers of rounded, budlike projections or filaments, at first connected with and finally disconnected from the erythrocytes. Progressive increase in this process of fragmentation was associated with the appearance of spherocytes, microspherocytes mixed with occasional "ghosts" and many erythrocytic fragments varying in diameter from 1 to 2 millimicrons down to innumerable small particles, approximately the size of bacteria, showing active brownian movement in a wet preparation. Coincident with the appearance of spherocytes and microspherocytes in the smear, the osmotic fragility of the red cells increased above normal and progressed to a maximum range with the progressive increase in spherocytosis of the erythrocytes. When the osmotic fragility increased to the maximum range, some of the red cells were susceptible to hemolysis as ob-

served in the fragility test in isotonic (0.85 per cent) sodium chloride solution. Hemolysis of the red cells varied with the temperature and with the duration of heating. The amount of hemolysis was negligible when the osmotic fragility was normal, when it was increased only moderately, and in many cases when it was increased to the maximum range. Temperatures of 55°C. or above pro-

duced fragility test and in vivo by injection of the heated blood into the same animal. None of the animals were burned. Five healthy dogs weighing from 12 to 18 kg. were bled of one sixth to one fourth of their blood, followed by the intravenous injection of an equal volume of isotonic sodium chloride solution containing 40 cc. of molar sodium lactate. In observations on dogs 1, 2 and 3, about

FIGURE 5. Stained Blood Smears after Burns ($\times 1000$).

The preparation on the left was made half an hour after the burn in Case 14; that on the right, sixty hours after the burn in Case 4. Both show densely stained spherocytes, and that on the left, a certain number of fragmented forms.

duced hemolysis that was progressive, ranging from 2 to 5 per cent of the red cells to complete hemolysis at 65°C. These thermal changes were inherent in the red cells themselves and did not depend on the medium in which they were suspended, whether plasma (heparinized), serum or isotonic salt solution, and were produced in vitro out of contact with the tissues. The serum from heated blood did not hemolyze or change normal red cells, and the serum from unheated blood did not reverse the changes in heated erythrocytes. When subjected to severe mechanical trauma for an hour in a test tube, blood that had previously been heated to 50°C., with a slight increase in osmotic fragility, showed no significant increase in susceptibility to hemolysis. However, after heating to 52, 55 and 58°C., respectively, the osmotic fragility and morphologic changes were maximal, and hemolysis from trauma increased progressively with the higher temperatures and was significantly greater than the hemolysis of blood heated to 50°C.

The susceptibility to hemolysis of heated blood from dogs was observed in vitro by the osmotic-

one fifth of each animal's blood volume was heated in vitro to approximately 53°C., producing maximum changes in morphology and in osmotic fragility, whether the red cells were heated in serum, washed and resuspended after heating in hypertonic (1.275 per cent) sodium chloride solution or washed and resuspended before heating in isotonic (0.85 per cent) sodium chloride solution. The heated suspension of red cells in each case was cooled to room temperature and injected into the same dog. Blood samples removed from these three animals immediately after injection showed an abnormal osmotic fragility comparable to the "mixed-population" fragility curves produced in vitro by mixing 20 to 30 per cent by volume of heated blood with unheated blood. The stained smear showed spherocytes immediately after injection. In the course of several hours after injection the spherocytes and abnormally fragile erythrocytes disappeared coincident with extreme hemoglobinemia and hemoglobinuria lasting for twenty-four to thirty-six hours. All three dogs recovered without reactions, without azotemia, and with the excretion of copious amounts of urine with a pH of

65 to 85°. As a control observation in dog 4, one fifth of the blood volume was removed, defibrinated, heated to 50°C., and reinjected. This degree of heat did not change the osmotic fragility of the red cells. Following injections there was no change in morphology or osmotic fragility, no disappearance of the animal's red cells and no hemoglobinuria. In a second control observation in dog 5, one fourth of the blood volume was removed into sodium citrate as an anticoagulant and heated to 53.7°C., and only the plasma, obtained by centrifugation, was reinjected. The heating produced a maximum increase in the osmotic fragility and considerable hemolysis of the red cells. Injection of the deep-red plasma, which was free of cells and fibrin, did not alter the osmotic fragility of the dog's red cells and produced only slight and transient hemoglobinemia and hemoglobinuria.

DISCUSSION

It is evident that hemoglobinuria as a complication of severe thermal burns results from the rapid destruction of red cells, producing hemoglobinemia with consequent excretion of free hemoglobin in the urine. Concerning the mechanism of hemolysis of red cells, no cold or warm agglutinins or hemolysins were found in samples of serum obtained from 4 patients at a time when their erythrocytes showed increased osmotic fragility. In 6 patients, the increased osmotic fragility occurred without or before sulfonamide therapy. In a patient (Case 9) whose osmotic fragility showed the greatest increase obtained in this series no chemicals were applied to the burn. There was no apparent clinical complication, such as pulmonary involvement, which was common to all cases either with hemoglobinuria or with increased osmotic fragility. All 14 patients received intravenous injections of large volumes of human plasma both with and without the development of hemoglobinuria or increased osmotic fragility. Other possible causes for destruction of erythrocytes may include intravascular thrombosis and possibly the formation of capillary emboli.³⁰

By contrast, the positive evidence derived from the observations of the patients and from the experiments reported here in brief form supports the belief that the principal and immediate cause of the increased blood destruction in thermal burns is the heating of the circulating blood in the tissues adjacent to the burned area. This evidence can be summarized as follows: The red cells from certain of the cases reported here, examined promptly after the burn, revealed a mixed population of normal cells and of spherocytes of varying sizes. The erythrocytes exhibited varying degrees of increased osmotic fragility. In severe cases of burn, heating of the tissues probably occurs, since subcutaneous

temperatures of from 51 to 65°C. have been produced and maintained for several minutes experimentally in anesthetized animals by scalding¹⁹ and by igniting turpentine on the skin.¹⁷ The heating of human blood *in vitro* within the critical zone of 51 to 65°C. produced irreversible and progressive fragmentation and formation of spherocytes, a progressive increase in the osmotic fragility in hypotonic salt solutions and hemolysis of some of the red cells in plasma, serum or isotonic salt solution. The effects produced by heat were inherent in the erythrocytes themselves and were not caused by demonstrable hemolytic agents or dependent on the presence of animal tissue, serum or plasma. The process of fragmentation apparently produced spherocytes and microspherocytes, possibly by removing from the erythrocyte a larger proportion of surface than of volume. If the usual osmotic properties of the surface and contents of the fragmented cells are retained, then from observations of Gänsslen,³⁷ Haden³⁸ and Castle and Daland,³⁹ spherocytes and microspherocytes will show an increase in osmotic fragility because their spheroidal shape permits less swelling before hemolysis occurs on reaching the spherical form, which is the form permitting no further increase in volume without increase in surface.

When the blood of dogs was heated sufficiently to cause increase in osmotic fragility and was then injected into the animal, presumably those red cells susceptible to hemolysis *in vitro* in isotonic sodium chloride solution were subject to osmotic hemolysis *in vivo* in the isotonic plasma of the animal. As for the less fragile erythrocytes susceptible to hemolysis only in hypotonic solutions, the mechanism of their destruction is probably analogous to that, for example, found in congenital hemolytic jaundice. As suggested by Ham and Castle,⁴⁰ cells that are not hemolyzed in isotonic salt solution or plasma may be slowly destroyed as a consequence of erythrocytosis in the spleen and other organs. Thus, it has been demonstrated by the above authors and by Tsai et al.^{41, 42} that the sterile incubation of normal human blood *in vitro* or the stagnation of animal blood *in vivo* leads to progressive increases in volume, spheroidicity and osmotic fragility such that eventually some of the cells are lysed in isotonic salt solution, plasma or serum. The possible influence of mechanical trauma as a cause of hemolysis requires further study.

In contrast with the observations on hemoglobinuria in dogs, in which the urine was copious and neutral or alkaline in reaction, kidney complications developed in certain of the burned patients who showed hemoglobinuria. Most of the severely burned patients, during the first twenty-four hours, showed oliguria, acid urine and albuminuria.

uria, but this triad did not appear to be associated with the development of chronic azotemia. Of 3 patients without hemoglobinuria, terminal azotemia occurred in 1 and transient azotemia in 2. Similar observations have been reported by Lucido⁴³ and by Cope and Rhinelanders.⁷ When hemoglobinuria occurred with oliguria, however, chronic azotemia of moderate severity was observed in spite of re-establishment of adequate urine output in 4 of the 5 patients living more than five days. These were the only cases of chronic azotemia occurring in the 40 patients considered here whose burns involved from 15 to 65 per cent of the body area. This irreversible azotemia may represent a decrease in kidney function, but this cannot be established from the data available, especially in view of the large concentrations of nitrogen excreted in the urine, as reported by Taylor et al.³¹ Also, the azotemia might have regressed if these patients had lived longer than five to thirteen days and had recovered from their extensive burns. From the clinical observations, the use of triple dye in treatment of the burned area was not a factor common to the occurrence of chronic azotemia, since it was not used in 1 patient (Case 10) who showed this condition. Also triple dye was used in 1 patient (Case 8) who showed reversible azotemia. Large amounts of hemoglobin can be excreted by the human or animal kidney without azotemia if the urine is adequate in volume and neutral or alkaline in reaction.^{1, 2, 44} Hemoglobinuria^{44, 45} and methemoglobinuria⁴⁶ in animals excreting acid urine, however, have produced oliguria and uremia. In the patients considered here with irreversible azotemia, histologic examination of the kidneys post mortem revealed hemoglobin casts in each case, but there was no extensive obstruction of tubules by these casts or advanced changes in interstitial tissue or in tubular epithelium. The histologic changes did not explain adequately the apparent inability of the kidney to clear the blood normally of its content of nonprotein nitrogen products. The occurrence of azotemia together with hemoglobinuria in these patients is similar only in part to kidney complications following intravascular hemolysis from blackwater fever or transfusion of incompatible blood.^{44, 47} In these latter conditions the oliguria or anuria is usually protracted, resulting in higher degrees of azotemia, which may reverse completely with the re-establishment of diuresis. The mechanism of oliguria or anuria as related to the histology of the kidney in these conditions is a debated subject.^{44, 48, 49} The immediate treatment of a severely burned patient, however, should probably include the administration of fluids and

alkali in an attempt to establish prompt diuresis of neutral or alkaline urine.

In summary, it is probable that in thermal burns destruction of a considerable volume of erythrocytes may result directly from heating of blood at the site of the burn, depending on at least three major factors: the temperature attained by the blood, the duration of heating and the volume of blood subjected to these conditions. Accordingly, the thermal changes in blood may not correlate strictly with the area burned but may be anticipated in extensive third-degree burns. This concept possibly explains the high incidence of gross hemoglobinuria occurring in 9 out of 12 cases burned over a body area of 45 to 65 per cent in the Coconut Grove disaster. This fire may well have produced more intense and prolonged heating than did the source of burns in Cases 12 and 13, in which the patients were severely burned but showed no striking blood changes or hemoglobinuria.

The blood of burned patients, if examined early, may, as in this series, show alterations that vary from only slight spherocytosis of erythrocytes to advanced morphologic changes associated with an extreme increase in osmotic fragility involving 30 per cent of the patient's red cells, as indicated in Case 9 (Fig. 2). Correspondingly, blood destruction may be of a mild degree, as in Case 14 (Fig. 5), with no hemoglobinuria, or the rapid destruction of a considerable volume of red cells may be followed by hemoglobinemia, hemoglobinuria and possibly irreversible azotemia.

SUMMARY

Gross hemoglobinuria was observed in 9 cases and minimal hemoglobinuria in 2 among 40 cases receiving combined second-degree and third-degree thermal burns involving 15 to 65 per cent of the body area. The maximum excretion of hemoglobin occurred during the first twelve to twenty-four hours, then decreased rapidly.

The urine samples from patients with gross hemoglobinuria were scanty in amount for one or two days, varied from black to red to light brown, and were acid (pH 4.5 to 5.8), and the urines contained hemoglobin in solution, in precipitated form and in casts. The red and brown pigments were identified spectroscopically as oxyhemoglobin mixed with traces of methemoglobin. There was no evidence of myohemoglobin.

The plasma or serum from 8 cases showed hemoglobinemia. Spectroscopically, oxyhemoglobin and methemalbumin were detected in the serum examined from 1 patient.

Chronic azotemia of moderate severity occurred in spite of the re-establishment of adequate excre-

tion of urine in 4 of 5 patients with hemoglobinuria who lived five days or longer. In 6 patients with hemoglobinuria examined post mortem, the histology of the kidneys was consistent with hemoglobinuria in each case. It is suggested that the immediate treatment of severely burned patients should attempt to establish diuresis of alkaline urine.

No significant anemia developed in the first twenty-four to forty-eight hours in the 14 burned patients, of whom 10 showed hemoglobinuria.

If blood is rapidly heated to a temperature of 51 to 65°C, changes occur in the red cells consisting of fragmentation and the formation of spherocytes and microspherocytes, with a striking increase in osmotic fragility and hemolysis of the erythrocytes.

In patients with severe or moderately severe thermal burns, the red cells examined promptly after the burn exhibited changes in morphology and osmotic fragility similar to those obtained by the injection into dogs of the animals' own erythrocytes heated in vitro to approximately 53°C.

The increased osmotic fragility of heated red cells apparently results from conversion of the normal biconcave erythrocytes to more nearly spherical forms by a process of progressive fragmentation. The mechanism by which heat causes fragmentation of red cells is not defined. It is possible that destruction of the red cells with increased osmotic fragility in vitro occurred through a mechanism of swelling and osmotic hemolysis in the isotonic plasma of the animal.

In thermal burns a significant number of erythrocytes may be destroyed by heat, probably depending on the temperature attained by the blood, the duration of heating and the volume of blood subjected to these conditions.

CLINICAL NOTE

PNEUMOCOCCAL MENINGITIS:
RECOVERY FOLLOWING
TREATMENT WITH SULFADIAZINE
AND SPECIFIC ANTISERUM

REPORT OF A CASE

JAMES H. YOUNG, M.D.,* CHARLES SCHLOSBERG,
M.D.,† CHARLES N. GETTES, M.D.,‡ AND
SALVATORE A. MANCONI, M.D.§

CAMBRIDGE, MASSACHUSETTS

BEFORE chemotherapy became of common use, only in isolated cases was there recovery from pneumococcal meningitis. Prior to the use of sulfonamides, mortalities as high as 95 to 100 per cent were reported. The few scattered recoveries reported may have been due to specific

116/74. There was a marked bulging of the right tympanum, marked rigidity of the neck and positive Kernig and Brudzinski signs. Paracentesis of the right ear revealed purulent exudate. An x-ray film of the right mastoid showed no evidence of an acute inflammatory process. The spinal fluid was under a pressure of 250 mm. The fluid was cloudy, and a pure culture of Type 5 pneumococcus was isolated. There were 360 cells per cubic millimeter—260 polymorphonuclear leukocytes and 100 lymphocytes. The protein was 192.5 mg. per 100 cc., the chlorides 643 mg., and the sugar 20 mg.

During the course of the illness four lumbar punctures were performed (Table 1). Because the patient appeared to improve clinically, these punctures were avoided as much as possible. An initial puncture was done to establish the diagnosis and to determine the etiologic agent. Owing to the presence of eye signs due to increased intracranial pressure, this procedure was repeated on the following day. Subsequent punctures were done to determine the progress of the case. As is evident from the table, the patient showed marked improvement in the 10-day period between the first and the last puncture.

Immediately after admission the patient was placed on a regimen of sulfadiazine, 45 gr. at once and 15 gr. every

antipneumococcus serum alone or may have been supplemented by various forms of drainage.¹ With the advent of the newer chemotherapeutic agents, the prognosis has been more promising.^{2,3} Some observers⁴⁻⁶ have found that serum used in combination with the sulfonamides has made the outlook even better than when either is used alone. It is the purpose of this paper to report a case of pneumococcal meningitis with recovery and to give in detail the plan of treatment followed.

CASE REPORT

S. G. A., a 12-year-old boy, entered the Pediatric Service of the Cambridge Hospital on August 24, 1942, in a semi-comatose condition. Four days previously, an upper respiratory infection had developed, followed by earache on the right side. Approximately 20 hours prior to admission he had headache, stiff neck, nausea and intermittent vomiting. The family history and past history were irrelevant.

On admission the temperature was 105.5°F., the pulse 130, and the respirations 30. The blood pressure was

4 hours thereafter. The initial dose was retained but subsequent doses were vomited. As a consequence, sodium sulfadiazine was given intravenously. Forty-five grains in 5 per cent glucose and saline solution was first administered, and this was followed 2 hours later by an intravenous injection of 30 gr. dissolved in 50 cc. of physiologic saline solution. The chemotherapeutic agent was then administered orally, in doses of 15 or 30 gr. every 4 to 6 hours. Concentrations of sulfadiazine in the blood were maintained in the vicinity of 20 mg. per 100 cc. On September 1, red cells began to appear in the urine, and medication was discontinued. The patient's general condition was considerably improved.

Since it was believed that combined drug-and-serum therapy would be of greater value than if either was used alone, the patient was simultaneously given Type 5 specific antipneumococcus serum, according to Table 2. Horse serum was first used, but this was changed to rabbit serum on noticing a mild chill following the second administration of horse serum. The administration of serum was continued until the quellung test on the serum had been positive on 3 successive days; a total of 930,000 units was given.

The patient responded promptly to therapy, and on the 3rd hospital day the temperature had fallen to normal. During the succeeding 9 days, however, it ranged from 100 to 102°F., becoming and remaining normal on and after the 12th hospital day.

COMMENT

After the diagnosis of Type 5 pneumococcus meningitis was established by culturing the organisms from the spinal fluid, it was believed that

The tympanum of the right ear was incised on the day of admission and a purulent discharge was noticed. Culture from this exudate failed to reveal any pneumococcus organisms. This was, however,

TABLE 2 Dosage of Antipneumococcus Serum

DATE	TIME	DOSE OF HORSE SERUM		DOSE OF RABBIT SERUM		ROUTE	REACTION	REMARKS

	6 30 a.m.			15	60 000	Intravenously	None	
	11 00 a.m.			25	100 000	Intravenously	None	
	7 00 p.m.			25	100 000	Intravenously	None	
8-26	11 00 a.m.			25	100 000	Intravenously	None	
				25	100 000	Intramuscularly	None	Quelling test on serum negative
8-27	11 00 a.m.			25	100 000	Intramuscularly	None	Quelling test on serum positive
8-28	11 00 a.m.			25	100 000	Intramuscularly	None	Quelling test on serum positive
8-29	11 00 a.m.			15	60 000	Intramuscularly	None	Quelling test on serum positive

the case warranted the use of both sulfadiazine and specific antipneumococcus serum. As a result, the patient was given both forms of medication simultaneously. Because of his inability to retain the chemotherapeutic agent, the sodium salt of sulfadiazine was employed intravenously. Seventy-five grains of sodium sulfadiazine was thus used. This was followed by oral administration of the drug. At the same time specific antipneumococcus serum was given. The first ten doses were administered intravenously, and the remainder intramuscularly. During the first 24 hours, the patient received 670,000 units, consisting of 30,000 units from horse serum and 640,000 units from rabbit serum. A change to rabbit serum was made because of the apparent—though mild—chill reaction following the second dose of horse serum, because the prospect of large and repeated doses of serum would be required, and because it is thought by some that the rabbit serum antibody, being a smaller molecule than the horse serum antibody, may have a better penetrating action than the latter. Serum therapy was continued during the next 4 days by less frequent injections, mostly intramuscularly. A total of 930,000 units of Type 5 antipneumococcus serum was administered throughout the illness.

Apparently not a case of primary meningitis but one of meningitis secondary to otitis media. Frequent x-ray films of the right mastoid region were taken on the theory that if there was any evidence of an inflammatory condition, mastoidectomy with a view to wide drainage ought to be done immediately. The films showed no such inflammation at any time.

SUMMARY

A proved case of Type 5 pneumococcus meningitis with recovery is reported, with the plan of treatment outlined in detail. Both a chemotherapeutic agent and the specific antipneumococcus serum were employed. At no time did it appear advisable to institute mastoid surgery.

MEDICAL PROGRESS

THE ANEMIAS OF PREGNANCY

RAYMOND A. DILLON, M.D.*

BOSTON

IN 1842, Channing¹ described a condition of severe anemia that occurred in the course of, and apparently as the result of, pregnancy. In 1919, Sir William Osler,² in a paper entitled "The Severe Anemia of Pregnancy," again drew attention to this condition and suggested that it had not received the study that it deserved. It is only during the last few years that any serious attempt has been made to classify the various anemias associated with pregnancy and to discover the factors that are responsible for the changes in the mechanics of blood manufacture and maintenance during this period. Despite the fact that a woman with anemia is inadequately fitted to the trials of labor, routine red-cell counts and hemoglobin determinations are too rarely done, either at antenatal clinics or in private practice.

Although pregnancy is a physiologic and normal condition that in a normal woman, provided an adequate and reasonable diet is taken, has no effect on the general health and no pathologic effect on the hematopoietic system, the requirements of the growing fetus, the alteration in maternal metabolism and the ordeal of labor, with its consequent blood loss, frequently cause anemia. Adair, Dieckmann and Grant,³ at the Chicago Lying-in Hospital, in a survey of 7835 patients, found that 63 per cent were anemic. Other American investigators—Lyon,⁴ Galloway⁵ and Moore⁶—with various methods of estimation, examined groups ranging from 100 to 1176 in number, and gave figures varying from 19 to 81 per cent of patients with less than 70 per cent hemoglobin. Various investigators have found this same condition in other countries.

Reid and Mackintosh⁷ investigated a group of 1108 pregnant women and found that 45.9 per cent gave a hemoglobin reading of 86 per cent or over, 43.9 per cent showed a reading between 70 and 84 per cent, and 10.2 per cent gave a reading of below 70 per cent. When the women were divided into two groups according to the family income, it was found that the incidence of anemia was considerably higher in the low-income group. The investigations of Bland, Goldstein and First⁸ showed the same thing. Multiparity in good financial cir-

cumstances does not appear to have much influence, except in women with five or more pregnancies, in which group the percentage with a hemoglobin reading below 70 per cent is three times as great as in those with fewer pregnancies. Age, work outside the home and abnormality in pregnancy have no demonstrable influence on the degree of anemia.

The anemias that are encountered in pregnancy fall into the following simple classification:

- A. Coexisting with, but unrelated to, pregnancy.
 1. Pernicious anemia, chronic chlorosis and leukemia.
 2. Anemias due to pre-existing chronic disease (namely, chronic nephritis).
- B. Anemias due to complications of pregnancy (namely, pyelonephritis, sepsis and bleeding).
- C. Anemias due to pregnancy.
 1. Physiologic anemia of pregnancy.
 2. Hypochromic anemia of pregnancy.
 3. Macrocytic anemia of pregnancy.

In this paper it is proposed to discuss only the anemias directly due to pregnancy.

PHYSIOLOGIC ANEMIA

The gravid state is commonly associated with important and well-marked changes in the circulatory mechanism. One of the most important physiologic alterations is an increase of blood volume. Dieckmann and Wegner⁹ determined the blood volume by the intravenous injection of vital red, and calculated the relative proportion of plasma and red cells by means of the hematocrit. These determinations were made on the same patients at intervals throughout pregnancy. The authors found an increase in plasma volume, total red cells and total hemoglobin, but since the increase in plasma volume is greater than the increase in the other two, although the actual number of circulating red cells and amount of hemoglobin are increased, the blood is more dilute. By ordinary methods of estimation there is, therefore, an apparent anemia affecting both the red cells and the hemoglobin. These are both proportionately reduced so that the color index remains at unity. By this means one can quite easily differentiate

*The articles in the medical-progress series of 1941 have been published in book form (*Medical Progress Annual*, Volume III, 678 pp. Springfield, Illinois: Charles C Thomas, 1942, \$5 00).

*Resident physician, Boston City Hospital; assistant, Department of Medicine, Harvard Medical School.

this condition from the iron-deficiency anemias, in which the color index is below 1.0.

Adamson and Smith¹⁰ in a study of 116 normal pregnant women found that during the second trimester there was a gradual drop in hemoglobin from an average of 76 to 68 per cent, and a drop in the red-cell count to 4,000,000. During the third trimester the hemoglobin continued at an average of 67 per cent, the red cells remaining about the same. In the two weeks following delivery, however, the blood rapidly returned to normal. Only 2 per cent of the patients continued through pregnancy without some drop in hemoglobin. Kühnel¹¹ in a carefully controlled study concluded that there is a gradual drop in the hemoglobin, cell volume and red-cell count until the sixteenth to the thirty-second week. This low level is maintained until about the thirtieth to the thirty-second week, when these substances begin to increase, but at thirty-four to thirty-six weeks a level is reached that is still lower than the initial one. Dieckmann and Wegner's¹² investigations showed an average decrease in the hemoglobin concentration amounting to 15 per cent at twenty-five to thirty-five weeks. From then on until term the hemoglobin increased and in many cases reached a normal level. At term the blood volume showed an average increase of 23 per cent, the plasma one of 25 per cent, and the total red-cell count one of 20 per cent, thus accounting for the decrease in hemoglobin concentration, cell volume and red-cell count seen in normal pregnancy. These authors demonstrated for the first time that although there are marked variations of all the indexes, especially of the color index, in the same patient, the average for each remains close to 1.0. The cell volume is slightly increased between the twenty-sixth and thirty-fifth weeks, when the physiologic anemia is most marked. The corpuscular hemoglobin is also slightly increased, both in amount and in percentage, but is normal at term. The means for the hemoglobin concentration in pregnancy are 11.56 gm. per 100 cc. of blood, for the cell volume 37.31 per cent, and for the red count 3,770,000. From these figures Dieckmann and Wegner conclude that the minimal standards for normal pregnancy are 10 gm. of hemoglobin, a hematocrit of 33 per cent and 3,360,000 red cells. Wintrobe¹³ in a careful study has shown that the lower limit of normal for the hemoglobin concentration in nonpregnant women is 13 gm. per 100 cc.

In the course of investigating blood volumes in many types of cases, Keith, Rowntree and Geraghty¹⁴ observed a post-partum decrease in total blood volume of approximately 1000 cc. They con-

sidered that only about 300 cc. of this could be accounted for in blood lost at the time of delivery. This observation also serves to explain, on the basis of dilution, the low hemoglobin before delivery and the relatively high estimations observed after it.

The smear shows no abnormality. There is no evidence of pathologic destruction of red cells, and nothing to suggest abnormal regeneration, such as nucleated red cells, polychromatophilia or reticulocytosis. The rise in blood values that occurs just after confinement cannot, therefore, be due to new blood formation.

This type of anemia is quite common, and does no apparent harm to mother or child. It entirely disappears during the first two post-partum weeks and, being physiologic, requires no treatment.

HYPOCHROMIC ANEMIA

Hypochromic, secondary or, as it is sometimes called, microcytic anemia of pregnancy occurs in women who have a subnormal hemoglobin in early pregnancy, and when the physiologic anemia develops, the drop in hemoglobin is so great that symptoms and signs of anemia occur; these may clear up or persist after delivery. Hypochromic anemia is extremely widespread, having been reported from all European countries, India and the Far East. It may occur with pregnancy at any age (Bland, Goldstein and First,⁸ Strauss and Castle¹⁵ and Mackay¹⁶).

In 1929, Lyon⁴ showed that over 30 per cent of pregnant women of the hospital class manifest some degree of hypochromic anemia, and Adair et al.³ found that 23 per cent of 1176 patients at the Chicago Lying-in Hospital had a hemoglobin of less than 10 gm. per 100 cc. Adair states that in Bengal nearly all the anemias of pregnancy are of the secondary type, and that the average hemoglobin of a native woman is about 50 per cent.³⁶

Although in a normal and robust woman the circulatory and hematopoietic adjustments in physiologic anemia as outlined above are sufficient to compensate for the demands of pregnancy, it is obvious that a woman who ordinarily maintains her full complement only with difficulty may, by reason of the pregnancy, easily become anemic. The fetus requires large quantities of maternal iron; the appetite, especially for iron-containing foods, may be capricious; the gastric function may be temporarily deranged; and any anemia that already exists is liable to exaggeration.

The mother has to supply the fetus, not only with sufficient iron to begin life, but also with sufficient store in the liver to carry it while on a diet consisting chiefly of milk, which is poor in

this mineral. The demand on the mother by the fetus for essentials of hematopoiesis has been likened to a chronic blood loss from other causes and represents a drain on the mother, especially during the latter part of pregnancy. The iron stores for the fetus must come either from the iron stores of the mother or from her food, according to Heath and Patek.¹⁷ They state that if 10 per cent reduction in hemoglobin results from hydremia, which may account for hemoglobin levels of about 70 per cent, a further reduction of 20 per cent, owing to demands of the fetus for iron, would reduce the hemoglobin to 50 per cent, assuming no stores or food source in the mother. There are said to be 500 mg. of iron in the average fetus (Sodeman¹⁸). Since the fetus requires more and more iron as it becomes larger, it is obvious that hypochromic anemia would tend to manifest itself or become definitely severe during the last three months of pregnancy. It is thus easy to see that this mineral drain by a ruthless intrauterine parasite may readily bring about an acute anemic breakdown in the mother, whose own reserves are thereby exhausted.

The maternal iron reserves are dependent on two factors, intake and absorption. If the intake is small, the maternal store may easily become depleted, and it is well known that a patient with the capricious appetite found commonly in pregnancy often does not relish the iron-containing foods. There is a widespread belief that meat is bad for pregnant women, and many women on their doctors' orders to take a diet throughout pregnancy that is deficient in essential factors, especially iron.

Impaired gastric secretion, leading to defective utilization of iron, appears to be a contributory factor. Strauss and Castle¹⁹ and Davies and Shelly²⁰ found that patients with hypochlorhydria or achlorhydria have a severer degree of anemia than do those with normal acid secretion. The anemia is typically hypochromic and microcytic. The hemoglobin is below 70 per cent and is commonly in the region of 50 per cent when advice is sought. The red cells usually number from 3,500,000 to 4,000,000 per cubic millimeter. The mean corpuscular volume, the mean corpuscular hemoglobin and the mean corpuscular hemoglobin concentration are all low. The leukocytes and platelets are unaffected. The red cells have a low mean diameter.

Strauss and Castle¹⁹ carefully followed during pregnancy 30 consecutive patients with uncomplicated hypochromic anemia whose hemoglobin and red-cell concentrations were less than half of normal. The chief presenting symptoms, appearing

usually at about midpregnancy or later, were a lack of sense of well-being and an excessive sense of fatigability. The average age of these patients was thirty-two years, and the average number of previous deliveries between five and six. In the severer cases pallor was observed. Atrophy of the papillae of the tongue was common. Brittle and suggestively spoon-shaped fingernails were seen in a few patients. Splenomegaly, disappearing with adequate treatment of the anemia, was observed in 4 cases. Achlorhydria persisting until after delivery was found in 17, hypochlorhydria in 10, and normal acidity of the gastric contents in only 2 of the 29 patients examined. The red-cell count of these women ranged from 2,120,000 to 4,830,000, and the hemoglobin from 25 to 44 per cent.

Patients do not die of this type of anemia. No knowledge of the post-mortem findings is therefore available, nor have biopsy examinations of the bone marrow been made.

Except in severe cases, the ultimate prognosis is good and labor is uneventful if there is no undue post-partum hemorrhage. The fetus itself is born with a normal red-cell count. In severe cases there may be great prostration with dyspnea and edema. Albuminuria may occur. The patients who are efficiently treated may go to term without difficulty and recover completely during the puerperium after a few weeks of iron treatment.

A regular rest period during the day should be insisted on. A full diet, including meat and fresh green vegetables, is important, although the appetite may require stimulation. The essential treatment is the taking of iron. There are many effective preparations available, but ferrous sulfate, 0.8 gm. daily, ferric ammonium citrate, 6 gm. daily, and Bland's pills, 4 gm. daily, are time-tested agents. Liver preparations have little or no effect on this form of anemia. Constipation should be corrected, provided treatment with iron does not eliminate this fault.

When hypochromic anemia is complicated by infection, a low basal metabolic rate, nitrogen retention or severe damage to vital organs, the effect of iron therapy may be disappointing, but the attempt should nevertheless be made.

MACROCYTIC ANEMIA

The macrocytic anemias of pregnancy constitute a much more dangerous complication than those of the iron-deficiency group, but are uncommon in this country. In the past the mortality rate was quite high, and it was probably this type that drew the attention of Channing in 1842 and Osler in 1919. With the development of modern methods and modern classifications, the macrocytic form of

anemia can now be clearly separated from the hypochromic anemia of pregnancy, and it is probable that the next few years will enable a proper estimate to be made of the true incidence of the former disease. Bardy,²¹ in 1924, reviewed 68 cases collected from the literature of Europe and America during a period of thirty-eight years. Esch,²² in 1921, was able to find only 23 cases in the German literature.

This anemia is often referred to as pernicious-like or pseudopernicious anemia of pregnancy to differentiate it from true pernicious anemia. In deed, the blood smear shows all the characteristics of pernicious anemia. Occasionally the differential diagnosis is difficult. Macrocytic anemia occurs in younger patients than does pernicious anemia, and usually develops during the last three months of gestation, but is often not recognized until shortly after delivery. Usually the pregnancy continues in a normal manner, with the patient becoming gradually paler or exhibiting a slightly jaundiced appearance, until the sixth or eighth month, when fainting, collapse, edema, albuminuria or excessive paleness may occur quite suddenly. In severe cases, edema and albuminuria give a clinical picture suggestive of nephritis, whereas coma may suggest toxemia. Syncopal attacks and retinal hemorrhage are not uncommon, but spinal-cord changes and glossitis do not arise. Rarely after the stress and shock of labor and delivery, the enfeebled patient suddenly collapses and becomes moribund. Premature labor is common, and the outlook for the infant is poor. Fever without demonstrable infection is not unusual, and when it occurs post partum may suggest puerperal sepsis. It disappears with anemia therapy. Retinal hemorrhages have been described by Hoskin and Ceiring-Cadle²³ and Cornell.²⁴ Gastrointestinal disturbances are of common occurrence.

Strauss and Castle¹⁹ found in a series of cases, that the red-cell count varied from 1,050,000 to 2,500,000 and the hemoglobin from 20 to 50 per cent (Sahli), resulting in a color index above 1.0. The red cells showed moderate variation in size and shape, with microcytes, occasional poikilocytes, oval macrocytes and rare megaloblasts. The leukocytes and platelets were either normal or slightly decreased. The mean corpuscular volume ranged from 105 to 130 cubic microns.

There is considerable disagreement concerning the question of recurrence in future pregnancies. Allan²⁵ does not consider that there is an association between the two. Reist,²⁶ on the other hand, says that the anemia, once established, tends to recur in subsequent pregnancies at an earlier date and to grow severer with each successive pregnan-

cy. This has also been stated by Vermelin and Vigneul²⁷ and Murdock.²⁸

The prognosis of both mother and child has been greatly improved in recent years owing to the development of blood transfusion and liver therapy. In untreated cases the mortality rate is high, being from 30 to 75 per cent for the mother and even higher for the infant. Cases that are treated early and energetically can safely be allowed to go to term. MacLeod and Wilson²⁹ describe a patient who was quite symptomless and uncomplaining until she suddenly collapsed and became moribund, and there are many other similar cases in the literature. Recovery is considerably retarded by sepsis. Most patients begin to recover with the birth of the child, and many have recovered spontaneously without treatment, once delivery is over. Soon after delivery there is usually a marked increase in reticulocytes.

The earlier writers called the macrocytic anemia of pregnancy "hemolytic anemia of pregnancy," but this term should be discarded because hemolysis is not a feature of the disease and is not caused by a hemolytic or toxic agent. Strauss and Castle¹⁹ have shown that the hematopoietic principle is probably deficient because of a temporary derangement of gastric secretion due to the pregnancy. The response of liver therapy is exactly the same as that found in true pernicious anemia, so that it is assumed that the anemia is due to the lack of hematopoietic principle. A deficiency in absorption may also be a factor.

Treatment consists in the administration of large doses of liver extract parenterally, and the response is as dramatic as in true pernicious anemia. Generally the use of liver preparations can be discontinued a few weeks after delivery, but it is well to maintain patients under observation, since it is possible for them subsequently to develop true pernicious anemia. If labor is not imminent, there will usually be sufficient recovery to allow of a normal labor without excessive danger or distress to the mother. Since there is frequently a partial deficiency of iron, it is well in addition to use iron in moderate dosage.

Patients who are desperately anemic or in whom infection is present and labor imminent should receive a blood transfusion, which may have to be repeated. Kersley and Mitchell³⁰ stress the value of transfusion in preventing obstetric shock in anemic patients. Matching of the blood for transfusion may be difficult owing to the factor of autoagglutination, which is sometimes present to a marked degree. Stewart and Harvey³¹ state that there is no difficulty if the test is performed at a temperature of 37°C.

In recent years, with the increasing popularity of blood transfusion as a therapeutic procedure, occasional cases are encountered of hemolytic reactions following the use of blood of the same group as that of the patient. These have been attributed to the presence of irregular isoantibodies in the patient's serum, but in all cases such antibodies were not demonstrable by cross-matching tests. New information on this point was obtained in 1940 when Landsteiner and Wiener³² detected a new factor in human blood (Rh) unrelated to agglutinogens A and B, and shortly thereafter Wiener and Peters³³ observed 3 cases of hemolytic reactions, 1 fatal, in which isoantibodies for this factor were present in the patients' serums. There were patients who had received previous transfusions, the anti-Rh isoantibodies being most likely the result of isoimmunization. Furthermore, it was found that transfusion accidents can occur at an initial transfusion owing to isoimmunization in pregnancy, the fetus in utero supplying the antigen (Wiener and Peters,³³ Levine and Stetson³⁴ and Levine, Katzin and Burnham³⁵). Some of these accidents had previously not been recognized as related to the transfusion but were believed to be merely pregnancy complications. Apparently the great majority of the reactions in repeated transfusions and in pregnancy cases are due to the Rh factor.

The condition is usually easily prevented by the optimal nutrition during pregnancy. The diet should contain adequate amounts of meat, eggs and whole-grain cereals.

• • •

During pregnancy, a mild type of anemia, physiologic in origin, is usually present. It does no apparent harm to mother or child and requires no treatment.

In this country, hypochromic anemia of a mild degree during pregnancy is not uncommon, and although seldom dangerous to life, is nevertheless responsible for minor ailments and ill health in both mother and child. It can readily be cured by iron therapy and a generous diet.

Occasionally anemia of a severe and dangerous type occurs during and as a result of pregnancy. It demands detailed hematologic investigation and prompt treatment.

The hemoglobin level and of about the sixth month of an essential part of antenatal hematologic studies can then be carried

CASE 29441

PRESENTATION OF CASE

A thirty-eight-year-old man entered the hospital because of recurrent dyspnea of five years' duration.

Twenty-four years before entry, at the age of fourteen, the patient first noticed swelling in his neck. He was treated for several years by iodine and x-ray, without relief. At the age of twenty-one the right lobe of the thyroid gland was removed at an outside hospital. Following the operation he was told that he did not have a "toxic gland." The swelling and dysphagia, however, persisted. Five years later, at twenty-six years of age, the basal metabolic rate was said to have been normal and x-ray studies were said to have shown displacement of the trachea. He apparently received x-ray treatment and then was again operated on. There was a great deal of hemorrhage during the operation. Following the operation there was a persistent lump on the left side of the neck. Five years before entry he had a two-minute episode of dyspnea, during which he felt "strangled" and could not breathe in. Ten days before admission he had a similar episode while brushing his teeth. From both of these he recovered spontaneously. There had been no dysphagia, tremor or sweating. He had averaged 1 gr. of thyroid daily since the last operation.

An appendectomy had been performed two years before admission. One year later he had an attack of pain in the right flank and diarrhea.

Physical examination showed two transverse operative scars on the neck. Old x-ray changes were present in the skin over the suprasternal region, consisting of atrophy and multiple telangiectases. The left lobe of the thyroid gland was firm and measured 4 by 6 cm.; the isthmus was also palpable and firm. Examination was otherwise normal.

The blood pressure was 140 systolic, 90 diastolic. The temperature was 98.6°F, the pulse 70, and the respirations 22.

The blood showed a hemoglobin of 14.9 gm. and a white-cell count of 9100. The urine examination

^aOn leave of absence

was negative. The basal metabolic rate was +2 per cent.

An x-ray film of the chest showed a soft-tissue mass in the left side of the neck that displaced the trachea to the right and the esophagus posteriorly; no diverticulum was seen. The heart, lungs, aorta and diaphragm were normal.

On the fourth day a left thyroidectomy was performed under intratracheal nitrous oxide, oxygen and ether anesthesia. Considerable difficulty was encountered during the operation. The tissues seemed to be extremely vascular and densely adherent, without any planes of section. A lobulated mass, which in the upper portion measured 7 by 4 by 4 cm. and in the lower portion 5 by 4 by 4 cm., was finally removed. During the procedure the patient was carried under deep ether anesthesia, and at one time respirations had to be augmented by positive pressure to the bag, which was in the closed circuit. He received intravenous fluids and 500 cc. of whole blood. At the end of the operation his condition was fair. The systolic blood pressure was 60, and the pulse 120. On removal of the intratracheal tube, the airways remained clear. The blood pressure slowly rose with the patient in the shock position and continued intravenous fluids.

During the night of operation the systolic blood pressure was around 100, and the pulse 90 to 100. There was no evidence of hematoma in the neck, and only the usual moderate staining of the dressing. The patient remained in coma and twenty hours postoperatively had a right facial weakness. The pupils were moderately dilated and fixed. The corneal reflexes were absent. The blood pressure was 130 systolic, 80 diastolic. The pulse, which had been 80, increased to 100 but was regular. The temperature rose to 102°F. Twenty-four hours after operation he had an episode of projectile vomiting, following which the respirations became less frequent and more shallow. Although the air passages seemed clear, respirations finally ceased.

DIFFERENTIAL DIAGNOSIS

DR. J. H. MEANS: This seems to be a double header. I have to guess what kind of thyroid disease this patient had and also why he died.

Let us review a number of points that should be discussed. I am going to assume that the swelling of his neck at the age of fourteen was an enlarged thyroid gland. I have no adequate physical examination to permit me to make that statement flatly, but they say later on that they took out his thyroid, so I shall assume that it was thyroid. I might point out that there is no evidence in the story that the goiter was ever toxic. He was

treated, however, early in the course of the disease with iodine and x-ray without relief. That is not surprising because it does not sound like the kind of goiter that I should expect to be relieved by either of those procedures. The only goiters that I know of that are benefited by x-ray are toxic goiters, certain malignant goiters or that form of chronic thyroiditis known as lymphadenoid goiter or Hashimoto's struma.

I am interested in the fact that the patient had a great deal of hemorrhage from the second operation. Does that in any way have a bearing on the postoperative death at thirty-eight? I do not suppose it has, but it just passed through my mind that in women, sometimes after severe post-partum hemorrhage, the pituitary gland becomes infarcted and they develop *Simmonds's disease* later. I do not believe that anything of this sort occurred in this case, but I throw it out as something that might pass through one's mind in considering the case.

Even after the second operation the patient had a persistent lump in the left side of his neck. The episodes of dyspnea interest me. The caption at the top says that he came in for recurrent dyspnea of five years' duration. He had two attacks,—one at the beginning and the other at the end of this period,—which seems to me not exactly recurrent dyspnea of five years' duration. He did have two peculiar attacks that were characterized by dyspnea and a sense of strangling. That sounds to me like stridor of some sort rather than cardiac dyspnea or even asthma, although I suppose it could be.

He had received thyroid since his second operation. Why, I do not know. Nothing is stated to indicate that he was suffering from hypothyroidism. He had a good deal of the thyroid gland taken out, but we have no evidence on which to base a diagnosis of hypothyroidism.

We have to figure out what kind of goiter he had, and why he died. There are any quantity of things missing from this record that would be of diagnostic help to me. Perhaps to my later sorrow, I am going to throw out the pain in the right flank and the diarrhea as not bearing on the major issue.

This is a rather sketchy physical examination. There is no record of a Chvostek or Trousseau sign. I do know that when anyone gets a history of stridor after two thyroidectomies, one certainly would want to look at the vocal cords; but there is no mention of that either. I should like a better examination of the neck. They say that the thyroid gland was firm and that they felt the isthmus. I would want to know about the consistence and the surface, whether it was adherent to anything,

or if there were any palpable lymph nodes. Since they state that it was "otherwise negative," I shall assume that no lymph nodes were felt.

The x-ray examination disclosed a goiter in his neck, but, not in his chest, which pushed the trachea to the right and the esophagus backward. It would be disconcerting if this turned out to be not a goiter at all but some other cervical tumor. I should also like to know whether it went up or down when he swallowed. Maybe they did not try that.

DR. BENJAMIN CASTLEMAN: You have everything that is in the record, Dr. Means. I suppose the scantiness of the record is due to the fact that the patient was in the private pavilion of the hospital.

DR. MEANS: We know that the trachea and esophagus were compressed. Therefore, they did a thyroidectomy. That is right and proper. What are the indications for thyroidectomy in general? Thyrotoxicosis, under certain circumstances but not always, the production of pressure, and the suspicion of malignancy or the knowledge that it is malignant. I suspect they took out this goiter because of pressure. They may have thought it was malignant, or even that it was a constricting thyroiditis.

What kind of goiter did they take out? I do not believe that the patient had hyperplastic or simple colloid goiter. The general course and the chronicity of this disease are consistent with an old, nodular, partly adenomatous, partly cystic goiter. I cannot say that it is not some form of chronic thyroiditis, like Riedel's struma. On the other hand, I cannot say that it is, because we do not have the information. It could be a lymphadenoid goiter, but I do not believe that it was. He may have had an adenomatous or a cystadenomatous goiter for a great many years and had a malignant change in it. It would be impossible for me to say. Sometimes even the pathologist has difficulty in determining whether a goiter is malignant.

The next thing that intrigues me is the difficulty that the surgeons had at the time of operation. From the description it was difficult to remove this goiter. In fact the patient did not survive! We are told that the tissues seemed to be extremely vascular and closely adherent, without any planes of section. Does that tell us anything about the pathology of the goiter? Not a great deal, because of what had been done to it. The goiter had been subjected to enough heavy radiation to give telangiectases. We used to be told by surgeons that prolonged x-ray treatment did just this. The surgeons had difficulty in operating because the goiters were extremely adherent and vascular; indeed, just like this one. The x-ray treatment

may have contributed something, although I do not blame it for everything. If they had had a bad time twice before, one would expect the cleavage planes to be gone. They had a bad time with the anesthesia. I do not mean to say that it was not excellent anesthesia, but the patient did not do well under it. I am very much intrigued with the statement about deep anesthesia. I am also interested in the fact that the respirations had to be augmented by positive pressure; they practically had to give artificial respiration. The blood pressure faded out, and they had to give the patient a lot of fluid. Maybe they gave too much.

There was a severe degree of anoxia during the operation, and although I am not certain, possibly a brain injury was sustained during the operation that was irreversible. There is a queer statement that I cannot figure out. After transfusion they say that the patient's condition was fair, and later, that he remained in coma. When did he go into coma? Did he ever come out of anesthesia?

DR. CASTLEMAN: No.

DR. MEANS: The terminal event is strongly suggestive of something intracranial. We have no examination of the fundi. We have no complete neurologic examination. We do not know whether the facial palsy was central or peripheral in type. The patient probably had increased intracranial pressure just in the hours before death, and that may be what killed him. There is no mention of a lumbar puncture.

Why did he die? I should like to suggest as a possible cause for death that he had hypoparathyroidism, and that he had had it since after the first operation, or more likely since the second which was on the other side, not complete but low grade. That could have caused these two attacks of stridor, and it may be that they did not know he had it when they anesthetized him. At least there is no mention of any blood chemical studies. He may have had a low blood calcium plus anoxemia, and he may have gone into a state from which he could not recover, chiefly one of brain injury due to anoxia. He had no stridor, at least we do not know that he did, just difficult breathing.

I posted myself a little bit on hypoparathyroidism, the effect of low calcium and so forth, and found that one can get a number of cerebral manifestations in that condition. In one case in Dr. Albright's published series,¹ there was stiffness of the right arm and leg, and partial hemiplegia. Papilledema has been described, and I therefore think that hypoparathyroidism plus anesthesia might have accounted for death. Indeed, that is my first choice, although a risky one.

The patient may have had palsy of the vocal cords. If he had had an abductor paralysis and stridor, they would have inserted a tracheotomy tube. I am interested in all this intravenous fluid they gave because if they thought he had increased intracranial pressure they would not have given the fluid. The signs of intracranial pressure appeared, and no doubt this contributed to his death.

He may have had metastases from a malignant thyroid gland. The metastatic properties of the thyroid are bizarre. I can conceive of a solitary metastasis with hemorrhage from it; but there is no way of proving that and I think that it is unlikely. He may have had hypoparathyroidism, however. They could have removed too much of the parathyroid tissue at the first or second operation.

Did he have a mediastinal mass of any kind?

DR. GEORGE W. HOLMES: I should say that the lungs and mediastinum are absolutely normal. In the lateral view the trachea does not seem to be narrow or displaced. So far as I can make out, there is nothing to cause pressure on the trachea. One other possibility is that in certain cases with heavy x-ray treatment, the trachea collapses like a bag, due to absorption of the cartilaginous ring.

DR. MEANS: I had thought of collapse, but in the record it said that the airways were perfectly good. I therefore thought that the trachea had not collapsed.

DR. JULIA ARROWOOD: The mere fact that the patient had to have artificial respiration with bag and oxygen does not necessarily mean he had anoxia—in fact, quite the contrary. He had an endotracheal tube in place and could be perfectly well oxygenated even though he was not breathing for a time.

DR. WYMAN RICHARDSON: Did he have any preoperative medication?

DR. CASTLEMAN: That morning he had $1\frac{1}{2}$ gr. of Nembutal at 9:00 and $\frac{1}{4}$ gr. of morphine and $1/100$ gr. of atropine at 11:00.

DR. ARROWOOD: Again, in cases of cerebral anoxia one would expect a higher temperature than 102°F . and would not expect localizing signs on the right. Convulsions do not always occur. In 26 cases of cerebral anoxia reported by Courville² there was some type of muscular manifestations in all except those who died within a short time after operation.

DR. MEANS: The patient could have subarachnoid hemorrhage for all I know, but there is no neurologic evidence for it. He could have had some kind of apoplexy. He was only thirty-eight years old. Cerebral accident is a possibility.

DR. CASTLEMAN: Such as what?

DR. MEANS: Hemorrhage, either subarachnoid or ordinary cerebral hemorrhage, or thrombosis. It is all guesswork with this scanty evidence.

CLINICAL DIAGNOSES

Recurrent adenoma of thyroid.
Postoperative cerebral anoxia.

DR. MEANS'S DIAGNOSES

Nontoxic nodular goiter, adenomatous.
Postoperative cerebral anoxia.
Hypoparathyroidism?
Cerebral vascular accident?

ANATOMICAL DIAGNOSES

Multiple fetal adenomas of thyroid, with carcinomatous change in one.
Operative wound, recent: left thyroidectomy.
Cerebral embolus, left middle cerebral artery.
Cerebral infarct.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The surgical specimen removed was a nodular goiter that on section showed reddish to orange-brown nodules rather characteristic of what is known as fetal adenoma. One of these showed definite evidence of malignancy, but there were no metastases. The cause of death was cerebral, and Dr. Kubik will tell us about that.

DR. CHARLES S. KUBIK: There was an embolus in the left middle cerebral artery, with infarction of the brain in the distribution of the occluded artery. There were no thrombi in the heart to serve as a source for the embolus. Anomalous thyroid arteries are sometimes given off from the common carotid, proximal to the origin of the external carotid artery, and it seems reasonable to suppose that a clot might have been dislodged from such an anomalous vessel into the common carotid and might have been carried into the internal carotid and thence into the brain. The fact that the embolus was on the same side as the operation fits in with this theory. Microscopically the embolus consisted of very recent blood clot in which there was no organization.

DR. MEANS: Did you find any parathyroid glands?

DR. CASTLEMAN: No. The operative field was so scarred because of the previous operations and the x-ray treatment that we could not find anything that could be identified as a parathyroid gland. We cannot rule out Dr. Means's hypothesis that the patient had hypoparathyroidism, but there is no doubt that the cause of death was a cerebral embolus.

DR. MEANS: One has to explain the symptoms. It was suggested that the patient came in with recurrent attacks of dyspnea. They remain explainable unless the goiter caused them. They may have undergone some rapid enlargement on these occasions, with hemorrhage into a cyst. Do you find a cyst?

DR. CASTLEMAN: No.

CASE 29442

PRESENTATION OF CASE

First admission. An eleven-year-old boy entered the hospital because of abdominal pain of six days duration.

The patient had had measles, chicken pox and scarlet fever during his earlier life, but had been in generally good health until the age of eight. From this time on, he had numerous episodes of abdominal pain, diarrhea and vomiting. He appeared to tire easily and seemed unable to keep up with the other children. In general, however, he was in fairly good health. Six days before entry, while at a Boy Scout camp, he developed low midabdominal pain, which was present on waking and sometimes went away in one or two hours. The pain continued intermittently until the day of admission. For the two days before entry, he had had frequent attacks of vomiting, as well as diarrhea consisting of eight or nine nonbloody nonmucous stools daily. The day of admission the abdominal pain became constant and he had three bowel movements. There were no urinary symptoms, chills, fever or jaundice.

Physical examination showed a well-developed and well-nourished boy with a somewhat anxious expression. The heart and lungs were normal. The abdomen was flat but a dilated loop of bowel transiently appearing at the level of the umbilicus was seen by two observers. No masses were palpable. There was no spasm, but tenderness and rebound tenderness were present in the right lower quadrant and also referred there from other parts of the abdomen. The right testicle was located; the left was small and high in the scrotum. Rectal examination revealed tenderness on the right.

The temperature was 98.8°F., the pulse 80, and the respirations 22.

The urine was negative. The white-cell count was 17,000. A blood Hinton test was negative. A plain x-ray film of the abdomen showed

evidence of intestinal obstruction. A loop of gas-filled intestine, probably sigmoid, was seen superimposed upon the pelvis.

Ten hours after admission an appendectomy was performed through a pararectus incision. The appendix appeared grossly normal. The mesenteric lymph nodes were moderately enlarged. The cecum was fairly long and minimally inflamed. The terminal ileum was normal. There was no Meckel's diverticulum. The pathological diagnosis was "healing appendix." The postoperative diagnosis was mesenteric adenitis. He was discharged on the eighth hospital day.

Second admission (two weeks later). After discharge the boy remained well for the first three days, following which he began having sharp, crampy pains across the middle of the abdomen. The attacks lasted a few seconds, with intervals of about five minutes between the attacks. The pain became progressively severer and more painful so that he doubled up with the attacks and stayed awake at night. There were two episodes of vomiting, one occurring ten days and one eleven days before re-admission. During the attacks of pain the abdomen became distended, but the distention disappeared between the attacks. The abdomen, however, became more distended during the second week. He had alternating constipation and diarrhea. In the fifteen hours before entry he had two loose bowel movements. He was seen by his physician, who observed that during the attacks of abdominal pain there were audible peristalsis and definite coils of intestine moving against the abdominal wall. He was given belladonna without relief.

Physical examination showed a greatly distended abdomen, with marked tenderness but no spasm. Moderately high-pitched peristalsis was audible. There was some tenderness in the line of the incision, which was well healed. Rectal examination revealed mild tenderness high on the right, but only slight induration; the examination was otherwise not remarkable.

The blood pressure was 110 systolic, 70 diastolic. The temperature was 101°F, the pulse 110, and the respirations 22.

The urine showed a specific gravity of 1.025; the sediment contained 1 red cell and 2 white cells per high-power field. The red cell count was 5,460,000, with a hemoglobin of 100 per cent. The white-cell count was 9800, with 49 per cent neutrophils, which showed moderate toxic granulation. The stools were guaiac negative; and culture yielded no pathogens. The blood protein was 7.2 gm. per 100 cc, and the chloride 99.8 milliequiv. per liter. A Miller-Abbott tube passed with some initial difficulty to the upper jejunum

and considerably relieved the distention. He received a 400-cc. whole-blood transfusion and daily intravenous fluid.

On the second hospital day he had two bowel movements and was quite comfortable. At that

FIGURE 1. Opaque Enema Showing Obstruction of the Colon by a Mass (arrows) below the Splenic Flexure

Note the flecks of bismuth in the dilated colon above the obstruction.

time peristalsis was very active but "not obstructive." There was slight, constant tenderness below and to the left of the umbilicus, with rebound tenderness referred to the point of pressure. A plain film of the abdomen showed a loop of dilated small bowel in the right upper quadrant. There was gas within the colon. The right side of the colon contained flecks of opaque material, apparently representing bismuth. One day later the opaque material had moved to the region of the splenic flexure. At that time the tip of the Miller-Abbott tube was at the ileocecal valve, and the small intestine was deflated. An intravenous pyelogram was negative.

On the third day the boy vomited 50 cc. of fluid and had two loose bowel movements. The Miller-Abbott tube was draining fecal material, which frequently plugged the tube. He was not distended. The temperature was 100.5°F, and the pulse about 100. On the fifth day the temperature rose to 103°F. He had crampy abdominal pains, vomited once and had one bowel movement. One hundred cubic centimeters of stomach contents was aspirated with apparent relief.

A plain film of the abdomen showed the Miller-Abbott tube to be in the third jejunal loop. In

the left upper quadrant there seemed to be a mass pressing the colon laterally and deforming it. Neither the left kidney shadow nor the psoas contour could be made out. Some indefinite motting was seen in this area, which could have been in the large distended colon or in the mass. One dilated loop of fluid-filled bowel was present, but it was impossible to say whether this was large or small intestine. There were several loops of small bowel that contained gas but were not greatly dilated. A barium enema showed the opaque material to pass quite readily to the proximal descending colon, where an obstruction was encountered. The colon was compressed laterally against the abdominal wall, and there was a defect medially about 5 cm. long, over which the bowel was ragged and irregular. On one film there appeared to be an annular constriction which, however, was not seen on a subsequent examination.

An abdominal exploration was performed on the seventh hospital day.

DIFFERENTIAL DIAGNOSIS

DR. OLIVER COPE: The record evidently does not give the confusion that the clinical picture did at the time; to me the record on certain points is clear. I am struck by the fact that an intravenous pyelogram was done. At the second admission the kidney was again investigated. I wonder why so much attention was given to the kidney.

The child suffered from intermittent intestinal obstruction—that much seems to be clear. The second point that is clear is that the appendectomy did not cure him, in other words, the disease was not appendicitis. The third feature is that the correct diagnosis was not made at the time of the first operation. Perhaps the operator observed more than is given in the record, but one thing is important—namely, that he noted minimal inflammation of the cecum. Such inflammation in the presence of a normal appendix and signs of intermittent intestinal obstruction perhaps should have been diagnostic. It is difficult to be sure but it is possible that the surgeon who operated on the patient at the first operation failed to make a diagnosis when he could have. The other thing that the surgeon should have noted, if possible, having observed inflammation of the cecum and a normal appendix, is whether the cecum was attached by a loose mesentery. I get the impression that the cecum was fairly long. We ought to have a more accurate description of that in anatomic terms. I suppose it means that the cecum was on a loose mesentery. In addition we should have been informed whether the large bowel was

palpated and whether it was properly rotated. If a segment of large bowel had an ample mesentery it suggests that rotation may not have been complete.

After the first operation intermittent obstruction recurred, and the episodes on the second admission sound to me like obstruction, with beginning impairment of circulation of part of the bowel, causing a rise in temperature and an increase in the illness of the patient. The diarrhea fits with such a point of view. It is interesting that there was no blood in the stools.

DR. BENJAMIN CASTLEMAN: One out of four stool examinations showed a ++ guaiac test.

DR. COPE: That is reasonable. It would be unusual, I believe, for intussusception to exist as long as the final episode did without some blood in the stools. There are two diagnoses in my mind that fit the entire picture. The commonest one is intussusception. Although the x-ray picture is consistent, perhaps we should get the details from the X-ray Department before being too flat-footed about it. It would be unusual, however, not to find a mass palpable in the abdomen if the intussusception started at the ileocecal valve and telescoped enough of the large bowel to bring the mass into the left upper quadrant. The X-ray Department found a mass, but it was not felt on physical examination.

The other diagnosis that I think is the only other plausible one—perhaps I am being far too hasty—is torsion of a partially rotated large intestine. The x-ray examination suggests at one place that there is a large gas-filled loop, which is the usual accompaniment of torsion. Torsion is a less likely diagnosis than intussusception but one that could occur and cause obstruction at the splenic flexure. Both these lesions may form and relieve themselves and therefore may recur intermittently. It is only when the intussusception becomes advanced enough so that it cannot reduce itself, or when the torsion has been present for some time, that impairment of the bowel wall occurs.

DR. MILFORD SCHULZ: In the barium enema you can see an obstruction just below the splenic flexure. The colon is displaced laterally against the abdominal wall, and there is a constant defect, which is 5 or 6 cm. in length. The defect is not suggestive of an intussusception, since you can see fairly distended colon just above the area of obstruction, visualized by the bismuth that had previously been given as medication. Here is the annular constriction. Here it is on another examination. Something is fixed to the soft tissues, displacing the colon laterally. The impression at the time of examination was that it should have been a carcinoma, but in view of the boy's age a

compromise diagnosis of either lymphoma or an inflammatory lesion was suggested. The pyelogram was done because of the possibility of a retroperitoneal inflammatory process.

DR. COPE: The x-ray films are impressive. When I read the record I did not get the slant that I do now from your recounting and pointing out the characteristics of a malignant tumor. The thing that may be the red herring is the observation of inflammation of the cecum at the first operation. Such inflammation should mean either torsion or intussusception that had relieved itself.

Could an intrinsic lesion of the bowel explain the x-ray findings?

DR. SCHULZ: Yes, I think it could.

DR. COPE: May I ask for the confines of the mass described? Could it be accounted for by inflammation outside the splenic flexure?

DR. SCHULZ: Here you see the mass in the left upper quadrant with some mottling within it. It may be a distended colon with gas and fecal material, or it may all be extrinsic to the colon, perhaps with some necrotic material within it. I might say in passing that the x-ray appearance of intussusception is usually quite characteristic.

DR. COPE: Intussusception may result from a tumor so that the obstruction of the bowel becomes complete only when intussusception occurs. There is nothing in the history that excludes the presence of a large polyp or tumor that gave some mechanical difficulty resulting eventually in obstruction. The patient certainly had intestinal obstruction. We have some evidence of a mass or tumor by x-ray, which, if that were the primary agent of the obstruction, ought to have resulted, not in intermittent obstruction, but in permanent obstruction. It is possible that the episodes before the first operation were the initial phase of obstruction, over a period of months, and resulted in final obstruction at the time of the second admission. I am still impressed by the story of the intermittent character as it is given in the record and by the fact that the boy was apparently relieved of obstruction at the time of the first operation. Therefore, I shall stick to the idea of either intussusception or a volvulus of the large intestine in the absence of more positive evidence of intrinsic tumor. In the absence of the positive x-ray finding of intussusception, I am inclined, leaning heavily on the "loose" cecum, to make a diagnosis of volvulus of the large bowel with some degree of necrosis, possibly going on to abscess formation to account for the x-ray finding.

DR. SCHULZ: Does not a loop of bowel with volvulus usually contain a lot of gas?

DR. COPE: That is true. The two cases of volvulus of the right side of the colon that I remember vividly both had a big bolus of gas in the cecum. That was not found here, but in neither of my cases had the bowel been decompressed from above by a Miller-Abbott tube. We have evidence from the history that the Miller-Abbott tube had decompressed the small and large bowels, and fecal material had drained through the tube. So one would not necessarily expect to find a distended bowel proximally.

DR. ROBERT R. LINTON: How often does volvulus occur in a child of eleven? Volvulus of the large bowel has always occurred in older patients as I remember it.

DR. COPE: Some of the house staff may remember a physician who, at the age of thirty, had a volvulus of the right side of the colon. He had undoubtedly had intermittent attacks of the volvulus since the age of six. After one, the appendix had been removed. The story was much like this one only it lasted over a period of many more years. The doctor's father told me that when the attacks occurred in childhood, the boy would get down on his hands and knees suffering from intense colic and try to defecate. After an hour or two of rolling around the attack would be relieved. When he first came to us the attack had lasted three days—much longer than any previous attack. He had a volvulus with gangrene of the bowel and had a stormy time from generalized peritonitis. If one makes a diagnosis of volvulus in this boy, one has to assume that there was necrosis of the bowel to account for the increasing septic appearance of the chart and also for the x-ray findings.

DR. CASTLEMAN: If volvulus had been present all this time, do you not think that it would have been seen at the first operation?

DR. COPE: Volvulus could not have been present all this time. It would have to have been intermittent. The patients I have seen with intermittent volvulus or intussusception have had appendectomies following an attack and the correct diagnosis was not made at the first operation. I imagine it may be a difficult thing to recognize.

DR. FRANCIS MOORE: The surgeon who performed the first operation was no more satisfied with his findings than Dr. Cope is. He felt that the appendix did not account for the picture. At the second operation the boy was operated on through an incision in the left upper quadrant, because of the x-ray findings. The splenic flexure was found to be virtually totally obstructed by a large, ragged, hard, infiltrating, obviously neoplastic mass, which was mostly on the medial side of the bowel, with some on the lateral and posterior aspects and ex-

tension down along the aorta and vena cava. It did not look like an intrinsic bowel tumor. At that time biopsy of two or three lymph nodes was done, but frozen section was inconclusive. The only thing that could be done was to relieve the obstruction; hence an enteroenterostomy around the lesion was performed, anastomosing the transverse colon to the sigmoid.

CLINICAL DIAGNOSIS

Intestinal obstruction.

DR. COPE'S DIAGNOSIS

Volvulus of large intestine?

Intussusception?

ANATOMICAL DIAGNOSIS

Colloid carcinoma of colon.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The biopsy showed a characteristic colloid carcinoma.

DR. LINTON: What was the grade of malignancy?

DR. CASTLEMAN: Colloid carcinoma of the bowel is extremely malignant. I think that it is commoner in children than is adenocarcinoma. I can recall one other case of colloid cancer in a child of seven or eight, who came in with a mass in the groin that proved to be a metastasis from a cancer of the sigmoid.

COMMUNICATIONS should be addressed to the *New England Journal of Medicine*, 8 Fenway, Boston 15, Massachusetts

New York City, is chairman. The recommendations of this committee have been published in the October 16 issue of the *Journal of the American Medical Association*.

Food rationing is recognized as a vexing problem, particularly so in a food-producing country such as ours, a country geographically immense, with extremes of climatic conditions, with dietary habits varying in different sections and among certain racial components, with geographical variations in food availability and distribution, and with many important food groups still unrationed. The recommendations of the subcommittee cover these qualifying factors, without attempting to "provide an exclusive compendium of conditions in which extra rations are thought medically indicated." It is further stated, "They [the recommendations] are rather a guide to the vast majority of such conditions, any attempt to define all of which would vitiate the scientifically necessary flexibility inherent in any wise system of rationing for the sick." Recognition has been made of the precedent established by the Food Rationing Advisory Committee of the British Medical Research Council, which acts in an advisory capacity to the Ministry of Food. In England, however, the problem is actually somewhat simpler owing to stricter rationing of a more limited supply of food, practically all of which is owned by a governmental agency of a geographically small and cohesive nation.

The recommendations of the subcommittee call for the restriction of the authority to certify patients to "persons licensed to practice medicine and surgery in their respective states," for appeal committees of qualified physicians, for the annual renewal of certification, and for certain maximal allowances in specified diseases, notably diabetes mellitus, tuberculosis, chronic nephritis of the nephrotic type, cirrhosis of the liver, severe hepatitis, chronic ulcerative colitis, chronic suppurative diseases and sprue. The diagnosis of chronic ulcerative colitis or of sprue is not accepted unless certified by three physicians.

NATIONAL RESEARCH COUNCIL ON FOOD RATIONING

Soon after the inauguration of a point system of food rationing in March, 1943, the director of the War Food Administration requested the National Research Council to appoint a committee of physicians to advise on special dietary needs and the best method of meeting them. This group was organized, with Dr. William D. Stroud, of Philadelphia, as chairman, within the Division of Medical Sciences of the council, as the Subcommittee on Medical Food Requirements under the general jurisdiction of the Committee on Drugs and Medical Supplies, of which Dr. Walter W. Palmer, of

It is scarcely necessary to reiterate that food rationing constitutes a vexing problem. Processed foods present such a variety of types, from fruit juices that are mostly water to dried vegetables containing none, that it obviously makes little sense to measure them with the same yardstick or to weigh them in the same scales. The reason for grouping meats and fats is certainly one of organizational convenience that is not based on sound dietetic principles. Furthermore, a reasonably good sustaining diet can be built up of unrationed foods alone — when they are available.

In Massachusetts the policy of having a medical advisory committee to the state branch of the Office of Price Administration was adopted early in the summer, and this committee adopted the principle that, although it might be its brother's keeper, it did not wish to exercise police control over him. If a registered physician of Massachusetts wishes to employ dietary measures for the treatment of a patient and does so within reasonable limits and with apparently honest intent, the advisory committee will give him its support — nor does it challenge its colleagues' intellectual integrity by demanding the certification of three physicians for any diagnosis.

In our current years of trial, the more that can be accomplished by education and by mutual understanding and co-operation, the sweeter will be the taste of our ultimate success. It will be an unfortunate outcome if victory over our external enemies has to be won at the cost of increasing regimentation, coercion and force at home.

THE CHILDREN'S CENTER

THE Children's Center of Boston has now been in operation for over nine months, and the occasion seems suitable to review briefly its auspices, its purpose, its program and its accomplishments.

The Center was established in Roxbury, near a low-income community, in January, 1943, under the auspices of the Judge Baker Guidance Center

and aided by a grant from the Rockefeller Foundation. It was set up, however, as an independent organization, with its own staff under the direction of Dr. Marian C. Putnam and Mrs. Beata Rank. Its purpose was to provide day-nursery care and psychiatric consultation and treatment for infants and preschool children — a service that is almost unique, since the opportunity to begin educational and therapeutic guidance has hitherto rarely been offered in those family situations where emotional conflicts have appeared as early as the first or second year of the child's life. It is obvious that the best results can be obtained in these most formative years, and before unfavorable parent-child relations have become fixed.

The Center offers and has been furnishing a five-point program: day-nursery care, which is open to a group of thirty to thirty-five children with an age range from infancy to five years; inpatient care for a few children whose residence at home is temporarily inadvisable; therapeutic and educational work with parents and children; a consultation service available to the whole community; and facilities for the training and teaching of students in the various fields of child care. In this last respect, teaching programs are being offered for various professional people — social workers, nursery-school teachers, volunteers and students in child care and, ultimately, psychiatrists and pediatricians. A special grant from the Rockefeller Foundation helps to open the opportunity for study and research.

As evidence of the need that the Center is meeting and of the progress already made, it is interesting to note that during its first half year of existence applications were received for nearly 250 children. These came from thirty-seven agencies, from private physicians and through direct neighborhood contacts.

This new and valuable organization is particularly welcome in a community that, already richly endowed with them, knows how to utilize and appreciate its many health and social agencies.

MEDICAL EPONYM

HURLER'S SYNDROME

Although the term "gargoylism" as applied to this syndrome was first used by Ellis, Sheldon and Capon in an article entitled "Gargoylism (Chondro-Osteo Dystrophy, Corneal Opacities, Hepatosplenomegaly and Mental Deficiency)," which appeared in the *Quarterly Journal of Medicine* (29: 119-135, 1936), the source of the eponym is an article by Dr. Gertrud Hurler of the University Children's Clinic in Munich. Dr. Hurler wrote "Über einen Typ multipler Abartungen, vorwiegend am Skelettsystem [Multiple Degenerative Changes, Predominantly Skeletal]," which appeared in *Zeitschrift für Kinderheilkunde* (24: 220-234, 1919). A portion of the translation follows:

In the foreground of the clinical picture presented by our little patients stands the peculiar deformity of portions of the skeleton, namely of the head as a whole and especially the occipital region, of the clavicles, of the proximal end of the humerus and of the scapula. As the x-ray pictures show, we are dealing with changes in conformation particularly through extensive hyperostoses and defects (gaping sutures) in the skull, apparently the result of disturbances in ossification. The clavicles give the impression of being heavy, massive, excessively cured bony structures. The substance of the scapula seems very compact, the acromion markedly bulging, the joint socket shallow and small. In addition there is in both children a marked kyphosis, in one a funnel breast, in the other a pigeon breast, and in both, diffuse clouding of the cornea pronounced by the eye specialist to be hydrophthalmia, that is, a congenital defect, and as further stigmas of degeneration there are in both children crooked little fingers and contractures of the fingers.

R W. B.

CORRESPONDENCE

BOOK REVIEWS

To the Editor In view of the recent critical review of the book, *Surgical Practice of the Lahey Clinic*, I would like to make two suggestions which, I believe, are constructive in character. These relate not only to this review but also to others to be published in the future.

This review is published anonymously, as has always been the custom of the *New England Journal of Medicine*, and my first suggestion is that all reviews be signed. This is but simple justice to the author and the publication, will make the reviewer more conscious of his responsibilities, and will permit readers to decide (1) whether the reviewer is a qualified critic and (2) whether his criticism might be colored by personal prejudice.

The second suggestion is less important. Since a review, to my mind, gives an opinion as to the value of a book, it should be presented to the reading public soon after publication. This review of *Surgical Practice of the Lahey Clinic* appeared two years after publication, and

after it had been, according to the W B Saunders Company, among the best selling books for the year of publication.

The book is composed, as is stated in the preface, of a group of selected papers previously published. These were written by a busy and often overworked staff of surgeons, fellows, anesthetists and other specialists in the Clinic, with a desire to share with other members of the medical profession the methods they had found useful. The authors would be the first to admit that the book is not what might be described as a literary gem. However, its enthusiastic reception, as evidenced by the large circulation and the many complimentary letters from purchasers, indicates that it has pleased many readers and apparently has answered a definite need.

As to the reviewer's comparison of the American and British literary style, it is probably true that the criticism so often leveled at us of being too utilitarian is also true of our literary style. However, we are Americans, and our literature is read largely by Americans. Today our American utilitarian methods are serving us and our respected English allies to an extent that is gratifying to them and to us.

As surgeons we are interested primarily in saving lives and limiting suffering. Secondly, we are interested in presenting our experiences to others to accept or to reject according to their judgment and trust in us.

FRANK H LAHEY, MD

Boston

WAGNER-MURRAY-DINGELL BILL

To the Editor The time has come once again when it appears to me that one from the ranks should speak out frankly.

What I have in mind is the present approach in the way of argument in opposition to the Wagner-Murray-Dingell Bill, and similar proposals now before Congress.

It seems to me that any physician listening in on the "Forum of the Air" discussion of the evening of September 22, must have realized how much damage is done to the present methods of supplying medical care to the public by such forms of argument, either for or against the proposals. To my mind our leadership is weak in debate. The points presented are not persuasive. Brilliance of discussion is evident in full measure, but such points of view as are presented are antagonistic to the public. They gain us nothing in the way of support. On the contrary, they repel. Under such circumstances, one cannot fail to come out of the discussion with ignorance and prejudice, especially if there is profit in prejudice, without recognizing defeat.

The arguments of our leaders concern themselves with admitting gross defects. Our spokesmen seek sympathy and protection under the wings of our enemies. We pander to corporate practices of medicine, admitting that such practices are desirable. We strive to show that the bureaucratic groups are correct, and that we ourselves are attempting to do the very things that they propose. Therefore, we are now agreeing that they have been right all along, and that we have been wrong—that we are trying to do the same thing that they are trying to do,

and that we have been at fault. Such admissions are weak, nonconstructive and damaging.

Throughout recent years, when this problem has been acutely before us, I have adopted a very simple method of handling the situation insofar as the question has arisen amongst my personal contacts. I think that it has been practical, and I know that it has, in every case, been effective. Almost all the public are in favor of any method that will give them service at lower rates. They usually start off by telling me that they think it would be a wonderful thing. I agree with them, and add that it might work quite well for the medical profession. I point out that physicians have been donating services through clinics and hospitals to the extent of probably \$500,000,000 annually and that, in addition, poor collections in private practice virtually constitute a gift to the public of another enormous sum of indeterminate amount. I add that, if the Government or others took over the furnishing of medical care to the public, the doctors would be paid for all these present-day charity services. I tell them that, from a financial point of view, governmental supply of medical services might, and probably would, be a better thing for the doctors, since they would be compensated for these present charities by funds derived from taxation. I invariably find that the people who started off the conversation change their minds. They do not want anything like that if the doctors are going to profit or be paid by taxation or otherwise. They have come to think of doctors as public servants that should be poorly paid, or not paid at all. They tell me that they never thought of the matter from that angle. They are invariably converted, since they apparently are opposed to anything that will pay the doctors at any expense to themselves. Obviously, they were led to believe that they were going to get something for nothing.

Then on top of that I point out that many of the hospitals throughout the world have been provided through voluntary contributions by well-to-do citizens and that the Red Cross and other such organizations are likewise supported largely by voluntary contributions. I add that, if the Wagner-Murray-Dingell Bill or any similar bill went through Congress, these organizations would have to pass out of existence, insofar as control and voluntary contributions are concerned, and that they then would become a burden on the taxpayer.

I find that the public does not want state medicine under those terms, and it appears to me that some such general approach to the problem would be far more effective than the present one.

I do not believe that any businessman would argue his case in the way that our leaders are presenting their cringing arguments. He would approach the argument in a businesslike way. Looking for sympathy engenders only scorn. Admitting that we are wrong when we are not wrong, showing weakness when strength of argument should be our method, pandering, flattering and crawling, all seem to me to be the surest possible road to defeat. I believe that such methods have assured the passage of the Wagner-Murray-Dingell Bill during this session of Congress by an overwhelming majority.

Why not face facts squarely? I have no desire to sit here pounding out my heart and thoughts for publication in any wish for recognition as a leader. I desire no responsibility. But, it does stir up my wrath when I listen to such weak arguments, and see such bad leadership as

our spokesmen have given through these years in so many ways—leadership that is directing us straight into the path of defeat. Surely, some of us must have guts enough to come out squarely in such times, in order to try to let us see things straight and find a better way.

W. A. HUTTON, M.D.

Palmer, Mass.

REPORT OF MEETING

NEW ENGLAND PATHOLOGICAL SOCIETY

The first fall meeting of the New England Pathological Society was held in the auditorium of Boston University School of Medicine on October 21.

The first paper of the evening was "Immersion Foot and Allied Disorders" by Dr. Carl K. Friedland. Cooling the extremities of man to 15 to 18°C. causes simple vasoconstriction. Further cooling to, but not below, the freezing point results in tissue injury, an increase in capillary permeability and exudation of plasma into the tissues. Chilblain, pernio, trench foot and immersion hand and foot are all fundamentally due to the same pathophysiologic process, their apparent differences being the resultant of the site, type and duration of exposure. Other factors such as dependency, immobility, maintenance of body temperature and cold sensitivity also tend to modify the picture. Frostbite is designated as a separate entity because it is due to actual freezing and ice-crystal formation within the tissues.

In the discussion that followed Dr. Shields Warren described cases of prolonged immersion in which, after one and a half to two months, evidence of a mild to moderate Wallerian degeneration in the peripheral nerves was still present with an ultimate fair degree of recovery, although in one patient after six months a trophic ulcer due to anesthesia of the toe developed. In later periods there was pain thought to be due to fibrosis about the nerves. He also stressed the importance of the edema seen in this condition, which results in an increased amount of collagen with hyalinization so that the histologic picture simulates long-standing elephantiasis. The small arteries often show complete occlusion by old fibrous tissue, sometimes with recanalization consistent with the end result of thrombosis. Dr. Valy Menkin raised the point whether the substance responsible for the physiologic changes was due to histamine or a histamine-like substance. He believes that the changes are caused by a leukotaxin resulting in increased permeability, and cited experiments in which the exudate found in the tissues was dialyzed and the histamine-like substance and leukotaxin were removed. When this fluid was resynthesized with histamine, there was no change in capillary permeability. If the fluid was resynthesized with leukotaxin, the original effect was produced. He also raised the question of a neurogenic effect on the development of the inflammatory reaction. Dr. Moritz raised the question whether there were individual tissue specificities to thermal injuries, and in the discussion Dr. Warren brought out the point that the endothelium of the capillaries, small venules and lymphatics showed the earliest signs of injury, and he stated that he believed that this was the most susceptible tissue. Dr. Stanley E. Bradley presented the second paper.

Blast and Crush Injury During Warfare Extended naval operations and the bombing of crowded cities during the present war has aroused considerable interest in the immediate and remote clinical effects of the detonation of high explosives. Analysis of the physical character of an exploding charge indicates that the formation of a rapidly moving, high-compression wave front or blast may result in serious injury or death on land or in the sea unattended by marks of external violence. The syndromes of blast lung and water blast have been delineated and studied experimentally. In addition to the banal aspects of injury secondary to an explosion of any type, prolonged compression of the limbs by wreckage with subsequent renal damage and uremia has been seen fairly frequently and has inspired exhaustive experimental study. Renal functional changes during traumatic shock with special reference to the crush syndrome were briefly outlined.

In discussing the paper Dr Menkin raised the question whether there was elevation of glucose, the result of gluconeogenesis from injured tissue and whether the entire problem was related to the euglobulin fraction of the exudate—either euglobulin itself or a fraction, necrosin, causing particular injury to the liver and kidneys. The author's answer was that the carbohydrate metabolism was not altered; there was variable but usually insignificant adrenal damage, with no evidence of liver damage. The question was raised whether a subdural hematoma could be produced by blast injury alone. In the discussion it was brought out that most cases of subdural hematoma were the direct result of trauma secondary to the blast pressure.

The last paper was presented by Dr Robert W Williams on the subject Aviation and Cardiovascular System. In aviation the cardiovascular system must withstand two principal strains: centrifugal force due to sharp turns at high speed and low barometric pressure due to high altitudes. Centrifugal force in modern fighter planes may exceed eight times the force of gravity (8g). The vascular system in the dependent parts of the seated pilot is distended by blood under this tremendous force until there is insufficient blood circulating to the head. This causes visual blackout and then unconsciousness. The effects of centrifugal force may be counteracted by various mechanical devices that tend to prevent the pooling of blood in the lower parts of the body. At high altitudes the barometric pressure decreases until at about 50,000 feet it falls below the partial pressure of alveolar carbon dioxide and water vapor. Therefore at this altitude even with 100 per cent oxygen supplied by mask, life is impossible only with a pressurized cabin can man survive. Even at lower levels anoxia is proportional to altitude and causes not only central nervous but also cardiovascular pathophysiology. In addition, at altitudes above 18,000 feet, nitrogen dissolved in the tissues comes out of solution and may collect as bubbles. The symptoms of the bends—whether articular, pulmonary, cardiovascular or central nervous—depend on where these bubbles appear. The bends can be prevented by prebreathing oxygen, or better, by using pressurized cabins.

In discussing the paper the question was raised whether it is possible to train groups of aviators to tolerate these effects of centrifugation. It was Dr Williams's opinion that this was not possible.

BOOK REVIEWS

Standard Nomenclature of Disease and Standard Nomenclature of Operations. Edited by Edwin J Jordan, MD. 12°, cloth, 1022 pp. Chicago: American Medical Association, 1942. \$4.00.

This volume, *Standard Nomenclature of Disease*, first published as a book in 1933, revised in 1935 and now completely revised, is combined with *Standard Nomenclature of Operations*, first published in June 1942.

The basic plan used for the work was adopted officially at the second National Conference on the Nomenclature of Disease. In 1937 periodic revision was taken over by the American Medical Association. In connection with the third edition a fourth National Conference on Medical Nomenclature was held under the auspices of the American Medical Association in Chicago in March, 1940, with Dr Haven Emerson of New York City serving as chairman. The present edition is the result of this conference. There is no essential change in the arrangement of the material in this edition, however, about thirty-five hundred additions, deletions and corrections have been made in individual diagnostic entries. The entries in the section Disorders of Endocrine Glands and Hormones which appeared in the classification

Body as a Whole in previous editions have been reclassified under the appropriate organs. The present edition is authoritative, since it represents the consensus of about sixty delegates to the conference from interested organizations and institutions.

Following the classification of disease, there is an extensive index referring to etiologic classification, and a useful table of eponymic diseases is appended. The aim of the work is to include every disease that is clinically recognizable and to avoid repetition and overlapping. English terms are employed, whenever possible, in preference to Latin or Greek terms although numerous exceptions occur, especially under diseases of the skin and of the eye.

The method of classification is based on two primary factors: the portion of the body concerned (topographic) and the cause of the disorders (etiologic). These two elements are designated by numerical digits separated from each other by a hyphen. The first three digits in the disease code describe the topographic site; the last three, following the hyphen, describe the etiologic agent.

The nomenclature of operations was compiled as a parallel to the code of disease in response to a demand from various sources. The compilation is a combination of all well known operative terminologies of various hospitals and associations. The division of fundamental surgical procedures into eight main categories was carried over, to a large extent from the *Classified Nomenclature of Operations* of the New York Hospital. This code attempts to bring about standardization in designating operations. It likewise has a complete index referring back to the various operations. All hospitals and others concerned with scientific medicine should adopt a standard nomenclature, particularly if they do not have a complete schedule of their own.

This book constitutes a standard reference source. It should be in the office of every surgeon and physician, especially those who are concerned with hospital service.

Borderlands of Psychiatry. By Stanley Cobb, M.D. 8°, cloth, 166 pp., with 28 illustrations. Cambridge: Harvard University Press, 1943. \$2.50.

Dr. Stanley Cobb, now psychiatrist-in-chief at the Massachusetts General Hospital, has long been a student of the borderlands of psychiatry. Beginning as a neuro-pathologist, with neurophysiologic leanings, he first became a neurologist, later an experimentalist and finally a psychiatrist. He has, during these years, wandered widely in the fields of the psychoneuroses, epilepsy, the organic disorders of the central nervous system, alcoholism and speech defects. This borderland, or to most psychiatrists the hinterland, contains, according to Cobb, a population of six million people, a vast number when compared with the six to seven hundred thousand who make up our hospital population for mental diseases, the primary field used for the major training center of most psychiatrists. With Cobb's background, therefore, physicians have long awaited the Lowell Lectures given by him in 1940. They will not be disappointed in this book, a somewhat elaborated and expanded text, geared to a more medical audience than usually attends a popular-lecture series.

Much of Cobb's training and fundamental thinking comes out in this book. He soundly views each field of the borderland, carefully evaluates the acreage, the quality of the soil, its previous history, its presumptive yield and its crop prospective in view of future tillage. Much of the field has been previously explored, such, for instance, as the old body-and-mind problem, now fertilized and revitalized as psychosomatics. Cobb presses and strains out the essentials in a brief, penetrating manner, leaving one sure of the way he feels, and almost certain that he is essentially right in his deductions. At least his review is based on a thorough study of each subject, neglecting no aspects, be they physiologic, anatomic, psychologic or psychiatric.

The whole book makes one think of a New England boiled dinner. There are many ingredients, all well cooked and furnishing sound, hearty fare. But one cannot digest quickly such varied provender as "the parallel evolution of speech, vision and intellect," "the function of the frontal areas of the human brain," "the anatomical basis of the emotions," "consciousness" and "concerning fits." Taken in small pieces, chewed and ruminated, each portion makes a tidy meal, and one well worth the time. Some psychoanalysts may not favor their portion, but neither will all the structuralists nor all the behaviorists. The meal, however, is excellent and everyone will find something at the table to his liking. If he does not, he had better go hungry.

The style of writing leaves something to be desired. Cases are treated "from more than one angle"; "cryptogenic" is discarded, as being a "long" Greek word, although Cobb does not hesitate to use "dysrhythmia," "anosognosia" or "strophosymbolia." Graves's name is constantly misspelled, as is that of Lorente de N6 and J. F. Fulton. There is a good index to the book, and selected references at the end of each chapter. The reviewer cannot conceive how anyone could not find both nourishing and thought-provoking sustenance in this stimulating, well-organized monograph. It is hoped that in future editions the textual errors will be erased.

Psychosomatic Medicine: The clinical application of psychopathology to general medical problems. By Edward Weiss, M.D., and O. Spurgeon English, M.D. 8°, cloth, 687 pp., with 2 tables, 9 illustrations and 4 charts. Philadelphia and London: W. B. Saunders Company, 1943. \$8.00.

The old body-and-mind relation takes on a fresh aspect when, in modern times, it becomes "psychosomatic medicine." A periodical, first issued in January, 1939, with the designation *Psychosomatic Medicine*, was the early effort in the field. Now comes a book, stemming from the same impulse. The senior author learned about twenty years ago that one patient's illness, the chief symptom being headache, "was her infantile way of expressing disapproval of her brother's marriage and, when the meaning of the illness was made clear to her, she promptly recovered." Now he finds that similar cases are by no means the exception in the practice of medicine. Many authorities, he states, agree that cases like the above constitute about a third of all practice, and that another third concern patients who have emotional factors complicating and adding to the burden of their physical disease.

This book deals with the problems of the emotional factors in the cause or augmentation of illness. The volume stresses personality development and the establishment of psychopathology early in life. In a series of chapters, each division of the body structure is taken up in detail. The gastrointestinal and cardiovascular systems, as might be expected, receive most attention, but the endocrine, special-sense and the genitourinary systems are not neglected. There is a brief chapter on military medicine, a timely effort but somewhat out of place in this volume, and four final chapters on treatment.

In the opinion of the reviewer, the book presents a mass of data, somewhat poorly evaluated and often presented without ordinary scientific discrimination. Many case histories are used, but they are often feeble arguments for positive generalizations. As in the case noted above, all symptoms tend to disappear only too quickly once the inner springs of discord are touched. In other words, the authors make happy endings almost as frequent as in motion pictures, a goal seldom reached in the practice of most psychiatrists.

In spite of these shortcomings, the book offers much thoughtful material for medical students and practitioners. It at least brings forcibly to their attention one of the most pressing problems in medicine today. The authors demonstrate that the emotions may play a role in illness, as in our daily lives; what they fail to show in an entirely convincing manner — possibly the time is not ready to show it — is how that role is played. From time immemorial emotions have colored our lives; this book leads one to believe that the coloring early in life is of greater importance in disease than any coloring that may come later and that many illnesses, the result of pathologic changes, come as the result of the emotional strain. Although there is some evidence that such statements may be true, much more must be known before a broad generalization can be made. This book forms part of the stimulus that arises from an awakened interest in psychosomatics and, as such, deserves a wide reading.

ENDOCRINE AND PSEUDOENDOCRINE PROBLEMS IN CHILDHOOD*

RICHARD WAGNER, M.D.†

BOSTON

RIGHTFULLY endocrine and pseudoendocrine problems in childhood deserve consideration together. Many anomalies and disturbances of growth and development and certain cases of retarded sexual development, of an abnormal accumulation and distribution of fat, of dwarfism and even of mental retardation are often mistakenly grouped as the expression of an endocrine imbalance. There are many more, and to a certain extent more important, problems that are often considered as endocrinopathies but that have only a very loose relation, or no relation at all, to a disturbance of one of the hormone glands. Regarding true endocrinopathies that are of importance in general pediatric practice, if one were to count them on the fingers of both hands, there would certainly be quite a few fingers left over.

There are three large groups of diseases and anomalies that have certain features in common but that differ from each other by their etiology as well as by the dominance of certain characteristics. These characteristics determine the condition in question and classify it under the heading of one of these three groups, which are as follows:

Group 1. True endocrine disorders caused by a pathologic process or anomaly of an endocrine gland, which may be even a congenital absence.

Group 2. Accentuations of physiologic phases of development, which sometimes imitate true endocrinopathies. Constitutional and familial factors are frequently involved. Transitory states, such as transitory infantilism, certain forms of obesity and disharmonic development, should be included.

Group 3. Congenital anomalies and multiple deviations, retardation of development, somatic

as well as mental, sometimes mistaken for endocrinopathies and showing some of their essential features. Nor infrequently they overlap. This group should properly be called genopathies rather than endocrinopathies.

When dealing with a possible endocrine disorder in childhood, certain routine measures should be carried out so that the condition may be more accurately classified. The following is a brief outline of such a scheme:

Exact body measurements (standing and sitting height, circumferences of head and chest, breadths of chest and pelvis, and span); appraisal of proportions (stem index); velocity of growth and relative growth rate when the patient is observed over a longer period of time.

Determination of the bone age by x-ray; eventually, x-ray examination of teeth and skull.

Appraisal of the genital and extragenital characteristics.

Examination of eyegrounds and visual fields.

Laboratory tests appropriate to the given case, such as basal metabolic rate, specific dynamic action, sugar-tolerance test (glucose or galactose), determination of blood cholesterol and cholesterol ester levels, and assays of sex hormones in the urine and follicle-stimulating hormone in the blood. (Certain laboratory tests are important only for selected cases, such as the insulin-tolerance test and the dextrose-insulin tolerance test in the diagnosis of endocrinologic disorders of dextrose metabolism, and determination of the sodium and potassium levels in cases of possible suprarenal involvement.)

Psychometric tests.

Accurate records of response to treatment.

In the physical examination, special attention should be given to hematologic studies (hypochromic anemia in myxedema), the heart and electrocardiogram (characteristic changes in hyperthyroidism and hypothyroidism), the blood pressure (elevation in adrenocortical obesity with macrogenitosomia) and the size of the liver (hep-

atomegaly in dwarfism due to glycogenesis). All cases should be examined from the point of view of somatic stigmas, according to a certain schedule, which space does not permit discussing in detail here. Of particular interest is the mesenchymatous group of stigmas, such as curved fifth finger, brachydactylia, fusion and other anomalies of the ribs, malocclusion, ear nodules and so forth—not only their presence but also their occurrence together.

To illustrate Group 1, the true endocrinopathies, I shall select only two examples—congenital cretinism and pituitary dwarfism.

Figure 1 shows a case of congenital cretinism in a child of five weeks with all the characteristic signs. Early diagnosis and treatment are essential

FIGURE 1. *Congenital Cretinism in a Five Week-Old Baby (Nobel et al.¹).*

The photograph shows the characteristic facies, the macroglossia and an umbilical hernia

in order to prevent further progressive stages of deterioration, which are never completely reparable, as is demonstrated in Figure 2. Even if the somatic development shows good progress, as illustrated by the improvement of skeletal development under the influence of thyroid treatment, the end result is poor so far as mental development is concerned.

The next example is concerned with pituitary dwarfism. Many mistakes are still made in the diagnosis, although it is usually quite simple. Figure 3 shows a pituitary dwarf of fourteen years. The only obligatory clinical signs are dwarfism and complete failure of sexual development if the condition has an onset during the early period of childhood, or atrophy of the genitalia if these have developed before the onset of the condition. The lack of mental retardation is important. All the other signs and symptoms, such as obesity, gero-derma and diabetes insipidus, and many of the laboratory findings are nonobligatory for the diagnosis. Changes of the eyegrounds and visual fields may or may not be present, depending on the site of the lesion and the duration of the process. The underlying lesion in the case shown in Figure 3 was a cystic tumor of the hypophyseal duct, consisting of squamous epithelium. The same picture may be observed without the presence of a tumor. The primary deficiency in pituitary dwarf-

ism may be the result of congenital absence of the acidophilic cells, surgical ablation, pressure necrosis, infection, infarction, calcification or any destructive lesion in or in the immediate vicinity of the gland. The midbrain is sometimes involved,

FIGURE 2. *Congenital Cretinism in a Seventeen-Year Old Girl (Nobel et al.¹).*

Before treatment (photographs on left), the height and bone age corresponded to those of a child of one and a half years. After seventeen months of thyroid treatment (photographs on right), the height had increased 18 cm. and there was striking progress in skeletal development.

with repercussion on the gland. One of the youngest cases on record is now under observation at the Boston Floating Hospital and the Boston Dispensary (Fig. 4).

The treatment of pituitary dwarfism consists of surgical removal of an existing tumor and of hormone therapy in the other cases. Methyltestosterone, which is given by mouth, is the best of the preparations available at this time for the hormone treatment of pituitary dwarfism (Fig. 5). It is a specific factor stimulating linear growth and the interstitial tissue of the gonads. The drug stimulates the development of the secondary sexual characteristics but has no influence on the maturing process of the gonads proper. It does not stimulate spermatogenesis and therefore does not lead to early closure of the epiphyses. Only completed sexual maturity arrests skeletal growth and leads to the fusion of the epiphyses. The growth-

stimulating effect of testosterone derivatives in hypogonadal subjects has been studied by several investigators (Moricard and Bize,⁶ Villaret, Justin-Besançon and Rubens-Duval,⁵ Webster,⁹ Webster and Hoskins,⁷ and Browne and Ross⁸). The in-

and those giving negative follicle-stimulating hormone tests with the urine. The cases in the latter group exhibit a rise in the 17-ketosteroid assay with chorionic gonadotropin therapy. Albright and his co-workers believe that this syndrome is of pi-

FIGURE 3. Pituitary Dwarfism in a Fourteen-Year-Old Boy (Nobel et al.¹).

The height was only 107 cm., corresponding to that of a child of five and a half years. The bone age was consistent with that of a child of three years. The testicles were atrophied, and there was atrophy of the optic nerve, with temporal hemianopia. The x-ray film of the skull shows a suprasellar cyst and increased convolutional markings.

roduction of a methyl radical greatly enhanced the peroral effects of testosterone, as shown by Miescher and Tschopp.⁹

Pituitary hormones and the chorionic gonadotropins are on the whole a disappointment so far as the treatment of pituitary dwarfism is concerned. So long as there are no synthetic hormones available, as, for example, in the case of the sex hormones, but only crude extracts, the therapeutic results are doubtful and not consistent. On the other hand, in some supposedly hypopituitary conditions—for example, in certain selected cases of cryptorchidism—treatment with chorionic gonadotropins is valuable.

In the differential diagnosis between panhypopituitarism and male eunuchoidism the 17-ketosteroid assay and that of the follicle-stimulating hormone test in the urine have recently become of great importance. According to Fraser, Forbes, Albright, Sulkowitch and Reifstein,¹⁰ patients with panhypopituitarism have no 17-ketosteroids or very low assays. Cases of male eunuchoidism are divided into two groups, those giving positive

pituitary origin. Chorionic gonadotropin produces no rise in the 17-ketosteroid excretion in male castrates and in eunuchoid patients with positive follicle-stimulating hormone tests.

Group 2, the pseudoendocrinopathies, is composed of those children who at some time during their growth period deviate from the normal but who do not have a real abnormality of any of the endocrine glands. A great number of prepubescents, who will ultimately develop into normal adults, are often mistakenly diagnosed as having endocrine disturbances. The problem in these cases relates to the size of the genitalia, obesity or growth. One of the commonest errors is concerned with the management of obese boys. The distribution of fat in these boys resembles that found in women and adult eunuchs. The physician is therefore inclined to make a diagnosis of obesity of the Frölich type, particularly since the genitalia appear small. This type of obesity is not at all abnormal in boys of a pyknic somatotype. The apparent hypopituitarism is due to the fact that the penis is usually embedded in suprapubic fat. When the fat pad

The height was only 75 cm., corresponding to that of a child of one year, as did the bone age.

FIGURE 5. Stimulation of Growth in a Pituitary Dwarf.

The growth curve is compared with Engelbach's standard. The abbreviations are as follows: G.H., growth hormone; Wh.G., whole gland; A.P.L., anterior-pituitary-like hormone; and M.Tes., methyl-testosterone.

FIGURE 6. Pseudo-Fröhlich Syndrome in a Fourteen-Year-Old Boy (Rosenstern²).

The boy was of normal height but was markedly obese, with the testes embedded in suprapubic fat. The condition subsided spontaneously, and at eighteen years of age (photograph on right) the boy had normal build and complete sexual development.

FIGURE 7. Temporary Early Leanness (Rosenstern²).

The photograph on the left shows leanness at eleven years of age; that on the right, an appreciable fat deposit with the advent of puberty at thirteen.

is pushed back and the penis and testes are measured, the genitalia are found to be within the normal range, furthermore, there is no delay in the onset of pubescence and development may occur earlier than usual. Since there is no hypogonadism, the diagnosis of adiposogenital dystrophy of Frohlich's type is not at all justifiable. After reaching the age of maturity, most of these boys grow taller and slimmer, although they maintain their characteristic somatotype through life. Treat

ment consists of a low calorie diet, particularly low in carbohydrates and fat, supported by thyroid medication (Schonfeld¹¹). At the beginning it is advisable to adjust the intake below the basal metabolism and induce the patient to burn his own body fat.

Figure 6 shows a case of pseudo Frohlich syndrome. At fourteen years the patient had all the characteristics of obesity of prepubescence. Four years later all signs had subsided. He is now completely mature. No specific treatment was supplied. The pseudo Frohlich syndrome occurs in girls as well as in boys. There are other pseudo endocrine problems in girls, some of which are concerned with anomalies of the menstrual period.

That in many of these cases of obesity one is dealing simply with an accentuation of a physio

FIGURE 9 *Late Sexual Development in Universal Infantilism (Rosenstern*)*

adjuncts to the plication technics in increasing the number of favorable results. The best promise of satisfactory treatment, however, has issued from the recent work of Kennedy.

Most plastic operations involving the vesical neck and urethra are based on the original Kelly⁴ principle, which outlines the mattress suturing of the bladder neck and urethral sphincter. Briefly, the operation consists of exposing and separating the urethra and bladder through a longitudinal incision in the anterior vaginal wall and the approximation of the torn or relaxed sphincter muscles and fascia.

Kennedy⁵ describes the most frequent causes of incontinence as follows: trauma to the inner and middle third sphincters of the urethra, causing them to become partially fixed by fine bands to the posterior lateral margins of the adjacent pubic rami; and damage in the midline to those voluntary fibers that pass under the middle third of the urethra and are attached to each ramus of the pubis, posteriorly constituting a sling support.

Subsequent to a careful study of the anatomy and physiology of the bladder and urethra, and after the use of roentgenography in elaborating the function of the urethra, Kennedy reported that it was possible to cure incontinence by breaking down the fine bands between the urethra and the pubic rami and plicating the urethra in its midline to prevent any further connection with the rami laterally, and bringing together in the midline beneath the inner and middle thirds of the urethra the injured "sling" fibers. He⁶ reasoned that the voluntary sphincters functioned better when they were circular and without attachments and were suspended freely in a sling. He presented a detailed exposition of the technic employed to obtain these conditions.

The reports of the results in operative procedures for urinary incontinence vary according to the methods used and the ability of the plastic surgeon, as well as the period of time that elapses between the injury and its repair. It is obvious that the fascia and muscle fibers to which Kennedy attaches so much importance are available for only a limited time. Their attenuation after years of relaxation and injury makes their approximation problematical and the end results irregular. Since many of the women who seek treatment have endured incontinence for years, the reports of satisfactory repair show remarkable variation. One of the early papers concerning the surgical treatment of urinary incontinence is that of Kelly and Dumm,⁷ who had successful results in 75 per cent of 20 treated cases. Watson⁸ operated on 105 cases, with success in 66 per cent, improvement in 22 per cent and no improvement in 12 per cent.

He also found that two out of three patients with incontinence showed a cystocele.

Furniss^{9,10} reported 17 cases of incontinence treated surgically. Success was obtained in 76 per cent and relief of symptoms in 11 per cent, and there was operative failure in 13 per cent. Of 28 consecutive operations by Kennedy,⁶ only 2 were failures; that is, 93 per cent were completely satisfactory. Peightal,¹¹ in a discussion of Kennedy's work, revealed that 11 of 12 cases were successfully treated by the latter's technic. Stress incontinence was present in the single failure. According to Barnes,¹² the cures vary from 36 to 100 per cent and repeat surgery from 6 to 15 per cent. He emphasized the general inadequacy of the treatment. Matassarini¹³ revealed that 10 to 20 per cent of the patients visiting Schaumann's gynecologic clinic have urinary dribbling and 1 to 2 per cent have complete loss of control. He believed that 90 per cent of these patients would secure continence from simple cystocele repair and that the remaining 10 per cent would respond only to a more extensive operative procedure. In his hands, plication of the urethra in the anteroposterior plane with the addition of Kelly stitches placed at the trigone resulted in a complete cure in 6 cases. Berkow¹⁴ stated that when the Kelly technic is employed, 15 to 40 per cent failures are revealed by the literature. His own procedure differs from that of Kennedy in that he does not free the fascial sling so widely, but rather raises the urethra to the clitoris and closes the structures beneath it. He analyzed 19 cases from two months to three years after operation and found that 89 per cent were continent. Aldridge³ believes that 10 to 20 per cent of the operations for urinary incontinence fail.

TECHNIC OF KENNEDY OPERATION

In the Kennedy operation for incontinence, the cervix is fixed by a Jacob's volsellum, if it comes down readily; if not, the anterior vaginal wall is picked up at the level of the uterine isthmus by a guy suture of black silk. A second guy suture of the same material is placed in the anterior vaginal wall 1 cm. below the urinary meatus. A longitudinal incision is made in the anterior vaginal wall between these two sutures. It starts about 1.5 cm. below the urinary meatus and ends about 1.5 cm. above the suture placed at the level of the uterine isthmus. The anterior vaginal wall is dissected from the urethra and the bladder (Fig. 1). The urethra is next separated from the pubic ramus on each side. By starting the separation close to the bone, a plexus of veins and branches of the inferior vesical artery may be avoided. If these vessels are torn, they are picked up and ligated with fine chromic catgut.

The separation is carried out into the paravesical space. This dissection is facilitated by retracting the edges of the vaginal wall by means of guy sutures of black silk or by Allis forceps. The

FIGURE 1.

The anterior vaginal wall has been opened to within 1.5 cm. of the external urinary meatus. The urethra has been separated from pubic rami, and the bladder neck is exposed.

fibrous adhesions between the urethra and the pubic rami having been severed, the former regains its mobility. In order to restore and maintain continence, the urethra must not be permitted again to become adherent to the pubic rami. With this end in view, the tissues under the urethra are plicated by three mattress sutures of No. 1 chromic catgut, which, when tied, keep the urethra away from the pubic rami (Fig. 2). A second row of three mattress sutures introduced in the edges of the fascia-like structures on each side of the urethra further separates it from the pubic rami (Fig. 3). If necessary, a fourth mattress suture may be placed at the lower part of the urethra in the region of the internal sphincter (a suture placed in this region formed the basis of the Kelly operation for incontinence). The excess of the anterior vaginal wall on each side that formed the urethrocele is then resected. In accomplishing this, the damaged portion of the voluntary sphincter is removed with the vaginal wall.

The intact voluntary sphincter fibers that remain after the resection of the vaginal wall are approximated by No. 1 chromic catgut sutures, usually three in number, with simultaneous closure of this portion of the anterior vaginal wall. These chromic catgut sutures begin at the highest point of the vestibule and extend down about 2 cm. In their course, they pick up the vaginal wall close to the pubic rami, so as to enclose the muscle fibers of the constrictor urethra muscle (voluntary) and the inferior layer of fascia of the uro-

FIGURE 2.

Three mattress sutures of No. 1 chromic catgut have been placed in the fascialike structures on the sides of the urethra. When tied, they pull the urethra away from the pubic ramus of each side. The lower mattress suture (3) plicates the vesical sphincter.

genital diaphragm on both sides. The remainder of the anterior vaginal wall is closed with similar sutures (Fig. 4). Originally, we used silver wire for the three uppermost sutures in the anterior vaginal wall, as recommended by Kennedy, but this has been replaced by No. 1 chromic catgut sutures without any apparent change in the result. A plain, male soft-rubber catheter is introduced into the urethra and left in as an indwelling catheter for seven days. The patient usually voids normally after its removal, and she is allowed out

of bed on the tenth postoperative day. Figure 5 illustrates the completed operation.

RESULTS

A detailed survey of 23 cases, all of which received typical Kennedy operations, revealed the following data. The average age of patients was 47.1 years, the youngest being thirty-five and the oldest sixty-nine. In the thirty-to-thirty-nine-year group there were 4 cases, in the forty-to-forty-nine year group 13 cases, in the fifty-to-fifty-nine-year group 2 cases, and in the sixty-to-sixty-nine-year group 4 cases. The average parity was 3.6. Primigravidas numbered 3 (13 per cent), biparas 3, triparas 5 (22 per cent), quartiparas 5, quinparas 4 (17 per cent), sexiparas 2 (9 per cent) and septip-

for more than thirty years. Two patients had slight stress incontinence of indeterminate duration.

In addition to the primary urethral relaxation, there were 13 cases (57 per cent) of concomitant

FIGURE 3.

A second row of three mattress sutures of No. 1 chronic catgut has been placed in the fascia-like structures on the sides to enfold further the urethra and pull it away from the pubic rami.

aras 1 (4 per cent). Seven (30 per cent) of the patients had undergone previous operations for their urinary incontinence; in 5 of these cases (22 per cent) the procedures were cystocele repairs.

The presenting symptom of incontinence had existed for widely divergent lengths of time, with an average period of ten years and three months. The shortest duration was seven months and the longest thirty-two years. Three patients (13 per cent) had had incontinence for less than one year, 4 (17 per cent) for one to four years, 6 (26 per cent) for five to nine years, 6 for ten to nineteen years, 1 (4 per cent) for twenty to twenty-nine years, and 1

FIGURE 4.

The constrictor urethral muscle and the urogenital diaphragm have been reconstructed, and the remainder of the incision in the anterior vaginal wall is about to be closed.

cystocele, 10 cases (44 per cent) of relaxed vesical sphincter, some with previous cystocele repair, and but 3 cases (13 per cent) of relaxed urethral sphincters alone. Seventeen of the patients also received gynecologic surgery in addition to the Kennedy operation; namely, trachelorrhaphy in 1 case, the Manchester operation in 3 cases, posterior colporrhaphy in 2 cases, perineorrhaphy in 12 cases, hysterectomy in 2 cases, and cervical amputation in 5 cases. Only two anesthetics were used — spinal in 14 cases (61 per cent) and general in 9 cases (39 per cent). The average length of hospitalization was 17.1 days, with the majority of patients (18 cases) remaining for thirteen to sixteen days. Except for mild transient cystitis (5 cases) that responded immediately to conservative therapy, there were no postoperative complications.

All the patients were successful in controlling their urine two to four weeks postoperatively. One woman who had a dilatation and curettage.

cervical amputation, Kennedy operation and perineorrhaphy experienced some hesitancy at the beginning of micturition, but this gradually disappeared. The late results were likewise gratifying.

FIGURE 5.

This sketch shows the result of the completion of the operation.

ing. Late check-ups on all the patients included in this report were obtained from two months to four years and nine months after operation, with an average period of seventeen months. Complete late recovery of bladder function was attained in 18 cases (78 per cent), and marked improvement in 3 cases (13 per cent). The total number of cases with either complete recovery or marked improvement was therefore 21 (91 per cent). The failures numbered 2 (9 per cent); a study of these follows. In no case was there any aggravation of symptoms after surgery.

CASE REPORTS

CASE 1. Mrs. M. H., a 46-year-old quartipara, had had dribbling and stress incontinence for 17 years. A relaxed vesical sphincter and moderate cystocele were present. No previous surgery had been attempted. A dilatation and curettage, Kennedy operation and perineorrhaphy were done under spinal anesthesia, and the postoperative convalescence was uneventful. When a discharge examination was made 15 days after surgery, the urinary control

was excellent, but within 2½ years the stress incontinence had returned to its original degree. In retrospect, this case might have responded better to such a procedure as that of Aldridge,³ in which abdominal fascia is used as a sling for the weakened urethral sphincter.

CASE 2. Mrs. H. C., a 41-year-old tripura, had had incontinence for 7 years associated with a relaxed sphincter. Throughout her 14 days in the hospital, the bladder function was perfect, but 3 months later the incontinence was as severe as on entry.

DISCUSSION

The need of a careful urologic study in incontinent women is self evident. Barnes¹² has suggested three tests for adequate diagnosis and evaluation of the type of incontinence, giving the technic of each: direct measurement of intravesical pressure, direct measurement of urethral resistance and indirect measurement of internal sphincter strength. His work emphasizes the fact that stress incontinence is the result of failure of the voluntary urethral sphincter fibers to function. The involuntary fibers control other vesical pressures. This suggests that operations such as that of Aldridge³ are of great benefit in cases where stress incontinence is superimposed on general urinary dribbling. The inadequacy of the Kennedy procedure alone in such cases is well illustrated in the first of our two failures.

It is important to re-emphasize the significance of the lapse of time between the injury that caused the incontinence and the treatment of the condition. In our first failure seventeen years had elapsed, and in the second seven years. It is possible that an incontinent patient with a cystocele and urethral sphincter relaxation of more than five years' duration requires more than an anterior colporrhaphy. In especially recalcitrant problems resort to the methods of Goebell¹⁰ and Aldridge³ is of real value.

SUMMARY

A presentation of the general problems of urinary incontinence in women is made.

Twenty-three women with incontinence were treated by the Kennedy operation, with either marked improvement or complete late recovery of bladder function in 91 per cent in an average of seventeen months after operation.

Two failures occurred in the series; the possible causes for failure are discussed.

Suggestions are offered regarding the study, classification and treatment of urinary incontinence in women.

CLINICAL NOTE

ACTINOMYCOSIS OF THE CHEST WITH SPREAD TO THE ABDOMEN*

REPORT OF A CASE CURED WITH SULFADIAZINE

WILLIAM E. LADD, M.D.,† AND
ALEXANDER H. BILL, JR., M.D.‡

BOSTON

BECAUSE of the known severity of actinomycosis, particularly with thoracic involvement, we have thought it worth while to present the following case. The older literature shows a poor prognosis for actinomycosis of the chest. Of the cases reviewed at the Royal Victoria Hospital by Morton,¹ 5 out of 7 thoracic cases resulted in death. This was in contrast to the somewhat better prognosis for the abdominal cases and the considerably better prognosis for the cervicofacial group. This impression is confirmed by Cope,² Hanes³ and Schmitt and Olsen.⁴

In the last five years a number of reports of successful treatment of actinomycosis with sulfonamides have appeared. The first is that of Walker,⁵ who treated a soldier with appendiceal actinomycosis and a draining sinus. Sulfanilamide was used, with dramatic results. Following this case, the reports of Hall,⁶ Sudler and Johnson⁷ and Miller and Fell⁸ in this country and of Dorling and Eckhoff⁹ and Ogilvie¹⁰ in England appeared in fairly quick succession. Others¹¹⁻¹⁴ followed. The cases reported were all treated with sulfanilamide or sulfapyridine, with cure or improvement. In some cases other means of treatment, such as x-ray and iodides, were used together with the sulfonamide drug. The use of sulfathiazole is reported in only 1 case, in which it was unsuccessful after a very short course of therapy.¹⁵ Two of the cases reported above were of the thoracic type

(Wilkinson¹¹ and Dobson et al.¹³). None of these reports contain cases treated with sulfadiazine.

The rationale of the sulfonamide treatment of actinomycosis has been studied by Cutting and Gebhardt,¹⁶ who have shown that the growth of *Actinomyces hominis* in vitro is inhibited by the drugs. Of the drugs studied by these authors, sulfathiazole and sulfadiazine were found to be about equally effective and to be more effective than sulfanilamide in similar concentration. On the strength of this study and because of the low toxicity of sulfadiazine, it was used in the treatment of our case.

CASE REPORT

D. O'K., a 9-year-old boy, was admitted to the Surgical Service of the Children's Hospital on January 31, 1942, complaining of draining sinuses of the back and right flank.

Sixteen months before admission the patient had developed a cough and fever. This continued until 14 months before admission, when an egg-shaped swelling appeared on the right chest posteriorly. The patient's physician sent him to a hospital near his home, where it was thought that he had empyema necessitatis. An x-ray film of the chest showed slight density at the right base, which was interpreted as probably in the lung rather than in the pleura. This swelling was drained and proved to be an abscess. Surgical and medical measures were undertaken, and during the next 12 months the patient underwent six operations for drainage of persistent and spreading abscesses on the posterior chest and in the right flank. The right pleural and subdiaphragmatic spaces were opened for drainage during this time. He is reported to have been given sulfapyridine and sulfanilamide at times, but the quantity given and the duration of treatment were unknown. Clinically he did poorly, with profuse drainage and gradual loss of strength. Two months before admission he was taken home from the local hospital against the advice of his physician.

During his stay at home the patient continued to go downhill. He was feverish in the evening and coughed continuously. On two occasions he coughed up blood. Also, he developed pain on straightening his right leg. His condition grew progressively worse, and he was admitted as an emergency case 16 months after his first symptoms.

The patient lived in the factory district of a small New England shoe town. His mother and father and one brother were healthy. The past history was negative.

Physical examination showed a feverish, emaciated and apprehensive boy weighing only 49 pounds. He was

†William E. Ladd Professor of Child Surgery, Harvard Medical School; Chief of Surgical Service, Children's Hospital.

‡Formerly, intern, Children's Hospital.

occasionally seized with paroxysms of coughing. The skin was loose, pale and dry, and was covered with fine lanugo-like hair. The back was honeycombed with sinuses interspersed with raw areas of granulation. Thick, yellow pus could be expressed from the sinuses. One sinus extended into the right flank, apparently beneath the liver, for the length of a Kelly clamp. There were

doubtful on admission, positive on February 6, and negative on February 12. A Congo red test showed no retention of dye. Examination of the pus revealed no sulfur granules or fungus. Stains and guinea-pig inoculations showed no tubercle bacilli.

X-ray examination of the chest on admission showed cardiac enlargement, bilateral pleural effusion and increase

FIGURE 1. Photomicrograph of Granulation Tissue Showing a Cluster of *Actinomyces* ($\times 700$).

rales in the right chest and dullness anteriorly up to the 4th rib. The left side of the chest was clear. There was an apical systolic murmur (Grade III), with a precordial thrill. The abdomen was distended and shiny, and there was an area of flaccidity and sensory loss below an operative scar in the right upper quadrant. The operative scar extended into an abscess involving the abdomen below the liver. The presence of free fluid in the abdomen was suspected but was never proved. The spleen was palpated 4 fingerbreadths below the ribs on the right. The right hip was held in 45° of flexion and could not be straightened. There was suggestive clubbing of the fingers and toes.

Laboratory examination showed a red-cell count of 3,400,000 and a white-cell count of 33,600, with 74 per cent neutrophils, 20 per cent lymphocytes, 4 per cent monocytes and 2 per cent eosinophils. Examination of the urine was normal on admission and remained so throughout the hospital course. Two blood cultures taken shortly after admission were negative. The blood non-protein nitrogen was 25 mg. per 100 cc. and the serum protein was 7.4 mg. Blood Hinton reactions were

in the lung markings in the lower two thirds of each lung field. Portions of the 10th and 11th ribs had been resected on the right.

The patient was studied for the first 5 days, during which time he required several copious dressings to the back each day. The temperature reached 102 or 103°F. each evening, and he was frequently shaken with a severe nonproductive cough.

On the 6th day, incision and drainage of the deepest sinus in the right flank were carried out. A biopsy of this tissue was taken, and pathological examination of the granulation tissue showed "peculiar yellowish brown staining masses with club ends around the periphery, characteristic of actinomycosis."

The patient continued to run a fever and on the 12th day was started on sulfadiazine, 0.5 mg. six times a day. The temperature fell to normal after 5 days of this therapy and remained normal subsequently. The drainage became negligible within 2 weeks. The right leg was put in traction and physiotherapy was given, with gradual return of motion. The sulfadiazine level was followed every 3 or 4 days and remained chiefly between 8 and 12

mg. per 100 cc., the lowest level recorded being 4.5 mg. and the highest 145 mg.

The drug was continued, and after 4 weeks the patient had gained 5 pounds and seemed much better. After 6 weeks the back was dry and epithelialized. The sulfa-

A case of actinomycosis in a nine-year-old boy is presented. The disease was of sixteen months' duration, starting in the chest and extending through the diaphragm into the retroperitoneal space

FIGURE 2. Photographs of X-Ray Films of the Chest before and after Treatment.

The film on the left shows actinomycotic involvement of the right lung; that on the right, taken five months later, shows complete clearing.

diazine dose was cut to 0.5 mg. four times a day, but the level remained within the former range. After 8 weeks the patient was walking, and subsequent to this his convalescence was uneventful. He was discharged on May 20, weighing 63 pounds.

For 8 months after discharge sulfadiazine was continued at a dosage of 1.5 mg. daily, and the patient was seen at regular intervals.

On June 16, 5 months after admission and about 1 month after discharge, there were no signs in the chest.

On his latest visit, on February 15, 1943, the patient was not recognizable as the same boy who had been admitted a year previously. He weighed 85 pounds and walked without a limp. The cardiac murmur had disappeared, the chest was clear, and the sinus tracts were well healed. The spleen was no longer palpable, and the liver could just be felt. The weakness of the abdominal wall on the right was still present. X-ray films showed the right diaphragm to be still somewhat raised, but the lungs were normal. The patient was going to school and leading an entirely normal life.

SUMMARY

A review of the literature shows a group of cases of actinomycosis favorably influenced by treatment with sulfanilamide and sulfapyridine.

Treatment with sulfadiazine without other therapy resulted in a rapid cure.

MEDICAL PROGRESS

THE PLASMA PROTEINS: THEIR IMPORTANCE IN CLINICAL MEDICINE AND SURGERY*

CHARLES A. JANEWAY, MD†

BOSTON

DURING the past few years a great amount of effort has been devoted to studies of the plasma proteins in health and disease. With the development of satisfactory methods for the preservation of plasma, which has been of great importance in military medicine and which has made plasma widely available to practitioners, the need for an understanding of the functions of the different constituents of plasma is obvious. This report is intended to supplement Loeb's¹ excellent and comprehensive review on the plasma proteins, with a more detailed discussion of their functions and a consideration of methods for the treatment of various types of protein deficiency.

METHODS OF STUDY

Progress in the field of blood proteins, as in most other fields of medical research, is dependent on the chemist. Blood plasma is a complex fluid consisting of a mixture of crystalloid substances and protein in water. The proteins of the plasma comprise a large group of molecular species that differ over a wide range in chemical characteristics and physiological functions. The primary aim in the chemical study of these substances is to separate them into fractions of sufficient purity so that they may be accurately characterized chemically. This aim is now beginning to be realized² on a sufficiently large scale to make it possible to use these fractions extensively in the treatment and study of disease.

In making the different plasma proteins available in a highly purified state, the chemist is providing the clinician and the physiologist with a fundamental tool essential to the satisfactory study of their functions. The importance of having a plasma protein relatively pure is obvious from the standpoint of the therapy of a deficiency of that protein, but its importance for the controlled investigation of its functional significance cannot be overemphasized.

As Loeb pointed out, recent advances in the chemistry of the plasma proteins have been aided by the development of new analytical tools, although methods for the preparation of pure protein fractions in some cases antedated their use. The first of these, the ultracentrifuge, makes it possible to analyze proteins by means of their rate of sedimentation in a centrifuge rotating at a tremendously high rate of speed. The rate of sedimentation depends on the size and shape of the molecule. The second tool, the electrophoresis apparatus, enables the chemist to separate and analyze a mixture of proteins on the basis of their rates of migration in an electric field. This in turn depends on the size, shape and particularly the net charges of the respective molecules. Since the net charge depends on the hydrogen ion concentration of the buffer solution in which the protein is dissolved, it is essential always to know the pH, and particularly the type of buffer used in any analysis.

Tiselius, whose name is borne by the modern electrophoresis apparatus that he developed, divided the plasma globulins into three components—alpha, beta and gamma. Albumin migrates most rapidly, alpha globulin next, then beta globulin and fibrinogen and finally gamma globulin, which exhibits the slowest rate of migration in the electric field. In each of these electrophoretic components of plasma, as in the fractions prepared by salting out with different concentrations of neutral salts, there is not one protein, but a number of different proteins that happen to exhibit a common type of behavior under the particular conditions of the analysis, but that may be further separated under different conditions. The value of both ultracentrifugal and electrophoretic analysis depends to a large extent on the ease and accuracy with which the results can be read, which in turn are due to the fact that a complicated optical system devised for each makes it possible to record the results graphically.

These two tools, which analyze proteins on the basis of quite different attributes of the molecule, have been very useful as guides and checks on the more conventional and important methods of

*The articles in the medical progress series of 1941 have been published in book form (*Medical Progress Annals*, Volume III, 678 pp., Springfield, Ill., no. 4, Charles C. Thomas, 1941, \$5.00).

†From the Department of Pediatrics, Harvard Medical School, the Department of Communicable Diseases, Harvard School of Public Health, and the Children's and Infants' hospitals.

‡Assistant professor of pediatrics, Harvard Medical School and School of Public Health, and one physician, Children's and Infants' hospitals.

gm. of a normal mixture of plasma proteins. It has likewise been demonstrated that the quantitative response to the injection of concentrated albumin solutions is what might be expected from these accurate in vitro measurements.²⁹

Although albumin seems to behave in the human circulation as might be expected on the basis of its physicochemical properties, it should not be regarded as an inert substance trapped in the circulation like gum acacia. Rather, it is in a constant state of dynamic equilibrium with the tissue proteins. For example, shortly after the injection of acacia the concentration of serum albumin falls markedly, presumably to compensate for the increase in oncotic pressure produced by the acacia, which cannot be so readily removed from the circulation.³⁰ Furthermore, albumin, and to a lesser extent some of the other serum proteins, are not held completely within the blood vessels, but apparently do pass in small amounts across the capillary walls, as the extensive researches of Drinker³¹ and Landis³² have shown, and even perhaps across the glomerular capillaries, as the work of Dock suggests.³³ Plasma proteins that pass across the capillary wall into the tissue fluid, as well as other proteins derived from the tissues themselves, probably do not pass back directly into the capillaries but are returned to the circulation by the lymphatic system.³¹

Whereas serum albumin plays an important role in the regulation of blood volume, it is not the only factor concerned. If it were, the nephrotic patient would have virtually no circulating plasma, because of the extremely low levels of serum albumin in nephrotic plasma and its low oncotic pressure. Pressure within the tissues themselves, — which rises with the accumulation of edema fluid,³⁴ — the intake of salt and fluids,³⁵ the permeability of the capillary wall, and arterial and venous pressures, all play a role in the regulation of amounts of fluid held within and without the main circulation.

There is nothing to add to the discussion by Loeb¹ on the source of plasma albumin in the body. Considerable evidence implicates the liver and particularly the hepatic parenchymal cells as the main site of albumin manufacture, but it cannot be said that albumin is manufactured *only* by the liver.

Plasma Globulins

Although plasma albumin constitutes a relatively homogeneous group of closely related proteins, the plasma globulins are multiple and complex. As a group, they differ from albumin in their greater molecular asymmetry, lower net charge and, in most cases, larger molecular size.³⁶ The stability of most globulins is less than that of the albumins,

but this is not universally true. In fact, one cannot generalize about the globulins, which are a large group of complex and very different proteins.

Whereas serum albumin is developed early in life, the pattern of serum globulins increases in complexity with growth and development and as a result of the contact of the organism with its environment. Thus, Rapoport and his co-workers³⁷ have recently reported on the plasma protein fractions in the neonatal period and infancy. They have shown that whereas both albumin and globulin concentrations of the plasma are somewhat lower shortly after birth and increase slowly throughout infancy, the increase in the globulin fraction is proportionately greater. How much of this is due to the normal processes of maturation and how much to the response to various antigenic stimuli is not yet clear. This relative hypoproteinemia of early infancy is of interest in relation to the ease with which edema develops in newborn infants shortly after delivery. The following discussion will be confined largely to the importance of the globulins from the functional point of view, which is of interest to the clinician, rather than to their chemical characteristics, which in many cases are still to be defined accurately.

Reactions of immunity. That antibodies are globulins is supported by abundant data derived from the study of both human and animal serums.³⁸ Much of the antibody globulin found in the plasma of the newborn infant is derived from its mother.³⁹ This may be acquired in two ways: by passage across the placenta from the maternal circulation, and by transfer in the colostrum. The latter route seems to be the sole method of transfer of antibodies in certain herbivorous animals such as the cow,^{40, 41} in which the structure of the placenta is such that there is a far less intimate relation between maternal and fetal circulations than exists in the human placenta, with its very thin layer of syncytium and cells separating the two circulations. The placental route of transfer in human beings is almost certainly the more important of the two. Recent studies of the etiology of erythroblastosis fetalis indicate that the passage between the two circulations can be a two-way one, since the mother is immunized by cells derived from the fetus, and her antibodies then return to the fetal circulation, where they produce the destruction of fetal cells and the severe form of hemolytic anemia associated with erythroblastosis fetalis.⁴²

The duration of this inherited placental immunity seems to vary in proportion to the concentration of antibody inherited. Most of this inherited antibody is lost at the end of six months, but during the first six months of life most infants

are protected from scarlet fever, diphtheria, poliomyelitis and measles, provided their mothers possess antibodies to these diseases.^{3,4} On the other hand, infants possess little or no immunity against other diseases, such as pertussis, for which adults do not possess circulating antibodies in an appreciable concentration. It is in the age period from a few months to two years that the mortality of most infectious diseases is highest; that is, during the time between the loss of inherited immunity and the acquisition of active immunity as a result of outside stimuli. The antibody globulin pattern of the adult is gradually built up as a result of the repeated antigenic stimulation of frank infections latent or unrecognized infections and artificial immunization. Before the age of six months, infants, like young rabbits, do not respond well to antigenic stimuli,³⁰ and it is for this reason that active immunization against pertussis, diphtheria and smallpox is usually deferred until the age of six months is reached.

Few specific antibody globulins have been characterized chemically, with the exception of those found in the serums of highly immunized animals, which have been found to be gamma globulins; that is, globulins that migrate slowly in the electric field. Methods for the detection of antibodies have been entirely nonchemical in the past but with the development of quantitative immunologic techniques, the chemist has gradually begun to invade the province of the immunologist.

Although antibodies are extremely useful in the diagnosis of many infectious diseases, and their presence in the serum usually indicates a state of resistance, their primary importance in bringing about the cure of specific infections is in many cases open to question. In general, passive immunization by the administration of sufficient preformed antibody is more universally effective in prevention than in the treatment of infectious disease. Thus, tetanus antitoxin can prevent tetanus when given in sufficient quantities, but its therapeutic effect is dubious. On the other hand, both diphtheria and scarlatinal antitoxins are unquestionably therapeutically effective when administered early in the disease, and the antibacterial serums developed against the pneumococcus⁴³ and the influenza bacillus⁴⁴ have proved their worth in the clinic. In such a disease as typhoid fever, and in most virus diseases, the administration of antibodies is ineffective as a form of treatment, possibly because the etiologic agent multiplies within the body cells,^{45, 46} where it is protected from the action of the antibodies.

Most evidence indicates that the antibody globulins, or at least those globulins produced in response to antigens that gain access to the body from out-

side,* arise in the reticuloendothelial cells. Evidence for this view is not overwhelming but is extremely suggestive.⁴⁷

Besides the antibodies, there are other globulin components of normal plasma that play a role in immune reactions. These are the fractions of complement or *alexin*, which are of protein nature. Complement has been divided into four components. Two protein components, the so-called "midpiece" and "endpiece," have been separated from guinea-pig serum by Pillemer, Ecker, Oncley and Cohn,⁴⁸ and from human serum by Ecker, Pillemer and their associates,⁴⁹ and have been shown to have mobilities that place them with the alpha and beta globulins. Further studies along these lines should help to elucidate this exceedingly complex field of immunology. There is little evidence on the source of complement, but it is known that this substance is regenerated very rapidly after depletion.⁵⁰ Although there can be no doubt of the importance of complement to in vitro immunologic tests, notably the complement-fixation reaction, there is far less evidence that complement plays any vital role in the resistance of the body to infection. Ham and Dingle⁵¹ have shown that complement is apparently responsible for the hemolysis of a patient's own blood that occurs in paroxysmal nocturnal hemoglobinuria, in which it acts in conjunction with an unidentified hemolysin. Complement action is also known to be essential to the Donath-Landsteiner reaction, and in all probability actually produces the hemolysis of the syphilitic type of paroxysmal hemoglobinuria, after the cells have been sensitized by the cold hemolysin. In both these instances, complement plays an adverse role in the body economy. In vitro it is known to enhance the speed of phagocytosis,⁵² and it is essential to the destruction of gram-negative organisms by the bacteriolysins of the serum, as shown by Spink and Keefer⁵³ for the gonococcus, and by Fothergill and his co-workers⁵⁴ for *Haemophilus influenzae*.⁵⁴ In vitro bactericidal tests carried out in our own laboratory with the beta-hemolytic streptococcus indicate that complement is essential to the bactericidal action of whole blood,⁵⁵ as had been demonstrated in the case of the pneumococcus by Robertson and his associates.⁵⁶ In the case of both these gram-positive cocci, phagocytosis precedes the bactericidal effect. Its importance in vivo has not, however, been clearly shown, but is suggested by some work of Rutstein and his co-workers,⁵⁷ who found that in certain cases of pneumococcal pneu-

*The isohemagglutins probably develop as a result of the maturation process and not in consequence of antigenic stimulation. Study of the chemical nature of these essentially normal antibodies which are readily identified by their activity in agglutinating the red cells of persons of other blood groups should be of great interest.

monia there seemed to be a partial deficiency of complement. That complement titers might fall during acute disease states in which an antigen-antibody reaction is probably taking place is suggested by the finding of low values in serum disease.^{57, 58}

CASE 29451

PRESENTATION OF CASE

A forty-nine-year-old mechanic entered the hospital because of substernal pain of one day's duration.

The patient had been in apparent good health until five years before admission, at which time, during the course of a physical examination, an aortic diastolic murmur was discovered. No history of a chancre could be obtained but the suspicion of syphilis was substantiated, however, by a positive serologic test. He was treated regularly for two years, medication consisting of intramuscular injections as well as about six intravenous injections. No other treatment was given until the month before entry when he received five intramuscular injections. Eighteen months before entry he noted moderate fatigue but continued working at his heavy job. One day, about three months before admission, he developed severe crushing substernal pain early in the morning, while sitting and waiting to go to work. Bromoseltzer gave some relief. He worked till the noon hour of that day. The pain recurred while eating lunch. His pulse was said to have been fast. The pain subsided after passing gas by rectum several times after one hour. Five weeks before entry he had recurrence of the same pain while eating; this lasted one or two hours. He continued to work for four days without distress but awakened each night with severe pain and dyspnea. He had difficulty in sleeping for three or four nights because of orthopnea. From this time on he experienced some pain on exertion and eventually stopped working. The blood pressure was said to have been "204 systolic." The radial pulse was 84, but at the "base of the heart" the rate was found to be 160. He was given quinidine, and in about thirty-six hours the radial pulse rate and the heart rate at the base of the heart were said to have responded. An electrocardiogram taken two weeks before admission showed a rate of 90, left-axis deviation, depressed ST segments in Leads 1 and 2 and inverted T waves in Lead 1. Moderate num-

bers of ventricular premature beats were present, at times in pairs, and also occasional auricular premature beats. The day before entry he awoke after two hours of sleep to void. He did not return to bed, and while sitting, he developed the same substernal pain, which was so severe as to necessitate a hypodermic injection by his physician. The day of admission he experienced substernal discomfort on the way to the hospital. He was said to have had no digitalis for one week, and before then one small tablet a day, after taking one three times a day for two weeks.

He had had gonorrhea twenty-six years before admission.

Physical examination showed an obese, apparently healthy man. The pupils were equal and reacted to light. An arterial pulse was visible in the neck. The heart was enlarged to the left, the apex being 13 cm. from the midsternal line in the fifth interspace. The sounds were of fair quality and regular. There was a blowing aortic diastolic murmur and a Grade 2 aortic systolic murmur. The pulse was Corrigan in type. The lungs were clear. The abdominal examination was negative. The deep tendon reflexes were active.

The blood pressure was 180 systolic, 55 diastolic. The temperature was 98.6°F., the pulse 96, and the respirations 25.

Fluoroscopic examination revealed a large transverse heart with a base measuring 9.5 cm. The heart width measured 15.7 cm., as compared with 23.5 cm. for the inner diameter of the chest. In the left anterior oblique view there was a curve in the midthird of the cardiac silhouette that extended out 3 or 4 cm.

The patient was given nitroglycerin on admission, and this was repeated two and four hours later, giving a total of three doses. There was some relief from pain, but morphine was also given because of the severity of the pain. The patient was apprehensive and tense and ate sparingly; he was, however, able to sleep. He received two 0.2-gm. doses of digitalis. Fifteen hours after admission, at about 5:00 a.m., he signaled for the nurse, who found him with his head back, gasping, unconscious and pulseless. He died twenty minutes later.

DIFFERENTIAL DIAGNOSIS

DR. PAUL D. WHITE: We can assume that this patient had aortic regurgitation. At the age of forty-five, aortic regurgitation means either rheumatic heart disease, which is more probable in this part of the world, or aortic syphilis, which is less common here than in many other places. It rarely means anything else, but we did see a patient at medical grand rounds this morning with aortic regurgitation due apparently to hyper-

*On leave of absence

sion—that might be called functional regurgitation, without aortic-valve disease. In the record of this case there is no statement of early dyspnea, nor did the patient complain of paroxysmal tachycardia. Of course, paroxysmal tachycardia due to coronary or myocardial insufficiency may precipitate symptoms not previously present. We cannot be sure of what happened at first in this patient.

When pain did begin its duration was intermediate between what we usually find with angina pectoris on effort (or decubitus) and what we usually find with myocardial infarction.

It is distinctly unusual, although possible, for pain due to coronary insufficiency to occur first at rest and only later on effort. Almost invariably it is the other way around, some weeks, months or years elapsing before the pain finally occurs at rest. Here we have the reverse. I expect that the description of the pain would have been the same throughout. I assume that it was substernal oppressive pain. It is said that the radial pulse rate was 84, but that at the base of the heart the rate was 160. I do not know what was meant by that. There is no further description. Was the heart rate regular? It is important to determine whether the patient had paroxysmal fibrillation, which can give a heart rate of 160 and a radial rate of 84—a very large pulse deficit. Although unusual in this kind of patient, it is possible. It is unlikely that a coupled rhythm would have caused every other beat to have been premature, thus failing to reach the wrist; a bigeminal rhythm is rare with a rate as fast as 160. I do not believe that we can be quite sure what did happen, but the best bet is tachycardia with auricular fibrillation; with tachycardia of other sorts a pulse deficit of this degree usually does not occur.

Quinidine usually is given for arrhythmia, sometimes for tachycardia. Perhaps it was given for both in this patient. Whether the rhythm became normal as a result of quinidine or spontaneously we cannot be sure. There was some arrhythmia later, with auricular premature beats; hence the patient might readily have previously had an auricular tachycardia. Otherwise the electrocardiogram is simply characteristic of a big left ventricle from any cause. Such a big left ventricle is due most commonly either to hypertension or to aortic-valve disease. We know that the patient had aortic regurgitation, and so that fits best—namely, a big heart with aortic regurgitation. Coronary heart disease is one other possibility, but we do not as a rule find left-axis deviation with uncomplicated coronary heart disease. He may have had a combination of heart diseases. He had a systolic blood pressure of 204. There is no clear indication, however, from this electrocardiographic record of any fresh myocardial infarct. That point is rather im-

portant because from the history it is possible that he might have had several myocardial infarcts. Depressed ST segments do not have the same significance from the standpoint of acute myocardial damage as elevated segments, which in Leads 1 and 2 or in Leads 2 and 3 present reasonable evidence of acute myocardial infarction. We find *no* note of precordial leads, which would have been helpful in such a problem.

DR. BENJAMIN CASTLEMAN: They were not taken.

DR. WHITE: There is a possibility of some digitalis effect in the electrocardiogram, although the patient had not had a great deal of digitalis.

This man's height and weight are not given, but obviously the apex impulse was a long distance out. We can assume from physical examination that he had a very large heart.

I should have liked to have a grading of the diastolic murmur, as well as of the systolic. Perhaps it was Grade 3 or 4, somewhat louder relatively than the systolic murmur and a little more in keeping with aortic regurgitation and dilatation of the aorta than with rheumatic, syphilitic or calcareous aortic stenosis. The findings would have been reversed with a loud (Grade 4) aortic systolic murmur, and perhaps a Grade 2 diastolic murmur, if the case were one of rheumatic aortic stenosis. The Corrigan pulse is further evidence of free aortic regurgitation.

The deep tendon reflexes were active. It does not look as if the patient had any obvious evidence of syphilis of the central nervous system to go with the aortic syphilis; both are often present in the same patient.

We have not two readings of the diastolic pressure, which is sometimes recommended in cases of aortic regurgitation. There may be quite a difference between the sound changes in trying to determine the diastolic level. It is often wise, especially in aortic regurgitation, to record two readings. If the sound changes and disappears at about the same time one reading is enough. Not infrequently one will get a diastolic reading of 40 as the sound changes, and zero when it disappears. No one knows which is correct, so far as I am aware. Here we have the one reading of 55: quite likely there was a distinct change in note at that point.

"Fluoroscopic examination revealed a huge transverse heart, with a base measuring 9.5 cm." The base should be much wider to be called wide, if it is the width of the heart in the anteroposterior view that is meant, but if this refers to the cardiac pedicle—that is, the shadow of the great vessels,—9.5 cm. is distinctly wider than normal. The width across the great vessels is normally 6 or 7 cm.

"The heart width measured 15.7 cm., as compared with 23.5 cm. for the inner diameter of the

chest." With reference to the transverse diameter of the heart, the normal in a patient of this size is about 12.5 cm., so that there was at least 3 cm. of enlargement by x-ray.

Now we come to one of the oddities of the case. Everything has gone along easily up to this point "In the left anterior oblique view there was a curve in the midthird of the cardiac silhouette that extended out 3 or 4 cm." That is evidently something unusual. There is no statement about the anteroposterior view.

DR. CASTLEMAN: No films were taken.

DR. WHITE: Then this must have been a fluoroscopic observation; but there is no statement whether the bulge was in front or in back, whether it pulsated or what its action was.

DR. CASTLEMAN: There is no further statement.

DR. WHITE: The point is rather important. I think that fluoroscopy by ourselves might have been helpful in our present dilemma.

This was not an abrupt death—that is, one due to acute coronary insufficiency, such as we find with ordinary angina pectoris and sometimes even with coronary thrombosis. A tamponade or a coronary occlusion could explain it.

Regarding the diagnosis, the presence of both coronary and myocardial insufficiency with pain and dyspnea in a man in the forties with a history of venereal disease, a positive serologic reaction, fairly free aortic regurgitation, a big left ventricle and aorta and early death, indicates almost certainly the presence of syphilitic aortitis with aortic regurgitation, left ventricular weakness and partial occlusion of the coronary ostia. As a matter of fact this history is almost too perfect for syphilitic aortitis with involvement both of the valve and of the coronary ostia. In such cases it is common to have both dyspnea and pain, and the pain is likely to be just as atypical as this—that is, atypical for coronary heart disease, either angina pectoris or myocardial infarction, the pain coming as it did for an hour at a time and not leaving any distinct trace on the electrocardiogram. The only real oddity is the unusual heart shadow by x-ray. It is not quite described as a bulge, but I suppose it would be if it measured 3 to 4 cm. in depth. It is important to remember that the aorta starts in the middle of the heart shadow. The beginning of the aorta cannot be seen in any view by x-ray. The first 2 or 3 cm. are buried in the heart shadow, almost in the center of the heart. Thus some lesion related to the base of the aorta would be the best bet for this unusual shadow. What could it be? An aneurysm at the root of the aorta is, I suppose, the best explanation of that shadow—an aneurysm possibly involving a sinus of Valsalva and extending out in one direction or another or even located just above the sinuses of Valsalva.

An aneurysm sometimes presents itself some distance from the site of origin. A myocardial aneurysm of the left ventricle is lower than this bulge in position and so is unlikely here.

DR. CASTLEMAN: Dr. Currens is here and can answer your questions about the fluoroscopy.

DR. WHITE: How would you describe the bulge, Dr. Currens? Did it pulsate?

DR. JAMES CURRENS: It did not seem to pulsate any more than the rest of the aorta. If there was any pulsation it was transmitted. It was fairly round in contour, that is, it was regular in contour and did not extend out necessarily as a definite discrete mass.

DR. WHITE: Did it seem to be a part of the heart shadow? Could you distinguish it from the rest of the heart shadow except as it came out beyond it?

DR. CURRENS: No.

DR. WHITE: Was it anterior or posterior?

DR. CURRENS: Anterior. It seemed to be above the heart. It was in the region of the aorta rather than that of the heart.

DR. WHITE: It says here that it was in the middle third, but it was probably in the upper third too.

DR. CURRENS: Between the middle and upper thirds, I should say.

DR. WHITE: Could you see the bulge in the anteroposterior view?

DR. CURRENS: Yes; but not nearly so well as in the left anterior oblique view.

DR. WHITE: And the heart otherwise was large? There was no engorgement of the lung hilar shadows?

DR. CURRENS: Not particularly.

DR. WHITE: One other site for a syphilitic aneurysm in that region, which I have never encountered myself, but which is on record, is an aneurysm at the beginning of one of the coronary arteries. However, that is an extreme rarity. When the coronary arteries are involved, they are usually atherosclerotic. They may once in a while be invaded by a dissecting aneurysm of the aorta. There are two cases with involvement of the coronary artery itself without dissection of the aorta that we have tucked away to report sometime. In these cases there was rupture of the coronary artery and hemopericardium secondary to dissection of the wall of the artery. One of them was that of a patient with recent or fresh coronary thrombosis. A definite bulge of the heart shadow could not have been seen by x-ray in those cases.

The other question here concerns the matter of death. If this aneurysm was located in this region, how did the patient die? It is common for a patient with syphilitic aortitis to die by rupture of the aneurysm into either the pleural cavity or the pericardium. It would be quite consistent with

the story here for an aortic aneurysm near the mouth of the aorta to rupture into the pericardium with death in twenty minutes or so. That all seems too easy, however, except for the unusual position of the bulge, which might nevertheless have been an aneurysm.

I have put down other less probable possibilities, but I believe that we should take the diagnosis that I have just presented as the most likely, even though it may not be correct. Syphilitic aortitis plus coronary heart disease could have been the answer—that is, independent conditions, the coronary heart disease having resulted in death.

A hypertensive aorta with dissection into the sinuses of Valsalva, with or without aortitis, and a final rupture into the pericardium might have been the answer. Or even rheumatic heart disease or subacute bacterial endocarditis could explain the aortic regurgitation, with syphilis of the aorta on the side. Neoplasm of the heart is another odd condition that could have been present, or a congenital aneurysm of a sinus of Valsalva. A congenital defect superimposed on a bicuspid aortic valve has been described by Maude Abbott,¹ in which there may be a large sac extending out from the base of the aorta and involving a sinus of Valsalva with dissection of the wall and rupture into the pericardium. If that were present here, and were not due to syphilis, it would be in addition to the syphilitic aortitis.

I think that, despite all these other possibilities, we are probably justified, with what we have here, in diagnosing simply aortic syphilis with aortic regurgitation, marked cardiac enlargement, coronary insufficiency secondary to the syphilitic involvement of the aorta involving the ostia of the coronaries, and an aneurysm at the mouth of the aorta, perhaps involving a sinus of Valsalva, with rupture into the pericardium. Sudden death is possible in syphilitic cases without rupture of an aneurysm, but such a death would be more sudden than is stated here.

CLINICAL DIAGNOSES

Syphilis, cardiovascular, with aortic regurgitation and aneurysm of the ascending aorta.
Congestive heart failure.

DR. WHITE'S DIAGNOSES

Syphilitic aneurysm of aorta, with rupture into the pericardium.
Hemopericardium, with cardiac tamponade.
Syphilitic aortitis, with aortic regurgitation and with involvement of coronary ostia.
Coronary insufficiency.
Cardiac hypertrophy.

ANATOMICAL DIAGNOSES

Dissecting aneurysm of ascending aorta, with rupture into the pericardium.
Hemopericardium, with cardiac tamponade.
Syphilitic aortitis, with aortic insufficiency.
Cardiac hypertrophy, hypertensive.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: At autopsy this man had a tremendous pericardial sac that was filled with about 500 cc. of blood producing obvious cardiac tamponade, which was the immediate cause of death. Within the pericardium we found a large aortic aneurysmal sac that contained a fair amount of blood clot, both old and new. This corresponded to the bulge observed fluoroscopically. When the aorta was opened there was obvious evidence of syphilitic aortitis throughout its entire length, with all the classic findings—stellate scarring, linear tree-barking and so forth. About 2 or 3 cm. above the aortic valve was a horizontal rent in the intima communicating with the aneurysmal sac, which was within the media of the aorta. This sac extended distally for 6 or 7 cm. to the opening of the innominate artery and down to the base of the heart, but did not reach the level of the coronary mouths. This sac was therefore a dissecting aneurysm of the aorta that had dissected for a relatively short distance.

I believe that three months before entry he had the initial intimal tear, and because of the syphilitic scarring in the media the progress of the dissection was slow and stopped at the arch, in contrast to the usual rapid dissection through the arch and down into the abdominal aorta. The pressure in the aneurysm increased, since blood was getting in but could not get out, and eventually produced external rupture and death.

DR. WHITE: How far down did the syphilitic process extend?

DR. CASTLEMAN: It extended down to the aortic valve, but the coronary mouths were not involved. The aortitis had produced slight but definite separation of the cusps at their commissures, which accounts for the regurgitation. There was little coronary sclerosis.

DR. WHITE: How much did the heart weigh?

DR. CASTLEMAN: The heart was huge, weighing about 900 gm., and was hypertensive in type.

DR. WHITE: The patient had had quite a number of attacks of pain. Do you think he tore his aorta every time?

DR. CASTLEMAN: No; I think that the distention of the aneurysm as it enlarged was enough to produce pain.

DR. WHITE It is possible to have angina pectoris when an enlarged heart has a wall so thick that it is not receiving enough blood through the coronary circulation, even though everything is open. Thus angina pectoris may occur without coronary heart disease, due to relative coronary insufficiency. That could be a plausible explanation of much of the pain here. The patient did have hypertension, of course, which helps a little toward the diagnosis of dissecting aneurysm. Do you remember, Dr. Castleman, that in the series of dissecting aneurysms that Glendy, you and I reported the history was generally different from that of this case with respect to pain—usually there was one extremely severe attack of pain at the time of the first rupture and then a few hours, days or weeks later there occurred another attack of pain with death, without these recurrent pains. This case is unusual.

DR. CASTLEMAN: Yes; I think the aneurysm was being gradually built up.

DR. WHITE But then so were the others.

DR. CASTLEMAN: They were much longer in aneurysms, extending all the way down the aorta and without the increased tension that you have here in the localized dissection.

DR. CURRENS: In light of the anatomic findings this case is of considerable interest to me. The late Dr. Soma Weiss in discussing dissection of the aorta cited dissecting aneurysms that dissect up to a region of syphilitic aortitis and then stop. He had one or two cases of this nature, and it was his impression that syphilis actually predisposed against dissecting aneurysm. The case under discussion is an exception to this thesis.

DR. WHITE: I am impressed by the occurrence of dissection of the aortic wall in just that part of the thoracic aorta—the ascending portion—in which the syphilitic process is the most active. This is in contrast to a few nonsyphilitic cases that I have seen in which the dissection of the aortic wall did stop at the arch because of the marked calcification of the entire descending aorta, whose wall was too hard to dissect. In this case the aortitis may have favored the dissection.

DR. CASTLEMAN: I can recall one case of dissecting aortic aneurysm in which the dissection was apparently stopped by syphilitic scarring in the media.³

CASE 29452

PRESENTATION OF CASE

A nine-year-old schoolgirl entered the hospital because of a "stuffed-up nose," coryza, fever and joint pains of six days' duration.

The patient had been in good health until about two weeks before entry, when she developed a cold that "never came to a head." There was no fever or loss of appetite. She felt well. Two days prior to entry she complained of being very cold. Her feet hurt when she walked. Her temperature was 103°F. A systolic murmur was heard for the first time by the family physician. The white-cell count was 18,500, with 77 per cent neutrophils. Urinalysis was negative. The family physician placed her on sulfadiazine, of which she received 160 gr (nearly 11 gm) up until the time of admission. The fever, however, persisted. Her appetite became poor but there was no vomiting or diarrhea. There was pain in the right foot and elbow, the neck and the shoulders, but no definite swelling or redness was seen. Motion in the legs and arms was limited. The day before entry she had several slight nosebleeds, and a moderately severe one on the day of admission. The pain shifted to the left elbow and midarm. On the day of admission she coughed up mucus and blood clots, which appeared to come from the pharynx.

Her tonsils and adenoids had been removed a year prior to admission. She had had measles, scarlet fever, chicken pox, German measles and whooping cough earlier in life. At seven years of age she had had "hives" twice, possibly caused by oatmeal.

Physical examination showed a well-developed and well-nourished child in no distress. Both eardrums were dull and slightly injected. Some blood-stained crusts were seen in the nostrils but no sinus tenderness could be elicited. The posterior cervical lymph nodes were slightly enlarged. The heart was of normal size. The sounds were of good quality and regular; there were no thrills. A blowing systolic murmur was heard at the apex and a short systolic blow at the pulmonic area. The pulmonic second sound was greater than the aortic. There was difficulty extending the left arm completely; the pain could be localized at the elbow and in the midarm.

The blood pressure was 110 systolic, 72 diastolic. The temperature was 104.2°F, the pulse 110 and the respirations 30.

The blood showed a hemoglobin of 14.5 gm and a white-cell count of 15,000, with 85 per cent neutrophils. The urine showed a + test for albumin but otherwise negative.

X-ray examination of the chest revealed slight increased density of the right lung, suggesting

Public Health Service and Procurement and Assignment Service.

It is my hope that this personal letter will serve to convince the doctors marked available that there is a real need for them to seek a commission in either the Army, the Navy, the Coast Guard or the Public Health Service.

FRANK H. LAHEY, M.D.
Chairman of the Directing Board

War Manpower Commission
Procurement and Assignment Service
Washington, D. C.

War Manpower Commission

PROCUREMENT AND ASSIGNMENT SERVICE FOR
PHYSICIANS, DENTISTS, AND VETERINARIANS

Dear Doctor ———:

I am writing you a personal letter — personal because I do not want it to be taken as a form letter from the Procurement and Assignment Service. I want it to be personal in order that I may convince you that the Army, the Navy, the Coast Guard and the Public Health Service need more doctors. The Navy in terms of its requirements is farther away from what it needs than any other branch of the armed services but we need also to supply more doctors to the Army, the Coast Guard and the Public Health Service. Every doctor who has been marked available should either seek a commission or appeal his classification.

You, as a physician of forty-five or under who has been marked available, will shortly receive a notice asking you to appear for a conference with a group made up of representatives of the Army, Navy, Public Health Service and Procurement and Assignment Service. This group will be able and willing to discuss with you any questions that may be in your mind concerning entering the service and applying for a commission.

I wish to give you my personal word that the Directing Board for the Procurement and Assignment Service assures you, one, that those doctors marked available who can pass the physical examination are needed, and two, that they can be spared where marked available without interfering with civilian care.

In the interests of the national need, will you not at least appear before this board as a man marked available to discuss the problem as it relates to you?

I am certain that you know that I would not write this personal letter unless the need was real and my conviction of its justice established.

Sincerely yours,

(Signed) Frank H. Lahey

FRANK H. LAHEY, M.D.
Chairman of the Directing Board

NOTICES

GREATER BOSTON MEDICAL SOCIETY

A dinner meeting of the Greater Boston Medical Society will be held at the University Club on Wednesday, November 17, at 7 p.m. Mr. William Gailmor, news commentator, Station WHN in New York City, and lecturer and propaganda analyst, will speak on the subject, "Russia's Role in a Postwar World." As an added feature, Lieutenant Commander David B. Stearns, U.S.N.R., will give a short talk entitled, "A Urologist at a Naval Air Station."

SOUTH END MEDICAL CLUB

The next regular meeting of the South End Medical Club will be held at the headquarters of the Boston Tuberculosis Association, 554 Columbus Avenue, Boston, on Tuesday, November 16, at twelve noon. Dr. Henry C. Marble will speak on the subject, "The Care of the Wound."

Physicians are cordially invited to attend.

NEW ENGLAND SOCIETY OF PHYSICAL MEDICINE

The regular meeting of the New England Society of Physical Medicine will be held at the Hotel Kenmore on Wednesday, November 17, at 8 p.m. Dr. William D. McFee will act as chairman.

PROGRAM

Fundamentals in Teaching Galvanic Technic Dr. Harry E. Stewart, president, Junior College of Physical Therapy, New Haven, Connecticut, and chairman, Section of Physical Therapy, Connecticut State Medical Society.

Ionization. Dr. Wilmot L. Marden.

A council meeting will be held at 6 p.m., and dinner in the Empire Room at 6:30 p.m.

NEW ENGLAND HEART ASSOCIATION

The next meeting of the New England Heart Association will be held in the Boston Medical Library on Monday, November 29, at 8:15 p.m.

PROGRAM

Observations on Re-examination of Men Rejected for Military Service for Cardiovascular Reasons. Dr. Paul D. White. Discussion by Drs. Burton L. Hamilton, Henry Jackson, Jr., and Samuel A. Levine.

Report of a Patient with Eisenmenger's Syndrome. Drs. C. Sidney Burwell and Eugene C. Eppinger. Circulation and Respiration During an Episode of Chill and Fever in Man. Drs. Mark D. Altschule, A. Stone Freedberg and Haim Haimovici.

Notes on the Transmission of Cardiac Murmurs Dr. Samuel A. Levine.

Interested physicians and medical students are cordially invited to attend.

NEW ENGLAND OTO-LARYNGOLOGICAL SOCIETY

The regular fall meeting of the New England Oto-Laryngological Society will be held at the Massachusetts Eye and Ear Infirmary, 243 Charles Street, Boston, on Wednesday, November 17.

PROGRAM

10 a.m.—12 m. Sound Motion Pictures (Mosher Laboratory).

2 p.m. Clinical meeting. Presentation of cases from the Massachusetts Eye and Ear Infirmary.

3 p.m.

Business meeting.

Two Instruments of Value in Tonsillectomy. Dr. Henry H. Amsden, Concord, New Hampshire.

The Significance of Eosinophilia in Rhinology. Dr. Daniel Miller.

Number 21

THE MEDICAL PROFESSION'S RESPONSIBILITY IN THE PREVENTION OF BLINDNESS*

HUGO B. C. RIEMER, M.D.†

BOSTON

ONE of the main objects of this paper is to describe what is being done by the state and federal governments for those suffering from defective eyesight. The family physician is the backbone of the medical profession. His guidance and co-operation are essential in any program of care and prevention of disease. That he should be interested in the prevention of blindness might seem to be outside his professional interest. But is the eye not a part of the human body? And certainly his interest is in the human body.

Interest in the welfare of those handicapped by reason of reduced vision has been greatly stimulated by the advent of the Social Security Act. This law was passed in 1935. It makes provision for the indigent blind by paying to the participating state half of all payments up to forty dollars a month; that is, if the state grants a person forty dollars a month, the federal government reimburses twenty dollars. The state, by accepting the benefits of the provisions of this law, actually becomes a copartner of the federal government in effecting its operation. Since the federal government has assumed a part of the responsibility, it naturally follows that it will participate in carrying out the provisions of this law. The federal government has promulgated certain regulations to make the law more universally applicable to all the states, and to see that provision is made for equitable treatment and distribution of funds to all applicants for and recipients of financial assistance.

In order to facilitate its operation, the Social Security Board, soon after the act became operable, made certain definite recommendations relative to blindness. In the first place, it proposed a definition of economic blindness. Secondly, it required that certain medical data be determined and that they be kept by the state agency for each

applicant for assistance, and further, it suggested that the medical examination be made *only* by an eye physician who holds a certificate of the American Board of Ophthalmology; this enables the state to have an authentic record of each person applying for aid to the blind. It developed a record form covering certain medical data, to be filled out by the eye physician after his examination. Massachusetts used the suggested form until recently, when the Medical Advisory Committee and the director of the Division of the Blind composed a new form that includes all the requirements set up by the Board but is developed in a way that best meets the need in Massachusetts. This form requires an accurate description of each eye, and a statement concerning the primary cause of blindness. The etiologic cause of blindness is required, a factor that eventually will establish authentic data that can be used as the basis of a real prevention program. Finally, the Board suggested the appointment of a trained ophthalmologist to review all medical reports.

Many of the states have appointed specialists to head their medical activities as supervising ophthalmologists. It is the duty of the supervising ophthalmologist to review the medical report of each applicant for blind relief. If the report is incomplete or unsatisfactory, a re-examination is required. When there is a doubt in the mind of the supervising ophthalmologist concerning the facts reported, he requests that the applicant appear before him for examination. In some states medical reports on all blind persons requesting any type of service from the state are required. In New York, medical forms on all blind persons who may become known to any public-welfare department are filed with the Commission for the Blind. These are catalogued so that with the aid of this file studies of any one cause of blindness can be initiated.

*Read at the annual meeting of the Massachusetts Medical Society, Boston, May 26, 1943.

†Consulting surgeon, Massachusetts Eye and Ear Infirmary, instructor in ophthalmology, Harvard Medical School.

It is now becoming possible to get reliable statistics about blindness. This has been made possible by the medical reports required by the Social Security Board. Even though such reports cover only the needy blind, a truer picture of the causes of blindness in this country will be secured. We may even hope in a few years to be getting adequate information concerning the incidence of blindness.

Statistical studies of the causes of blindness are of value only in proportion to the needs, faults and possible preventive and rehabilitative measures that they point out. There is no reason why blindness should not be a reportable condition—reportable to some official state agency as soon as it is established. There should exist in every state an official agency to which blindness in a person, young or old, rich or poor, is reported as it arises, thus giving a true picture of the incidence of blindness that is of more importance than the knowledge of the number of blind adults receiving assistance.

When the medical findings reveal that there is a reasonable chance of restoring sight, every endeavor should be made to persuade the applicant to have his sight restored.

One can say that the subject of blindness and its prevention has wide ramifications, the emphasis being placed in different states on the various phases of work. What is developed in the future will depend somewhat on how official and private agencies have been developed in the various states.

The Massachusetts Division of the Blind, concerned chiefly with the education and rehabilitation of the blind and with the care of the indigent blind, is now greatly concerned with the larger and more important program, the prevention of blindness. In this program, the responsibility rests not only on the ophthalmologist but on the entire medical profession. How well the medical profession performs and carries out the provision of the laws that aim primarily to prevent blindness will be one of the most important factors.

No one will argue that the use of prophylactic drops in newborn infants has not reduced blindness from ophthalmia neonatorum. Statistics have proved without a shadow of doubt that this is true. Within the past year not one case of a baby who was blinded because of this disease has been reported to the Division of the Blind. It becomes more important than ever to be vigilant in such cases, since it is a well-known fact that the incidence of venereal diseases increases in wartime. The law requires a Wassermann or Hinton test of pregnant women, making possible the treatment of syphilis when present in the early

stages of pregnancy not only as a benefit to the mother, but also to prevent the birth of syphilitic offspring who may later develop interstitial keratitis, one of the chief causes of blindness. The law requiring a Wassermann or Hinton test before marriage has the same aim—to prevent the birth of a syphilitic offspring who may later become blind.

When it is realized that communicable diseases and trauma are two of the most important causes of blindness, we will doubtless all agree that something can be done to reduce the number of blind in this category.

It is of interest to note that conservation-of-vision committees of state medical societies have been appointed in the following states: Alabama, Connecticut, Florida, Indiana, Kansas, Maine, Missouri, Nebraska, New Hampshire, New Jersey, Oklahoma, Oregon, Pennsylvania, South Carolina and West Virginia. Special committees under state medical societies, also concerned with conservation of vision, have been appointed in the following states: Delaware, Georgia, Iowa, Minnesota, New Hampshire, South Dakota, Tennessee and Wisconsin. Plans are also under way for the publication of an article in the *West Virginia State Medical Journal* that will discuss industrial accidents, glaucoma, ophthalmia neonatorum and trachoma.

Eleven hundred and seventy-six cases of blindness now receiving aid in Massachusetts have been coded in accordance with the standard classification developed by the Committee on Statistics of the Blind, and the results show that there is need of the following: more care in reporting the etiologic factors of blindness; the early detection of all cases of glaucoma; the detection of diabetes before the devastating effects of this disease become manifest; better care of traumatic cases; and authentic data on hereditary cases.

It has been shown by this statistical study that the causes of blindness correspond in percentages closely to those of other states that have made a similar study.

The first principal cause to be considered is infectious disease, such as diphtheria, gonorrhea, measles, meningitis, ophthalmia of the newborn, scarlet fever, smallpox, syphilis, trachoma, tuberculosis and typhoid fever. Three hundred and seventy-six cases (32 per cent) were found in this category. Of these, 128 (11 per cent) were due to syphilis, 51 (5 per cent) to ophthalmia of the newborn, and 150 (13 per cent) to infectious diseases not specified. This percentage can be greatly reduced, since the effectiveness of chemotherapy has been so well established. It requires greater

vigilance on the part of physicians, and when necessary the seeking of advice from a competent ophthalmologist. By following this plan it should be possible to cut this percentage in half.

Next in importance is trauma. From this cause there were 61 cases, or slightly over 5 per cent. It is true that there will always be some cases of blindness due to trauma, but the present rate is altogether too high. It should be recognized that a perforating injury of an eye may not only cause the injured eye to be blind, but may so affect the other eye from sympathetic disease that the victim becomes totally blind. It is the duty of the medical profession to educate the public in regard to this threatened danger, and to see that such cases receive the care of a competent ophthalmologist. A study by Kerby* of 4739 children who are in schools for the blind in the United States shows that 374 cases were due to trauma, and that in 4 out of 10 of the injured cases blindness followed from development of sympathetic disease in the uninjured eye.

Ninety-three (8 per cent) of the 1176 cases of blindness were due to general diseases. This includes diabetes and hypertensive disease, including the arteriosclerotic degenerative diseases. It may not be possible to accomplish very much with hypertension and degenerations resulting from arteriosclerosis; nevertheless, the early recognition of diabetes is most important. It happens altogether too frequently that diabetes is not suspected until the patient has visual complaints, and when he is examined by his eye physician it is discovered that the underlying cause is diabetes. Such a person should certainly have had proper treatment long before he or she reached this stage, blindness thus being prevented.

It was necessary to classify 463 cases (40 per cent) as having an undetermined cause. This seems a rather high figure, and a more careful investigation and study of the cases might have revealed the etiology of the disease.

In 348 cases (30 per cent) the etiology was classified as unknown. This group included cases of glaucoma, cataract and myopia. In cataract sight is of course often restored by removal of the cataract. Regarding myopia, there seem to be no means at present of checking the progress of this condition. The fact that heredity is a factor in myopia should be recognized. Glaucoma was the cause of blindness in 119 cases (10 per cent). This is usually a symptomless disease of middle life, and is one that the ophthalmologist always has in mind when examining anyone who seeks his advice. Often there is no warning whatsoever of the dis-

ease, since the central visual acuity is lost only in the latest stages. The family physician is the first to be consulted by many so afflicted, and they depend on him for advice. He should be sufficiently acquainted with this disease to give them competent advice. Only a trained ophthalmologist can recognize this disease in its early stages. If this is done, proper treatment and care can avoid blindness.

In 152 cases (13 per cent) the blindness was of prenatal or hereditary origin. It seems to be a reflection on the medical profession that so large a number are blind from these causes. Apparently the only way that this number can be reduced is by educating the public of the danger of transmitting these conditions to their offspring.

This year the director of the Division of the Blind, with the co-operation of the Medical Advisory Committee, has had the following laws enacted in Massachusetts. First is an act relative to recording the treatment of infants at birth. This law requires the physician or hospital medical officer to treat the eyes of an infant within two hours after birth with a prophylactic remedy furnished or approved by the Department of Public Health, and he must record on the birth certificate the use of such a prophylactic. Whoever violates this section is punishable by a fine of not more than one hundred dollars. Second is an act relative to reports of treatment of certain wounds. This act classifies wounds from a BB gun or other air rifle with the firearm or gunshot wounds that must be reported to the Commissioner of Public Safety or to the police authorities of the town concerned. Third is a law making it mandatory to report all cases where the vision is 20/200 or less in the better eye or where the peripheral field of vision has contracted to a radius of 10° or less, regardless of visual acuity.

Prevention of blindness should be the chief interest of all official agencies for the blind and of all other agencies concerned with the welfare and health of the population. This program for the prevention of blindness cannot succeed without the full co-operation of the entire medical profession. There are certain fundamentals on which such prevention work must rest. These are an adequate medical determination of blindness, the early recognition of the potentially blind person, the ability to care for those potentially blind, whether adults or children, in an adequate manner, proper prenatal care, and a proper liaison between official agencies for the blind and other agencies, such as the departments of public health and of public safety, industrial commissions, labor commissions and departments of education.

THE THERAPEUTIC VALUE OF TESTOSTERONE PROPIONATE IN ANGINA PECTORIS*

SAMUEL A. LEVINE, M.D.,† AND WILLIAM B. LIKOFF, M.D.‡

BOSTON

ALTHOUGH an acute attack of angina pectoris is readily controlled with nitroglycerin, the treatment available for the prevention of such attacks is unsatisfactory. It has been observed that an increase in arterialization of cutaneous blood results when certain organic diseases of the peripheral blood vessels are treated with the testicular hormone, testosterone propionate.¹ There is also some experimental evidence that androgens and estrogens bring about vasodilatation.² With the hope, therefore, of improving the cardiac blood supply by increasing the collateral circulation or the degree of vasodilatation of the coronary arteries, or both, testosterone propionate has recently been used in the treatment of angina pectoris. Published reports thus far have been uniformly favorable.³⁻⁷ The purpose of this paper is to record the results obtained with this form of therapy in an additional series of cases.

Nineteen patients, ranging in age from thirty-five to seventy years and presenting definite evidence of angina pectoris, were given tri-weekly injections of 25 mg. of testosterone propionate§ (Table 1). Eighteen were treated for four weeks, and 1 for seven weeks. Of the entire group, 16 were men. Nine patients had hypertension (a blood pressure of over 150/90 on repeated examinations). Three of these had a history of coronary thrombosis. Of 9 with normal blood pressures, 2 had had a previous infarction. The remaining case was that of a woman of thirty-nine with rheumatic aortic stenosis and insufficiency. The duration of angina pectoris ranged from one month to thirteen years, averaging six years. Each patient was accustomed to the use of nitroglycerin, and, with two exceptions, used a fairly constant number of pills a day. Reference to the daily nitroglycerin consumption offered some measure of the effectiveness of the therapy. The injections were generally given during the late fall and early winter months, so that observations were made during the time of the year when angina pectoris tends to become especially severe. This is important, for the interpretation of any therapeutic procedure carried out just before the advent of warm weather is

always open to question. In all but 2 cases, no other medication was given concurrently and no change was made in the daily routine once treatment was begun.

Evaluation of the results was based on the patient's estimation of the amount of physical activity he was able to perform without precipitating an attack of pain, and the number of nitroglycerin tablets necessary over a twenty-four-hour period. These observations were recorded at the beginning of, during and at the conclusion of the injections. They were again noted from one to fifteen months later. The degree of improvement was classified as marked, moderate and questionable. When the patient was able to reduce the number of nitroglycerin tablets by two thirds or more, the improvement was considered to be marked. This result was always accompanied by an increased tolerance for physical activity. Moderate improvement was considered to have occurred when there was some, but not marked, reduction in the use of nitroglycerin. Those who reported that they felt somewhat better but were unable to do with a smaller number of pills or to increase their tolerance for effort were looked on as questionably improved.

Marked improvement was noted in 5 of the 19 patients. Two, however, reverted to their former clinical state within six to eight weeks, and 1, after a period of fifteen months, obtained no relief when a second series of injections became necessary. Of the remaining 2 patients, one maintained the improvement for four months, the other for one month. It is apparent, therefore, that of the 5 patients who experienced definite relief only 2 continued to benefit after four months, and in 1 of these the result could not be duplicated when it became necessary to repeat the therapy.

Moderate improvement was observed in 1 case, but aminophyllin was given with the testosterone, and it is also likely that a coronary occlusion took place just prior to medication. Questionable results were obtained in 2 patients, but even that degree of improvement was maintained by only one of them during the subsequent months. Death occurred in the other patient who, although temporarily somewhat improved, was also receiving digitalis and a mercury diuretic.

In 11 patients no change whatever was seen at the conclusion of treatment or at any time there-

*From the Medical Clinic of the Peter Bent Brigham Hospital and the Department of Medicine, Harvard Medical School.

†Assistant professor of medicine Harvard Medical School, physician, Peter Bent Brigham Hospital.

‡Formerly, voluntary assistant in medicine, Peter Bent Brigham Hospital.

§The testosterone propionate used in this study was supplied by Ciba Pharmaceutical Products, Incorporated, Summit, New Jersey, under the trade name Perandren.

TABLE 1 Summary of Data

CASE	AGE	SEX	DURATION OF ANGINA	BEFORE THERAPY				ELECTROCARDIOGRAM
				LIMIT OF PHYSICAL ACTIVITY	METROGLYCERIN PILLS REQUIRED DAILY	BLOOD PRESSURE		
	yr		yr					
1	58	M	3	Pain after walking 100 feet on level ground no pain at rest	6-8	180/86	Normal	
2	52	M	1/10	Pain after walking city block also after shaving no pain at rest	6	180/100	Normal	
3	65	M	9	Pain after walking 1 or 2 blocks no pain at rest	1-2	190/88	Normal	
4	35	M	1/2	Pain when climbing stairs, no pain at rest	2-4	110/80	Normal	
5	54	F	1	Pain after walking half a block also with emotional upsets no pain at rest	5-7	180/100	Normal	
6	63	M	6	Semi invalid because of pain with the slightest effort no pain at rest	5	138/76	Left bundle branch block, T ₁ and T ₂ inverted	
7	63	M	10	Varying amounts of effort resulted in pain pain at rest occasionally	4-8	210/120	Diphasic T ₁ and T ₂	
8	39	F	2	Pain on little effort and at rest	3	130/70	T ₁ inverted	
9	50	M	6	Pain with effort and emotion and at rest	3	130/80	Diphasic T ₁ and T ₂	
10	50	M	1/2	Pain with effort after meals and at rest	2-3	196/126	Sharp inversion of T ₁ and T ₄	
11	70	M	12	Pain with little effort no pain at rest	5-8	140/72	Right bundle branch block	
12	56	M	6	Pain with little effort and at rest	4-5	150/80	Isosventricular block, T ₁ , T ₂ and T ₄ inverted	
13	39	M	4	Pain on effort after meals	0	150/88	Normal	
14	50	M	10	Pain after walking half a block	1	130/78	T ₄ sharply inverted	
15	42	M	2	Pain on walking	5-6	118/78	Normal	
16	60	M	13	Pain climbing stairs and at rest	2	145/80	Normal	
17	66	M	12	Pain after walking half a block	2-3	126/80	Right bundle branch block	
18	55	M	7	Pain on walking up incline	1-2	220/110	Normal	
19	40	M	6	Pain with varying types of effort	3-4	108/75	Normal	

CASE	THERAPY REVIEW	AFTER THERAPY			RESULTS
		METROGLYCERIN PILLS REQUIRED DAILY	BLOOD PRESSURE	FOLLOW UP PERIOD	
				mo	
1	10/9/42	1-2	170/60	4	Marked improvement original symptoms returned after 2 months
2	11/13/42	6	200/120	4	No improvement
3	11/23/42	1-2	178/78	2	No improvement
4	12/4/42	3-4	110/80	3	Questionable improvement, felt better for 2 months
5	12/9/42	5-7	200/100	3	Questionable improvement continued to feel somewhat better
6	1/14/43	0	140/60	3	Marked improvement, 1 month later developed pneumonia after which pain subsided completely
7	3/1/43	4-8	240/100	1	No improvement
8	3/15/43	3	128/78	1	No improvement
9	9/20/43	3	130/70	2	No improvement
10	3/22/43	1-2	190/120	2	Aminophyllin also given, coronary occlusion probably occurred just before therapy moderate improvement for 1 month
11	11/1/42	5-8	126/70	4	No improvement
12	1/12/43	4-5	156/100	1	Died 1 month after treatment was finished
13	10/14/42	0	140/50	4	Marked improvement which has been maintained

after. One of these developed a coronary occlusion two months after the injections were completed.

No changes in the blood pressure or electrocardiogram were observed in any case and no toxic effects or significant changes in libido were noted. The behavior of this entire group was not unlike what would be expected in following any average series of cases of angina pectoris over a short period of time, one patient having died unexpectedly and another having developed an acute coronary thrombosis.

The difficulty of appraising therapy in the treatment of angina pectoris is perhaps best illustrated by the history of one of the patients in this group. Thirteen years ago, R. S., then forty-seven years of age, had been seen by one of us (S. A. L.) and diagnosed as having coronary artery disease and angina pectoris. At that time he could not walk a city block without experiencing the crushing substernal oppression so characteristic of angina. During the following twelve years, while receiving no specific form of therapy, there was considerable spontaneous improvement so that it was not unusual for the patient to walk miles without pain. Obviously this improvement could have been credited to any treatment used at the beginning of that period. Over a year ago, when the attacks of angina again became very frequent, testosterone was administered and considerable relief was noted. Recently, however, another course of injections failed to duplicate that result. May not this entire sequence of events reflect the vagaries of angina pectoris rather than the true effect of any therapeutic agent?

SUMMARY

Testosterone propionate in doses of 25 mg. three times a week was given to 18 patients with typical angina pectoris for four weeks, and to 1 patient for seven weeks.

In all but 2 cases the patients received no other medication and continued the daily routine to which they had been accustomed.

Of the 19 patients, 9 were hypertensive and 1 had rheumatic aortic stenosis and insufficiency. Five had had a previous coronary occlusion.

Results were judged by the amount of physical activity necessary to produce an attack of angina, and the number of nitroglycerin tablets used daily. The degree of improvement was classified as marked, moderate and questionable.

Five were markedly improved at the conclusion of the treatment. Two, however, reverted to their former clinical state within six to eight weeks, 1 obtained no relief from a second series of injections after fifteen months of comparative comfort, and 1 has been followed for only one month. One patient was moderately improved, 2 questionably improved, and the remaining 11 obtained no benefit.

No change in the blood pressure or electrocardiogram and no toxic effects were noted.

Realizing that the clinical course of angina pectoris may vary a great deal spontaneously, we are unable to conclude that testosterone propionate has any beneficial therapeutic effect in this disease.

THE TREATMENT OF RHEUMATOID ARTHRITIS WITH GOLD*

ABRAHAM COHEN, M.D.,† AND ALFRED W. DUBBS, M.D.‡

PHILADELPHIA AND ALLENTOWN, PENNSYLVANIA

ALTHOUGH the history of the use of gold salts in the treatment of rheumatoid arthritis is extremely interesting and unusual, it will not be recounted here since it has been so adequately summarized by Cecil and his collaborators.¹ It is interesting, however, to note that the use of gold in arthritis probably owes its origin to Mollgaard, who in 1927 thought that this precious metal had value in the treatment of tuberculosis. Some French students of arthritis believe that tuberculosis is the causative agent in the rheumatoid form of this disease, and this may well have suggested to Forestier² the use of gold salts in the treatment of arthritis.

Gold is unique also in that it is practically the only form of therapy among the many hundreds suggested for the treatment of arthritis that has had consistently favorable reports. The fact that it was slow to gain favor, particularly in this country, was due to the obvious toxic properties of the agent and its untoward effects. That these are still large factors seems to be evidenced by the facts submitted by all the writers on the subject and will be prominently emphasized in this report.

PHARMACOLOGY

This study has not brought to light any positive facts concerning the action of gold salts in alleviating the symptoms of rheumatoid arthritis. Whether its action is bacteriostatic,³ shock-producing,⁴ immunologic to joint structures⁵ or stimulating to the reticuloendothelial system⁶ still remains in the realm of theory.

Physiologic facts in respect to the fate of gold after injection into the human body are quite well established. Freyberg, Block and Levey⁷ and Block, Buchanan and Freyberg⁸ have shown that colloidal gold and colloidal gold sulfide are poorly absorbed and that more gold per gram of tissue is found in the liver than in the kidney, and have found that the feces are the chief route of excretion. In the case of crystalline preparations (gold sodium thiomalate, gold sodium thiosulfate and sodium succinimide aurate), more gold was found in the kidney per gram of tissue than in the liver, and during the time this preparation was used most of the gold was excreted in the urine.

Experimentally, the site of the primary pathologic lesions following the administration of these

substances occurs in the organs where the greatest deposition of gold occurs.⁹ That this is also the case in human beings seems to have been borne out clinically. Another feature of importance is the large percentage of gold salt that is retained in the organism for months before elimination is complete.¹⁰

GOLD PREPARATION AND METHOD OF THERAPY

The gold salts used in this study were limited exclusively to aurothioglucose,[§] and the maximum dosage in any one course was 1.24 gm., given over a period of fifteen weeks. Ten-milligram, 25-mg. and 50-mg. doses were given intramuscularly semi-weekly for two weeks each, and 100-mg. doses were given weekly for nine weeks. A second course was never begun until after a six-week period had elapsed. Many of the cases received two courses and some of them three. The second course was repeated no matter what the result had been after the first, unless there had been untoward effects or reactions contraindicating such procedure.

CLINICAL MATERIAL

The type of case used in this series was to a large extent governed by the type of patient attending the clinics from which the material was obtained. The Arthritis Clinic of the Philadelphia General Hospital derives the greatest part of its case load from indigent chronic patients who have had the disease for some time and have made the rounds of hospitals. This is also true, to a great extent, of the clinic at the Jefferson Hospital although a great number of patients are referred there by physicians. The latter patients may be on an economic scale slightly above that of the patients of the Philadelphia General Hospital clinic but the type of case does not appear to differ a great deal. Thus most of the cases were far advanced (Table 1) and had received at some time or other throughout the course of their disease all types of treatment.

The usual study consisted of a complete physical examination, including a complete blood count, urinalysis, and determination of the sedimentation rate (Westgren), as a routine. Other studies were done as indicated. Further sedimentation rate determinations were made at the termination of each course of treatment and before the beginning of the next. Weekly blood-cell counts and

sient albuminuria was noted, but otherwise there was little of significance.

One patient developed a leukopenia (a white-cell count below 4000), and the fact that after treatment was stopped and liver extract administered intramuscularly a complete recovery ensued made routine blood-cell counts worth the effort. There was no appreciable change in the hemoglobin level or the red cell count. Many hundreds of determinations were made.

In all the cases an increased sedimentation time was a prerequisite for gold therapy (Table 2).

With the use of the Westgren method, 8 mm. per hour was considered as the upper limit of normal.

All the cases were polyarticular. Two showed spondylitis deformans. To the student of this disease it will be quite obvious that one rarely finds rheumatoid arthritis involving but one joint and at the same time fulfilling all the necessary criteria for diagnosis.

The cases were grouped according to a functional classification that has been used in our clinics for some time in the study of arthritic patients. It is as follows:

Class 1. Patients presenting the subjective picture characteristic of atrophic arthritis, with duration less than six months and with no demonstrable changes in the joints by clinical or roentgenologic examination.

Patients presenting the subjective picture characteristic of atrophic arthritis, with duration less than one year and joint changes demonstrable but of a moderate degree. There is usually complete subsidence following the removal of foci and adequate therapy.

Class 2. Patients with typical joint changes in one or more groups of joints. The changes are more or less permanent in character but of such a nature that activity is only slightly limited.

Class 3. Patients in whom joint changes have advanced to such a degree that physical activity is greatly limited.

Class 4. Patients with joint changes of such a nature that dislocations, ankyloses and contractures cause total disability. The patient must of necessity be confined to a wheel chair or to bed.

With this classification in mind, it will be noted that only cases of rheumatoid arthritis were in-

cluded in this study. Hypertrophic arthritis was not considered. The distribution of grades by ages is shown in Table 3.

TOXIC REACTIONS

The following is a list of untoward reactions reported as due to gold therapy.¹¹

- Skin:

Erythema
Exanthema
Papular eruption
Desquamation
Morbilliform rashes
Urticaria
Exfoliative dermatitis
- Liver:

Hepatitis
Jaundice
Acute yellow atrophy
- Respiratory tract:

Cough (gold bronchitis)
- Eyes:

Conjunctivitis
- Kidneys:

Mild transient albuminuria
Uremia
- Mouth:

Metallic taste
Anesthesia of tongue
Transient loss of taste
Dysphagia
Sore tongue and gums
Ulcerative stomatitis
- Central nervous system:

Eighth-nerve deafness
- Genitourinary tract:

Weight loss
Nausea
Vomiting
Epigastric distress
Diarrhea
- Hematopoietic system:

Epistaxis
Purpura hemorrhagica
Aplastic anemia
Agranulocytosis

Hartfall and Garland¹² reported 45 per cent toxic reactions in 100 cases. Later Hartfall et al¹³ reported 900 cases with 52.5 per cent toxic reactions. Crawford¹⁴ treated 27 cases with 44 per cent untoward reactions. Sashin and Spanbock¹⁵ had 18 per cent toxic reactions in 22 cases, and Parr and Shipton¹⁶ 26 per cent in 70 cases. Key et al¹⁷ 63 per cent in 44 cases. Snyder et al¹⁸ 15 per cent in 145 cases, and Ellman et al¹⁹ 27 per cent in 90 cases.

One cannot doubt that gold therapy is dangerous in the hands of the average physician when one glances at the long list of untoward reactions that have been reported in the literature. Much of this, however, is avoidable when reasonable care is taken. The purpose of this study is not only to add to the already long list of statistics but to contribute what is believed to be a simple method to reduce the incidence of untoward reactions. It has been suggested that large amounts of vitamin C be used.²⁰ It is, however, agreed that there is no scientific basis for this except perhaps that since most of the untoward reactions are reflected in the skin and mucous membranes it might be wise to attempt to decrease the capillary permeability with vitamin C. Therefore as adjuncts to the gold therapy, the patient was instructed to take 16 ounces of fruit juices as well as a minimum of $\frac{1}{4}$ pound of liver three times weekly. Any unusual signs or symptoms that might develop between visits were to be reported. The patient was especially warned to report itching of the skin, sore mouth or rash, regardless of severity.

Untoward reactions regardless of severity or whether or not attributable to gold were cause for interruption of treatment. Frequently, treatment was again begun when the reaction subsided. Reactions were treated by intramuscular injections of 4 units of crude liver extract three times weekly.

In Table 4 are listed the untoward reactions encountered in this study. In the group of 122 cases that received but one course of gold therapy reactions occurred in 12 cases (9.8 per cent). In the 38 cases receiving two courses, 7 (18 per cent) had reactions, and in the 16 cases receiving three courses, 1 case (6 per cent) had a reaction. Thus in one hundred and seventy six series of injections, reactions occurred in 20 cases. The table also shows the total dose of aurothioglucose received when the reaction became manifest.

RESULTS OF THERAPY

The results of any therapy employed in the treatment of arthritis are always extremely difficult to evaluate. The student of the disease is

frequently hard pressed to classify results in the single case. Factors that create this situation are the wide variance in susceptibility to pain and

discomfort the patient's psychic response to having someone take an interest in his plight and the resulting euphoria of some patients when under this influence. One must also consider the inherent tendency of rheumatoid arthritis to have natural remissions. All these must be dealt with and kept in mind when trying to evaluate results. In this study a simple classification of improvement has been attempted, and the cases have been divided as follows:

- Group 1 No change. No response whatsoever.
- Group 2 Improved. Few if any objective changes but definite subjective improvement evidenced by the patient.
- Group 3 Markedly improved. Both subjective and objective improvement: diminution of swelling and pain and ability to raise the arms above the head or to walk with or without aid.
- Group 4 Very markedly improved. Marked diminution or complete relief of all subjective and objective symptoms. In some of these cases there remain some stiffness and soreness.

From the tables it appears that there was improvement of a sort in 87 per cent of the cases. If one were to consider the improvement in Group 2 as of questionable nature, since the patient's own statements were the only guide, there remain 53 per cent that were benefited by this form of therapy.

As has been reported by others, there was generally a reduction in the sedimentation rate. Table

5 shows that 78 per cent of those patients receiving one course of treatment manifested a reduction in sedimentation rate. A reduction was noted in exists, even for many years, if pain is still present and the sedimentation rate is elevated, the patient should be given the benefit of gold therapy. If

47 per cent of those patients receiving a second course and in 62 per cent of those receiving the third course. At the end of the first course of gold 7 per cent of the patients showed an increase in sedimentation rate. In spite of this, many of the patients were improved.

Whether or not the gradual reduction in sedimentation rate has any bearing on the rate of improvement one cannot say. However, it would seem so until one examines those patients whose sedimentation rate showed no change or was even increased at the end of a course of treatment, when one finds that improvement existed without favorable change in this test.

Table 6 shows the sedimentation rates before and after treatment in the 38 cases receiving two or three courses of treatment.

Table 7 lists the therapeutic results according to the duration of the disease. It will be noted that in the majority of cases the disease existed for more than one year. Almost 70 per cent of the patients were afflicted for more than two years and 45 per cent for more than five years. This series consisted of only 8 patients with rheumatoid arthritis of less than one year's duration. Although the improvement in these cases was marked, the series is not large enough to agree with the finding of other investigators that the earlier the case, the better is the prospect of recovery. Twenty-four patients suffered for more than ten years. Of these, 33 per cent showed subjective improvement, 25 per cent were markedly improved, and 25 per cent were very markedly improved after one course of treatment. Two cases showed no change and 2 were actually worse. These findings are extremely significant in view of the average opinion among physicians that cases of this type should be considered hopeless. Whenever rheumatoid arthritis

the result can only be classified as "improved," it will have been worth the effort.

Table 8 lists the results of treatment according to age groups. The majority of patients ranged

between thirty-one and sixty years of age. It will be noticed that the age of the patient was no contraindication to treatment with gold, since the re-

sults obtained were essentially the same as those in the younger age groups.

COMMENT

In our experience in two large arthritis clinics over a period of more than fifteen years, no form of therapy has been encountered that offers so

courses of gold therapy. It is likewise borne out that more than one course of treatment is necessary to maintain relief. However, not so much improvement should be expected from subsequent courses of treatment as one is apt to get from the first one.

Ignoring those cases that showed only subjective

*Roman numerals refer to courses of total in any one course

vaccines, filtrates, snake venom, sulfur, vitamins, physiotherapy, artificial fever and so forth.

As has been reported by other writers, there is a decided tendency toward a reduction in the sedimentation time—78 per cent of 122 cases receiving one course, 47 per cent of those receiving two courses, and 62 per cent of those receiving three

tions in individuals receiving but one course of treatment is significantly lower than that reported by other authors. However, the incidence was twice as great in those receiving two courses, but there was only 1 such case in these 16 patients receiving three courses. The grand total of 11 per cent of untoward reactions in 176 courses of gold

therapy suggests a distinct reduction in the incidence noted by other investigators. With but one exception, reactions were not manifested until the patient had received at least the 50-mg. doses. When it is considered that 100 mg. has been advocated as an initial dose, it is understandable that a greater incidence of untoward reactions might occur. In this study, three factors are thought to have been responsible for the reduction of toxic reactions: namely, the use of large doses of fruit juices for vitamin C, the use of liver for vitamin B complex and extreme caution in the consideration of untoward reactions.

Age does not appear to be a contraindication to gold therapy. Significant changes in the blood were observed in only 1 case. Likewise, there were no important changes in the urine.

SUMMARY

A series of 122 patients receiving a total of one hundred and seventy-six courses of 1.24 gm. of aurothioglucose intramuscularly is reported.

The results of all courses of treatment were as follows:

Thirty-five per cent showed only subjective improvement, 17 per cent were much improved, 36 per cent were very much improved, 9 per cent showed no change, and 4 per cent were worse.

The percentage of untoward reactions was 9.8 per cent during the first course, 18 per cent during the second, and 6 per cent during the third, an incidence of 11 per cent in one hundred and seventy-six courses of therapy.

A simple method for the reduction of untoward reactions is suggested.

MEDICAL PROGRESS

THE PLASMA PROTEINS: THEIR IMPORTANCE IN CLINICAL MEDICINE AND SURGERY (Concluded)*

CHARLES A. JANEWAY, M.D.†

BOSTON

Clotting process Fibrinogen is classified as a plasma globulin and is the soluble precursor of fibrin, which makes up the matrix of a blood clot. The fibrinogen molecule has properties that make for elasticity and a firm clot. It is a long slender molecule exhibiting double refraction of flow.² Its source is in all probability the liver, but it can apparently be manufactured with such rapidity that only overwhelming hepatic damage will lead to a deficiency of plasma fibrinogen. This is occasionally seen in acute yellow atrophy and in carbon tetrachloride poisoning. A few cases of congenital fibrinogenopenia have been described.⁵⁰ Such deficiencies of fibrinogen are of little clinical significance because of their rarity.

On the other hand, two other globulins concerned with the clotting process are of great clinical importance, as recent work has shown. The first, prothrombin, is the precursor of thrombin, which, according to the classic clotting theory, is produced from prothrombin by the influence of calcium and thromboplastin derived from tissue juice or the breakdown of blood platelets. Prothrombin and thrombin apparently have the mobilities of beta globulins. Prothrombin is present in the circulation in considerable amounts under ordinary circumstances, but a marked fall in plasma prothrombin concentration occurs under certain clinical conditions, notably severe hepatic damage and severe obstructive jaundice. In the first case, the hypoprothrombinemia is apparently due to the failure of the liver to synthesize this protein⁶⁰ (it should be noted that the liver is again implicated), in the second case, the deficiency is not due to a primary failure in synthesis but to a failure of absorption of fat soluble substances in general, of which vitamin K is one.⁶¹ Vitamin K is apparently essential to the synthesis of prothrombin by the liver.⁶² If it is injected or given by mouth with bile salts to promote its absorption, there is a prompt restoration of the blood prothrombin level if hepatic function is adequate.⁶³

These discoveries are of great importance in biliary surgery, since one of the chief hazards of operations on cases of severe obstructive jaundice in the past was abnormal bleeding. In addition, the recognition of hypoprothrombinemia in cases of hemorrhagic disease of the newborn,⁶⁴ which may be prevented in some cases by the administration of vitamin K to the mother before delivery, is another important practical advance.⁶⁵

Since clinicians are interested not only in treating defective clotting but also in producing controlled defects in clotting, the work on dicoumarin^{66, 67} should be followed with interest. The use of this powerful drug, which seems to act specifically on prothrombin, in the treatment of thrombosis, has been delayed by the lack of suitable means of controlling the clotting defect once it is initiated. Hence, Davidson and MacDonald's⁶⁸ paper on the effectiveness of synthetic vitamin K₁ oxide in dicoumarin hypoprothrombinemia will be of great importance if further studies confirm their work.

The second globulin important in blood coagulation has been brought to light by the work of Tagnon, Taylor, Lozner and their associates. Nolf originally proposed that clotting is brought about by a proteolytic enzyme in the plasma that can produce clotting, or when present in larger amounts, lysis of clots.⁶⁹ Such an enzyme may be produced from plasma by treating it with chloroform. In addition to Nolf's work, which has been confirmed by Tagnon and his co-workers,^{70, 71} Taylor and his associates⁷² have for some years been interested in the substance that is deficient in hemophilic blood. This thromboplastin substance is definitely a globulin,⁷³ but its more accurate chemical characterization has not yet been carried out. This substance disappears fairly rapidly from hemophilic blood after administration, but it can be injected either in purified form or as fresh plasma, and temporarily rectifies the clotting defect of hemophilic plasma. It is of great interest that chloroform treatment of the globulin fraction, which rectifies the hemophilic coagulation defect, gives rise to a proteolytic enzyme.⁷⁴

*The articles in the medical progress series of 1941 have been published in book form (*Medical Progress Annual*, Volume III, 68 pp., Sept. 1941, field 11 line 5, Charles C. Thomas, 1942, \$5.00).

†From the Department of Pediatrics, Harvard Medical School, the Department of Communicable Diseases, Harvard School of Public Health, and the Children's and Infants' hospitals.

Assistant professor of pediatrics, Harvard Medical School and School of Public Health, and a lax physician, Children's and Infants' hospitals.

§For those interested in the complexities of blood coagulation and in the evidence for Nolf's interpretation of the experimental data, his review⁶⁹ is recommended.

Catalytic agents. As Salter⁷⁵ has recently pointed out, many of the most physiologically active and important substances are of a catalytic nature, and hence are present in very small amounts in the blood. Enzymes and hormones fall into this group. Chemical research has indicated that most enzymes are of protein nature, with prosthetic groups that confer on them their special properties. Minute but measurable amounts of certain enzymes such as amylase, alkaline and acid phosphatase circulate normally in the plasma. Marked increases in concentration have been found to characterize certain pathologic conditions, such as the rise in serum amylase that is found in acute pancreatitis.⁷⁶ The hormones, derived from the pituitary and thyroid glands, are likewise active agents present in minute amounts, probably in the globulin fraction of the plasma. None of these substances are ordinarily considered with the plasma proteins, but their presence in plasma is pointed out to emphasize its complexity.

Pressor substances. In recent years it has become apparent that, in addition to the elevation of blood pressure produced by adrenalin in emergencies, another humoral mechanism exists that can elevate blood pressure in response to renal ischemia.⁷⁷ This field has been confused by the fact that the two chief groups of workers have introduced different terminologies. However, the fundamental facts are these. Renin, an enzyme and probably a globulin, is liberated from the kidney under various conditions that produce renal ischemia. It does not itself elevate blood pressure, but acts on a substrate ("hypertensinogen"⁷⁸ or "renin activator"⁷⁹), which is one of the plasma globulins, to produce the true pressor substance ("hypertensin"⁷⁸ or "angiotonin"⁷⁹), which is probably a polypeptide. Although this humoral mechanism of hypertension has not been demonstrated in cases of human hypertension, it seems likely that it may explain those cases of hypertension that are definitely due to renal disease. Hypertensin or angiotonin has a number of interesting physiologic effects on the circulation that are under active investigation.⁸⁰

Abnormal globulins and hyperglobulinemia. A number of disease states are characterized by an increase in the globulin fraction of the plasma. The normal value for plasma globulin is from 2.0 to 2.5 gm. per 100 cc., and in some diseases this may rise as high as 6 or 7 gm. In many cases, but not always, this hyperglobulinemia is associated with hypoalbuminemia, so that the total protein value is a resultant of the two tendencies. Hyperglobulinemia may be due to an increase in the normal globulin constituents of the plasma, to

the presence of abnormal globulins or to both. Gutman and his colleagues⁸¹ have made a careful study of the plasma proteins in multiple myeloma, a disease characterized by extremely high plasma protein levels, and have shown that some cases are characterized by increases in different fractions of the normal serum globulins and some by abnormal globulins, one of which is the Bence-Jones protein, which appears in the urine and is characterized by its peculiar solubility behavior when heated. In addition to multiple myeloma, certain types of liver disease, particularly cirrhosis of the liver, are associated with hyperglobulinemia and the presence of abnormal globulins, and a number of chronic infectious diseases likewise manifest hyperglobulinemia. Of these, the commonest are the tropical diseases, particularly kala azar and chronic malaria; the chronic relapsing diseases thought to be due to allergy, such as acute nephritis, rheumatic fever, disseminated lupus erythematosus, periarteritis nodosa and dermatomyositis; lymphopathia venereum, which exhibits strikingly high plasma globulin levels; and a number of other chronic infectious diseases, such as subacute bacterial endocarditis and tuberculosis.⁸¹

Acute nonspecific responses to infection. One of the most interesting fields for speculation and study on the role of the plasma proteins is the response of the body to acute infection. The studies of Tillett, Francis, Avery, Abernethy and others have shown that there is a chemical fraction of the pneumococcus, the so-called "C carbohydrate," to which a group of rather peculiar immune reactions can be demonstrated in many acute infections, not necessarily pneumococcal in nature. Anti-C substance precipitins appear in the serum shortly after the onset of pneumonia and other acute infectious diseases, and disappear soon after recovery, unlike most antibodies that are specific and appear only after recovery. These antibodies manifest themselves by the appearance of a positive skin reaction to the C substance, which is intermediate between the immediate and delayed types, reaching its maximum in about eight hours.^{82,83} They differ from ordinary antibodies also in that precipitation of the C substance takes place only in the presence of calcium ions.⁸⁴ Further studies of this peculiar antibody have shown that, unlike other antibodies that are normally found in the gamma globulin fraction, it seems to be present in the alpha globulin fraction,⁸⁵ a fraction of serum that has been shown by Longworth and his colleagues⁸⁶ to increase during the acute stage of acute infectious diseases. Furthermore, it has been shown by immunologic methods to be a protein not present in normal serum.⁸⁷

Possibly related to this interesting alpha globulin is the discovery of Tillett⁸⁸ that any febrile illness results in a rapid increase in the bactericidal power of the patient's serum for certain strains of beta-hemolytic streptococci, and that this bactericidal power disappears shortly after the subsidence of acute symptoms. This bactericidal property of the serum has been shown by Tillett and Stock⁸⁹ to be associated with a globulin fraction. Of equal interest is Menkin's^{90, 91} recent discovery of the leukocytosis-promoting factor, which can be detected in the serum of animals with acute abscesses and can be concentrated from inflammatory exudates derived from animals and human beings. This factor is likewise a globulin,⁹² and its connection with the other responses to acute infection is one that invites speculation and further study.

Undoubtedly this catalogue of the physiologic significance of the various globulins present in normal and pathologic human plasma is far from complete, but it serves to illustrate the complexity of plasma. Just as changes in the albumin fraction, and to a much lesser extent in the globulin fraction, reflect changes in the state of protein nutrition of the body, so changes in the amounts of the various globulins reflect changes in the constantly shifting equilibrium of the organism with its environment, changes which, although recognized by alterations in the plasma, are fundamentally due to alterations in the activities of different groups of tissues and cells.

TREATMENT OF DISTURBANCES OF THE PLASMA PROTEINS

It should be clear from the foregoing discussion that alterations in the normal pattern of the plasma proteins are not diseases in themselves, but are merely reflections of more deep-seated changes in the body tissues. Therefore, treatment in most cases is not directed at the plasma protein disturbance itself, but at the underlying disease, except where alterations in the plasma, such as the hypoproteinemia of nephrosis, affect the whole organism adversely.

Hyperproteinemia

Hyperproteinemia, which is almost always hyperglobulinemia, is associated with diverse clinical conditions, the etiology of many of which is unknown, but for certain of which, such as kala azar, malaria and lymphopathia venereum, there are definite methods of treatment. Since hyperproteinemia per se has not yet been demonstrated to be harmful, its treatment at present would be unnecessary, even if the proper procedure were known. In a disease like hyperthyroidism the metabolic disturbances are related to the over-

production of thyroid hormone, which is circulating in the plasma. The absolute amounts of hormone, however, are so small, since it acts as a catalytic agent, that one does not think of hyperthyroidism as a specific type of hyperglobulinemia to be treated by suppression or removal of the organ giving rise to the globulin.

Hypoproteinemia

In contrast to excesses, deficiencies of the major plasma proteins are amenable to treatment, which is frequently required to correct serious disturbances of the body economy as a result of the deficiency of circulating protein itself or the underlying functional defect that it reflects. Two general lines of therapy are open to the physician: first, substitution or replacement therapy; and second, provision of adequate protein-forming materials or the stimulus to synthesis, thereby enabling the body to repair its own deficiency. The latter method is always preferable wherever possible, since it offers permanent rather than temporary relief. It takes time, however, and depends on the integrity of the synthetic processes, so that in acute emergencies, or where there is failure of synthesis, replacement therapy must be used.

A deficiency of circulating total protein is associated with the rapid loss of blood or plasma, such as occurs in hemorrhage, severe injuries and burns, although the plasma protein concentration and distribution may be normal. If the total amount of blood or plasma lost is so great that compensatory vasoconstriction is ineffective in maintaining the peripheral circulation, there occurs the marked fall in blood pressure characteristic of severe shock. Such a condition should be anticipated and prevented if possible by replacement therapy before collapse occurs. The capacity of the body to compensate for blood or plasma loss is conditioned by its ability to manufacture new plasma protein. This occurs at a remarkably rapid rate, provided an adequate circulation is maintained. Following a venesection of 15 to 20 per cent of the total blood volume a normal subject can replace the lost blood with new plasma in about three days.⁹³ Obviously, this is too slow to bring about recovery in traumatic shock, which may become irreversible in a few hours, and furthermore, it has been shown that plasma protein production in dogs is practically nil when the blood pressure is at shock levels.⁹⁴ It is because of this vicious circle that the early treatment of shock with fluids capable of maintaining blood volume is so important. Crystalloid solutions are too rapidly lost from the circulation and tend to lower the plasma protein concentration by dilution and by increasing the rate of plasma loss at the site of injury.⁹⁵ Foreign colloids, such as acacia,⁹⁶

pectin⁹⁷ and gelatin,⁹⁸ have been used successfully to improve the circulation in such emergencies. The ideal replacement fluid, however, is that which most closely approximates that which is being lost. Thus, whole blood or a mixture of whole blood and plasma are best, for wounds combining hemorrhage and trauma, whereas plasma is superior for crushing injuries, peritonitis and burns, where the factor of hemorrhage is minimal. Since the blood has a wide margin of safety in its oxygen-carrying capacity, it is usually possible to substitute plasma for blood for the sake of convenience in the emergency treatment of shock. This is the basis for the Red Cross Army-Navy dried plasma program, which provides a therapeutic agent that can be transported in the field without refrigeration and administered without cross matching. Since the effectiveness of plasma in restoring blood volume depends chiefly on its albumin content, the administration of sufficient albumin should be as efficacious as plasma in most shock cases. Because albumin is extremely soluble and stable it has been put up in concentrated form—25 gm. in 100 cc. of saline—to provide an instantly available, compact blood substitute for emergency use under military conditions, where space is at a premium.¹⁰ In clinical trials this has been shown to be effective,⁹⁹ but since it draws on the tissue fluids to increase the volume of circulating plasma, additional water and salt must sooner or later be given the patient by some route (per os, per rectum or parenterally), particularly in cases in which dehydration is present.

Hypoalbuminemia

Hypoalbuminemia, or a diminution of the albumin concentration below normal, gives rise to edema when the value for plasma albumin falls below 2.0 to 2.5 gm. per 100 cc., and is known to be associated with poor healing of surgical wounds, and even with wound disruption after operation.^{100, 101} Hypoalbuminemia is a manifestation of a poor state of nutrition of the tissues in general. Thus, the maintenance of an adequate level of serum albumin is undoubtedly of equal importance in the treatment of medical and of surgical patients. The causes of hypoalbuminemia are excessive loss of albumin, such as occurs in nephrosis or repeated tappings, excessive utilization, as in febrile illness, and inadequate production due to poor protein intake, poor absorption or failure of albumin synthesis. Any one or a combination of these factors may operate in any particular case. Replacement therapy requires large amounts of injected proteins. As Elman and his group¹⁰² have shown dietary nitrogen loss or gain in dogs is distributed between the tissue and serum proteins in a ratio of about 30:1. The protein stores

of the tissues must be replenished as the value for plasma albumin is restored to normal. Clinical experience has shown that this may take considerable time.

Wherever possible, the administration of protein-building material rather than simple replacement therapy should be undertaken. The patient should be put on a high-protein diet, with adequate calories in carbohydrate and fat to spare protein catabolism.¹⁰³ Where the appetite is poor, intravenous alimentation with a protein digest or an adequate amino acid mixture may be used to supplement the oral protein intake. This type of therapy is just coming into its own,^{104, 105} but there are still some practical difficulties in the intravenous injection of a sufficient amount of protein hydrolysate to maintain nitrogen balance. With surgical patients who cannot take any food by mouth, the addition of intravenous protein hydrolysates and parenteral vitamins to the conventional therapeutic regime of saline solution and glucose should do much to improve the postoperative course.¹⁰⁶ Unfortunately, there are some patients, particularly those with liver disease, in whom the synthetic processes are so impaired that replacement therapy with plasma may have to be given if the hypoalbuminemia is to be relieved. The enormous amounts required and the poor ultimate prognosis where liver function is seriously deranged make the value of such therapeutic efforts somewhat dubious. The favorable reports of Patek and Post¹⁰⁷ on improvement in some cases of cirrhosis of liver treated with a diet rich in proteins and the vitamin B complex suggest that definite return of the ability to synthesize albumin may occur on such a regime and that this is the procedure of choice in chronic liver disease. In acute hepatitis, the use of plasma to help tide a patient over a critical period of hypoalbuminemia may be indicated, since the ultimate outlook is fairly good.

It should be pointed out that the amounts of plasma protein required for the therapy of nephrotic hypoalbuminemia are large, since the deficiency of albumin is so extreme and the rate of loss in the urine so high. Until there is a better understanding of the fundamental disturbance in the nephrotic syndrome, however, some form of replacement therapy will have to be used in those patients whose edema does not respond to those simple measures or to those unknown factors that lead to diuresis in some patients. Binger and Goudsmit¹⁰⁸⁻¹¹⁰ have persistently advocated gum acacia in the treatment of nephrotic edema. There seems little doubt of its effectiveness in certain cases, and it has one great advantage over plasma protein—it is retained longer by the kidney and produces an increase in blood colloid. Unfortunately, acacia is deposited in the viscera, particularly the liver,

and may interfere with protein synthesis for that reason.¹¹¹ Hence, its use cannot be recommended. Concentrated human serum¹¹² and concentrated human albumin¹¹³ have both been advocated. Use of the latter, particularly in aqueous solution, is rational; even though the amounts required are extremely large. Protein hydrolysates and amino acid mixtures provide means of increasing the supply of protein-forming material to nephrotic patients and have a role in the treatment of patients with good renal function, as Farr, Emerson and Futcher¹¹⁴ have shown. In cases with poor renal function, the injected amino acids result in a rise of blood nonprotein nitrogen.¹¹⁵

Hypoglobulinemia

Deficiencies in certain globulins do occur and in certain cases can be rectified by appropriate therapy. The antibody globulins are frequently deficient, particularly in infants, since specific antibodies are probably not acquired except as a result of the stimulus of artificial immunization or from contact with the disease-producing agent. In many cases such contacts do not give rise to frank disease, but to latent infection or the carrier state, which may be equally effective in establishing immunity and stimulating antibody production.

Passive immunization is a form of replacement therapy whereby a specific antibody is supplied by injection of the serum from an immune person or an immunized animal. The use of heterologous antibody carries with it the risk of serum sickness, in which the lesions of periarthritis nodosa have recently been demonstrated.¹¹⁶ Because the risk of serum disease is obviated, there is an increasing use of human serum for passive immunization, particularly in the prophylaxis of measles and pertussis and in the treatment of pertussis and scarlet fever.¹¹⁷ The widespread use of whole-blood or plasma transfusions in infants with severe infections is based on the premise that the increased resistance of an adult is associated with an appreciable amount of circulating antibody that may be transferred to the infant. Although, as already pointed out, this is probably the case, studies analogous to those of Lyons on immuno-transfusion for hemolytic streptococcus infections are needed to put this practice on a more rational basis.¹¹⁷

Unfortunately, the fact that even human serum is not without its dangers has been forcibly brought home by the recognition of homologous serum jaundice. Recent studies indicate that this is probably due to a virus present in the blood of patients in the pre-jaundice stage of infectious hepatitis.¹¹⁸ Fortunately, such cases had been

comparatively rare in the United States, although cases have possibly gone unrecognized¹¹⁹ until experience with yellow fever vaccine containing a small amount of icterogenic human serum brought this matter to the fore.¹²⁰ On the other hand, in England, where epidemic jaundice has been relatively common in recent years, many cases of the transfer of jaundice to patients by the injection of human serum, particularly convalescent measles and mumps serum, have been observed.¹²¹ It is to be hoped that all clinicians using human blood, plasma and serum will keep careful records of the lot used, since this is essential for tracing the origin of the icterogenic agent when jaundice develops. The incubation period of this type of jaundice is from one to four months, so that unless a careful history is taken in all cases of jaundice the connection with an injection of human blood or its by-products may be overlooked. Studies on how to eliminate this danger are urgently needed.

The superiority of the method of therapy that depends on supplying the body with protein-forming materials is nowhere better illustrated than in the case of the antibodies. Here the protein-building material is easily supplied by the diet, but the stimulus to antibody formation must be provided by active immunization, which gives rise to a much more permanent and solid immunity than can be achieved by passive immunization. Cannon¹²² has suggested that in severe protein deficiency the ability of the body to form antibodies may be impaired. The results of his further studies will be awaited with interest, since they may have an important bearing on the health of the malnourished populations of Europe in the coming period of reconstruction.

Complement deficiencies, as already pointed out, are rare, but deserve further study.⁵⁸ It is possible that the occasional salutary effect of blood or plasma transfusion in severe infections is due not only to the passive transfer of antibodies or to the supply of some of the needs of the body for protein but also to the passive transfer of preformed complement. Experimental studies in animals¹²³ have suggested the necessity of an adequate vitamin C level for complement activity, but subsequent experiments have failed to substantiate this in man.^{124, 125}

Deficiency of clotting substances is frequently encountered in the clinic, usually owing to hypoprothrombinemia, but rarely, in cases of overwhelming liver damage, to fibrinogenopenia as well and, in cases of hemophilia, to lack of so-called "globulin substance." For the provision of these important globulins by replacement, fresh

or adequately preserved plasma must be used.¹²⁶ Either frozen or dried plasma is adequate, with preference for the frozen material, but commercial liquid plasma is inadequate, since it is kept under conditions that destroy the activity of these labile globulins and complement. Better than replacement therapy is the stimulation of prothrombin production by the administration of vitamin K. This is not usually successful where there is extensive liver damage. Unfortunately, no way of curing the coagulation defect of hemophilia other than blood or plasma transfusion is known, and the effect of such therapy lasts but a short time.

* * *

It is probable that the time may soon come when it will be possible to analyze protein deficiencies in terms of their individual components, and to supply the missing components in pure and highly concentrated form. It should, however, be emphasized that replacement therapy is a temporary measure, absolutely essential for acute emergencies, such as shock, acute infections and hemophilic crises. Equally important is the gathering of knowledge concerning the source and essential factors for the synthesis of the different functionally important plasma proteins. Again one is driven back to thinking about the functions of the tissues that are reflected in the pattern of the plasma proteins. In the case of prothrombin, the discovery that vitamin K is essential to its synthesis by the liver has made possible the rational treatment of prothrombin deficiency. Similar studies with regard to the other blood proteins—the essential dietary factors and amino acids necessary for their manufacture—should yield fundamental knowledge of great practical significance in clinical medicine and surgery.

CASE 29461

PRESENTATION OF CASE

A thirty-eight-year-old librarian was admitted to the hospital because of chills, fever and weakness of two weeks' duration.

About seventeen years before entry the patient began to have intermittent attacks of diarrhea and melena that occurred at varying intervals of weeks to several months and lasted several days. During the attacks she was "rundown" and weak, while between the attacks she was quite normal jaundice. The attacks were not related to diarrhea and melena. Two weeks before entry she had a similar chill. She became progressively feverish, weak and tired, and developed generalized malaise. There was a sharp pain in the right lower anterior chest on eating or on deep inspiration. The pain did not radiate.

Physical examination showed a well-developed but thin, pale, feverish, dehydrated woman in no acute distress. The tongue, palate and pharynx were injected and coated with a white exudate. Chest expansion was limited by pain over the liver anteriorly. There were decreased breath sounds over the right base posteriorly. Transient rales were heard over both bases. The heart was of normal size, and the sounds were of good quality and had normal bowel movements. Eleven years before admission she had an attack lasting for several weeks following which an ileostomy was performed. Her general condition improved and the ileostomy worked satisfactorily, requiring attention only about three times daily. Fecal discharge from the ileostomy was semisolid. Bowel movements from the rectum occurred about twice daily, except for brief bouts of increased frequency (five to ten a day) that occurred only about three or four times a year and lasted only one or two days. At these the stools were occasionally bloody but usually consisted of pink-staining mucus. She had an attack of chills and fever at intervals of several months. These lasted only a few hours and then subsided completely. There were associated malaise and occasional vomiting, but no

ity and regular. A blowing apical systolic murmur was heard. The abdomen was soft and tympanitic, with "normal bowel sounds." Moderate tenderness was present over the left flank. The ileostomy appeared to be functioning well, but the surrounding tissue was red and macerated.

The blood pressure was 110 systolic, 58 diastolic. The temperature was 103°F., the pulse 120, and the respirations 28.

Examination of the blood showed a red-cell count of 2,760,000, with 6.2 gm. hemoglobin. The white-cell count was 45,900, with 95 per cent neutrophils. The blood chloride was 89.1 milliequiv. per liter. The nonprotein nitrogen was 24 mg. per 100 cc., and the protein 6.2 gm. One blood culture was negative. A second blood culture showed proteus bacilli that overgrew gram-positive cocci in pairs and diphtheroids. The urine had a specific gravity of 1.018 and showed a ++ test for albumin. The stools were guaiac negative.

Fluoroscopic examination of the chest showed that the motion of the right diaphragm was limited—about 0.5 cm.; the left moved normally. The right diaphragm was elevated. The liver was thought to be slightly larger than usual. There were several linear areas of atelectasis in the right lower lobe just above the diaphragm. There was also an area of increased density, measuring about 3 by 5 cm., apparently above the diaphragm. On the anteroposterior projection a shadow of decreased density was seen through the liver shadow, but this was not present in the lateral view. There was no fluid in the right base.

The patient was given daily intravenous infusions of 2000 cc. of 5 per cent glucose in physiologic saline solution and large doses of vitamins. On the second day she was given 5 gm. of sodium sulfadiazine, followed by daily doses of 25 gm. She received several transfusions. Her condition, however, became progressively worse. Despite a blood sulfadiazine level of 10 to 12 mg. per 100 cc., the temperature remained above 102°F. for the first two days, during which time she had two chills. For the next five days the temperature ranged between 100 and 105°F., with almost daily chills. The pulse varied between 90 and 150 for the first ten days. The patient became progressively weaker and slightly icteric. X-ray examination of the chest on the eighth day showed the previously described area of increased density in the right lower chest to have increased in size. The serum bilirubin was 3.0 mg. per 100 cc. direct and 3.4 mg. indirect. A repeat van den Bergh two days later revealed the serum bilirubin to be 3.8 mg. per 100 cc. direct, and 5.3 mg. indirect.

During the second week the patient had fewer chills. The temperature remained between 101

*On leave of absence.

and 103°F. The pulse gradually rose to 150. She became dyspneic and cyanotic, and a gallop rhythm developed. The respirations became more difficult. The patient became comatose and died on the fifteenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. WYMAN RICHARDSON: I see no reason to doubt the fact that this patient had chronic ulcerative colitis for which she was given an ileostomy, apparently with considerable improvement. In spite of the fact that she had this illness before the Chicago Fair, it is possible for one to have amebic disease even though one does not go to fairs. I shall bring that point up again in a moment.

Beginning with the premise that she had chronic idiopathic ulcerative colitis and that this had gone on to bring about her death, I should like to start the discussion with the total white-cell count, which was very high—46,000. One thinks of causes that will produce as high a white-cell count as that and they are not too numerous, especially in an adult. They are, in general, infection, infarction and tumor. We probably can rule out leukemia of the obvious type on the basis of the blood picture, but if we take these three things, infection, infarction and tumor, and consider them from the point of view of this case, we can get some help from this white-cell count. In infection there is, as you know, a polymorphonuclear leukocytosis that is almost 100 per cent in severe infections. In this case there is said to have been 95 per cent neutrophils; the other 5 per cent are not quoted but were undoubtedly lymphocytes. If there were monocytes, my argument would not hold water very well. Massive infarction, on the other hand, will also produce a very high white-cell count. As you know, patients with mesenteric thrombosis may have a total white-cell count higher than this. In these cases of massive infarction, however, the leukocytosis is much more nearly a total leukocytosis, with increase not only in the polymorphonuclear cells but also in the lymphocytes and monocytes, so that the differential picture is much more nearly like that seen in normal blood. This is not just talk because it has been possible to differentiate infarction and infection by examination of the smear alone. This count therefore tends to militate against massive infarction. Tumor, particularly bronchiogenic carcinoma or carcinoma of the liver, may also produce leukocytosis or a leukemoid blood picture, but in these cases, more often than not, one finds a blood picture showing marked evidence of red-cell regeneration, presumably when the marrow is involved, and one is not so likely to see the complete polymorphonuclear leukocytosis that one does in in-

fection. Also, there are qualitative changes in the cells, which I shall not discuss because we have not the smear before us, and also because I have recently emphasized this too much in discussing other cases. So the evidence from this finding alone is that this patient had infection, rather massive infection with large areas of tissue destruction because of the very high white-cell count. I might add if there is not a considerable area of tissue destruction, and if there is not either a large abscess or many small ones, one does not obtain a great increase in the white-cell count. In a septicemia without abscess formation, even acute septicemia or acute endocarditis, the white-cell count is often at a normal or less than normal level.

I believe that the blood chloride was low because of the diarrhea and sweating.

I shall comment briefly about the bilirubin. The patient was definitely icteric, and the direct reaction of the van den Bergh test was in great preponderance over the indirect, that is, the total percentage of direct bilirubin was about 85. This suggests obstructive jaundice.

If one takes this picture and forgets the x-ray examination for the moment, it seems to me that we have a patient with ulcerative disease of the bowel, and that she very likely developed—as so frequently happens—a thrombophlebitis or pyelophlebitis, which could have involved the system of veins that go to the liver, with the subsequent development of either a single abscess or probably multiple abscesses of the liver. One should consider the possibility of subdiaphragmatic abscess. That still is a possibility, but it would not account for the jaundice. If one explains the jaundice on the basis of liver abscess it seems to me that there is evidence in favor of multiple abscesses, possibly associated also with a low-grade infection of the small ducts, a cholangitis. This is rather definite evidence against subdiaphragmatic abscess. One other bit of evidence is the lack of fluid above the diaphragm, which so often occurs in subdiaphragmatic abscess. There are no data from this record that enable me to rule out amebic abscess, but I believe that it was adequately ruled out. One would ordinarily have to keep that in mind.

I have reached the point where I shall call this liver abscess, probably multiple, with perhaps at least one large one. I should like to stop there, but unfortunately there is a 3-by-5-cm. mass in the chest that does not seem to be readily explained.

DR. MILFORD SEITZ: I do not see the mass on this film. All I can see can be explained by an elevated diaphragm and atelectasis.

DR. CHESTER M. JONES: That is what the doctor who took care of him thought.

DR. SCHULZ: There is no fluid in the chest that I can see. The liver is enlarged.

DR. RICHARDSON: What about the area of decreased density?

DR. SCHULZ: I cannot see that either. This is a gas bubble in the stomach. Someone may have requested films with greater penetration, which showed an area of decreased density in the liver; but it does not show in this film. Everything here indicates atelectasis and an elevated diaphragm, probably due to faulty respiratory effort.

DR. RICHARDSON: Usually when I come to this last stretch I know which horse I am going to bet on. Today I was going to make up my mind after seeing the x-ray films. I was thinking of two things. One was pulmonary infarct, but there was no history of cough with sputum and I was reluctant to accept that. The other possibility was coincidental carcinoma of the lung. From the appearance of the film and from Dr. Schulz's discussion I think that I shall leave the diagnosis as I originally stated it; I shall disregard this area of increased density and say that it was due to atelectasis. My diagnosis is chronic idiopathic ulcerative colitis with liver abscess.

DR. JONES: I am sorry that Dr. McKittrick is not here. This patient was very interesting. Dr. McKittrick and I felt that she had intrahepatic sepsis. As she was followed through her illness there was more and more compression tenderness over the liver, and some right subcostal tenderness. As a rule these signs when combined with a septic temperature are diagnostic of infection within the liver. The liver itself could be palpated even without compression and was quite tender. Before her death we were certain that she had abscess formation in the liver. Because of the succession of chills and fever I thought, and I believe Dr. McKittrick felt the same way, that there were multiple abscesses rather than a single one. Dr. Richardson mentioned the remote possibility of amebic abscess. As a rule a leukocytosis of this degree does not occur with amebic abscess; usually there is only a moderate leukocytosis. The fever can be extremely high in either amebic abscess or amebic hepatitis, but one usually does not get the combination of chills and fever and the intense leukocytosis that was present here.

There are one or two points I should like to add. In the first place there was no excuse for her developing such serious complications in her illness. This should represent a criticism of the medical treatment. The reason was that after

ileostomy she was reluctant to see a physician for any symptoms whatever and subsequently kept away from all physicians. Another point that is worth mentioning is the paucity of cases of ulcerative colitis that show intrahepatic disease. I have always thought that, with serious infection in the bowel draining eventually into the portal area, hepatic disease should develop more frequently. We have, however, seen only two or three cases associated with ulcerative colitis. It is the exception rather than the rule. When infection does occur it is usually localized in the pelvis or perianal region.

I was under the impression that there was one film that did show a probable cavity in the liver substance. On the basis of that and of the clinical picture, roentgenograms were taken after the administration of thorast to determine whether there was a single abscess or multiple ones.

DR. SCHULZ: We have the films here. The liver is riddled with multiple abscesses, which are in contrast to the liver substance where the thorast was taken up by the Kupffer cells.

CLINICAL DIAGNOSES

Multiple liver abscesses.
Ulcerative colitis.

DR. RICHARDSON'S DIAGNOSIS

Chronic idiopathic ulcerative colitis
Multiple liver abscesses.

ANATOMICAL DIAGNOSES

Ulcerative colitis, chronic.
Pylephlebitis, with liver abscesses, multiple
Pulmonary atelectasis.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: The autopsy on this patient showed evidence of long-standing, ulcerative colitis with little if any activity. The bowel wall was markedly thickened, so-called "hose-like," with a very narrow lumen. The widest circumference of the bowel was 2.5 cm., about a quarter of the normal bowel circumference, and at one point it was 1.5 cm. with only a tiny lumen. This atrophy was obviously due to disuse. (In one case, which came to autopsy about ten years after ileostomy, the rectum and sigmoid were so atrophic that in places no lumen could be found.) The liver was adherent to the diaphragm on the right side, was extremely large, weighing 3500 gm., and contained multiple abscesses (Fig. 1). The main portal vein contained an infected thrombus, which extended into both radicles, more into the right than into the left. There was also free pus in the

portal veins. There were many large, greenish abscesses throughout the liver. It is quite obvious that surgical drainage of so many abscesses would have been impossible. We cultured the abscesses and the blood, but recovered only proteus bacilli. The spleen weighed 450 gm, and there was throm-

bos in the splenic vein, but "at no time were they more than two weeks apart." There were no chills, fever, night sweats or chest pain until "recently," when he had noted sharp twinges of pain in the right upper chest unassociated with cough or hemoptysis. There had been no history of inhalation of for-

FIGURE 1 Photograph of Cross Section of Liver Showing Multiple Abscesses and Portal Vein Thrombosis

bosis in the splenic vein. Although we examined many of the veins in the pericolic fat we were not able to find the actual source of the liver abscesses. Nevertheless, the hepatic infection was unquestionably secondary to the colitis.

The bone marrow showed a marked myeloid hyperplasia with replacement of the fat cells. We found nothing but atelectasis in the lung to account for the roentgen shadows in the right lower lobe. This is the only case of liver abscess associated with idiopathic ulcerative colitis that I can recall.

CASE 29462

PRESENTATION OF CASE

An eighteen-year-old boy was first seen in the Out Patient Department, about one year before the present admission, because of hemoptysis of four years' duration.

At the age of thirteen, while playing, he coughed up several large blood clots. He had a similar episode one week later, and these were repeated intermittently up to the day of his visit to the Out Patient Department. The amounts varied from a speck to half a cupful. No statement was made concerning the fre-

quency of the attacks, but "at no time were they more than two weeks apart." There were no chills, fever, night sweats or chest pain until "recently," when he had noted sharp twinges of pain in the right upper chest unassociated with cough or hemoptysis. There had been no history of inhalation of for-

ign body, antecedent upper respiratory infection, known contact with tuberculosis or undue bleeding tendency. He had fractured the left collar bone one year before onset of his symptoms, for which he was in a cast for two months. Examination in the Out Patient Department showed a well developed and well-nourished boy in no distress. The chest was well developed. There was dullness over the right upper lobe posteriorly to the midscapular region and anteriorly to the fourth rib, with occasional expiratory bubbling and coarse crepitant rales posteriorly. Kronig's isthmus was slightly narrowed on the right. The lungs were otherwise clear. The heart was in its usual position and normal in size. The abdomen was negative. There was no clubbing of the fingers.

The blood pressure was 138 systolic, 68 diastolic. The temperature was 98°F, the pulse 60, and the respirations 20.

X ray examination of the chest showed a round, homogeneous soft-tissue mass in the upper posterior mediastinum measuring approximately 11.5 cm. in diameter, without any evidence of calcification or cavity formation. The tumor obliterated the upper portion of the right bronchus. The visible portion of the right

appeared clear. The hilar shadows were normal and equal on both sides. The heart was not remarkable. No definite bone involvement could be seen, but there was a questionable pressure de-

cially at night. No other information was given regarding these attacks except that "he was quite free of wheezes at times." He was free of pain and maintained his weight. Bronchoscopy showed "ex-

FIGURE 1. *Chest Roentgenogram (Bucky) Showing Mass in the Right Upper Chest.*
The arrows point to the irregular area discussed in text.

fect on the right lateral aspect of the fourth dorsal vertebra, with narrowing of the right pedicle. The trachea appeared straight in the midline, and there was no mediastinal displacement. No fluid was present. Bucky films of the chest confirmed the presence of the large mass in the lung. An area of probable slight erosion of the upper aspect of the sixth rib was also seen. There was an irregular air pattern in the region of the mass, probably due to partially collapsed lung that was superimposed on the shadow of the mass (Fig. 1).

While being followed in the Out Patient Department, the patient developed wheezing, espe-

trinsic pressure but failed to reveal the source of the bleeding, although a moderate amount of bright-red blood was seen in the trachea and right main bronchus." Hospitalization was advised but refused.

For the next ten months he remained free from pain, hemoptysis and cough. At the end of this period he obtained a job in a weaving mill, doing heavy labor. Eight days before entry he suddenly became dyspneic while working. The dyspnea forced him to leave his work. Six days prior to admission he developed severe pain in the right anterior chest and he was admitted to a commu-

nity hospital, where x-ray films showed a lobulated tumor mass in the upper half of the right lung, with pleural effusion. Two chest taps yielded 100 and 300 cc. of reddish-brown pleural fluid and gave considerable relief. He was transferred to this hospital.

Physical examination showed a poorly nourished, cyanotic and dyspneic man with anxious, pale facies and visible flaring of the alae nasi on breathing. The right chest was splinted during inspiration. There were dullness and diminished tactile fremitus and breath sounds over the right upper and lower lobes. Dullness was obtained over the right middle lobe, with egophony and increased tactile fremitus. Pectoriloquy was heard over the right upper lobe posteriorly and over the middle lobe anteriorly. The diaphragmatic excursion was poor on the right. The heart was normal. The remainder of the examination was not remarkable.

The blood pressure was 130 systolic, 60 diastolic. The temperature was 99.6°F., the pulse 128, and the respirations 25.

Examination of the blood showed a red-cell count of 4,100,000, with 75 per cent hemoglobin. The white-cell count was 11,000 with 89 per cent neutrophils. A blood Hinton test was negative. The prothrombin time was 28 seconds (normal, 16 seconds); the hematocrit was 39.2 per cent. The nonprotein nitrogen was 10 mg. per 100 cc., and the protein 5 gm. The van den Bergh test was normal. Urinalysis was negative.

X-ray examination of the chest, almost a year after the first one, showed the tumor mass still present. The right pleural cavity was filled with a fairly large amount of fluid and there was partial collapse of the right middle and lower lobes, which had a honeycombed appearance. The left lung appeared clear, but there was questionable crowding of the markings in the left lower lobe.

During the next ten days, three chest taps yielded 2800, 1500 and 1000 cc. of dark, bloody fluid, which on smear and culture was negative for organisms. No tumor cells were seen in the sediment.

Repeated x-ray studies after the taps showed that, instead of a fluid level, there was an area of increased density with irregular markings extending along the lateral axillary line. There were numerous irregular areas of decreased density in the right upper chest, either in the tumor or in the pleural cavity. None of the visualized bones, especially the ribs, showed evidence of destruction, and no other changes were noted. Another bronchography, a year after the first, was negative. No evidence of intrinsic or extrinsic tumor was seen.

On the eleventh hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. AUSTIN BRUES: I should like to discuss this case mainly from the standpoint of its natural history, which seems rather specific and characteristic. The boy had a lesion that had apparently existed for at least five years and first gave symptoms at the age of thirteen. The history divides itself into three phases. First, there was a long period in which the only symptom was rather persistent hemoptysis. Secondly, after four or more years there was a period of wheezing, suggesting bronchial compression. Finally, there was an acute sudden episode with pain in the anterior chest and dyspnea, and the rapid development of bloody pleural effusion. To this history we can add the finding of a round mass inside the chest, apparently arising from the posterior mediastinum, and presumably the seat of the symptoms. We have no evidence of disease elsewhere in the body, except that he had a prolonged prothrombin time and a low serum protein. However, the van den Bergh test was normal, and we have insufficient evidence to implicate the liver.

The question that we have to settle is, What sort of isolated mass in this location will progress to give this sort of history? Obviously this was not an acute infectious process. It might conceivably have been due to tuberculosis of the bronchial nodes or to tuberculosis arising from the spine. The entire early course of the process, however, was essentially silent except for hemoptysis, and there was no evidence of infection or tuberculosis elsewhere. I consider that an infectious process of any sort is unlikely. A hydatid cyst of the mediastinum, first giving rupture into the bronchus, later into the pleural cavity, might give rise to this sequence of symptoms; but we have no reason to suspect an unusual environmental association and the patient had no eosinophilia. Moreover, no eosinophilia was noted even after extension of the process into the pleural cavity, which, if due to rupture of a hydatid cyst, would have caused a certain amount of the cyst contents to be absorbed.

In a young patient we must think of a congenital anomaly—brouchostenosis or a lung cyst. A condition of this sort would most likely progress to serious symptoms only if it became secondarily infected. Again I point out that infection was not a perceptible element in the clinical picture.

This brings me to tumor. The long duration is in favor of a benign tumor or a tumor that underwent malignant change late, that is, during the last year. Lymphoma can exist for a period of

many years without characteristic progression. Such a lymphoma would be the giant follicular type or a very scirrhus type of Hodgkin's disease. I should point out that hemoptysis is a rare symptom in lymphoma, and if it does occur it suggests that one is dealing with a particularly invasive form, which would not be the type giving a long, relatively quiescent history. It seems to me the presumptive diagnosis is a teratoma, not well enough differentiated, as is the classic dermoid cyst, to show calcification by x-ray or to yield hairs or other recognizable elements in the sputum or pleural fluid. The life history of this process is emphatically in favor of this diagnosis. These tumors appear early in life, may give their first symptoms at puberty or later, and sometimes give hemoptysis over a long period. Eventually they are likely to undergo malignant change or to rupture. I should be in favor of rupture as the explanation of the final episode here because of the extreme acuteness of its onset, although invasion of the pleura is a possible explanation, and would point to malignant change. I do not believe that it is necessary to assume, however, that the process had become malignant.

The fly in the ointment is the location of the lesion. It was apparently posterior in position, whereas dermoid cysts and teratoid tumors are almost always found in the anterior mediastinum.

Typical neoplasms of the posterior mediastinum are of neural origin. The history, however, is against one of these. They grow behind the pleura, and one would not expect cough and hemoptysis to be the earliest symptoms. Because of their location they frequently produce Horner's syndrome or pain early in the course of their development. The first symptom here was hemoptysis, which suggests that the lesion was near the bronchi and not posterior to the pleura. There are various rare tumors, such as chondroma, endothelioma, angioma and lipoma, that might arise in this location. There is one thing somewhat in favor of the possibility of an angiomatous tumor—the characteristic picture of bleeding with which the history started.

I wonder if we might see the x-ray films.

DR. LAURENCE L. ROBBINS: These films show a fairly smooth mass arising posteriorly in the mediastinum, or apparently arising in the mediastinum. The one thing in favor of the neural type of tumor, in addition to its location posteriorly, is that there is a definite erosion of the pedicle of the fourth thoracic vertebra. So far as the ribs are concerned, I am not at all sure that there are any definite changes. This is the shadow described as an irregular area overlying the mass and representing aerated lung (Fig. 1). I am not

convinced of that. The only other possibility is that it is fat within the tumor. It is difficult to be sure, and most likely it is air in the overlying lung.

These are the films taken at the time of the second admission; they show a large amount of fluid in the pleural cavity and disease in the right lower lobe. The mass and the shadow, which is either air or fat, are still present. This view, with the patient on his side, was taken after a tap to determine whether there were pleural metastases. There are irregularities along the pleura, but they are most likely masses of fibrin rather than metastases, because fibrin is usually present with bloody fluid. One cannot, however, positively rule out metastases.

DR. BRUES: I am going to let my diagnosis rest on the history rather than on the location and to assume that the tumor arose near the bronchi rather than posterior to the pleura. I shall say that it was a teratoid tumor.

DR. RICHARD H. SWEET: Might I say as a representative of the service that saw the man before he was operated on that we did not believe, at least I did not believe, that he had a benign tumor. In fact I have never seen a benign mediastinal tumor produce bloody effusion. My personal diagnosis was, and I suspect some of the others who saw the patient were of the same opinion, a malignant tumor, probably teratoma. Dr. Brown operated on this patient. What does he say?

DR. ROBERT K. BROWN: We did a thoracoscopy and did not see much except a large empty space with implants of fibrin on the chest wall. Biopsies were taken of these and they were not malignant. Since we still thought that the tumor was malignant, the patient was explored. The preoperative diagnosis was malignant neurogenic tumor or neurofibrosarcoma, because we thought that it arose in the posterior mediastinum.

At operation there was a large cystic mass in the upper part of the right thorax. This contained a hole, and the rupture was probably the cause of the bloody pleural fluid. A biopsy specimen was taken from the wall of the cystic mass at the edge of the rupture, and on cutting, it was evident that there was lung tissue adherent to the wall of the mass. I thought this was collapsed lung plastered over the cyst. The patient died following operation.

DR. BENJAMIN CASTLEMAN: Would anyone want to venture a diagnosis at this point?

DR. RALPH ADAMS: I have no idea what was wrong with this man. I think that the lesion arose in his lung because of two factors that almost have to place it in the lung. First, there was frequently recurring hemoptysis. There was

a rule here a few years ago that daily hemoptysis meant carcinoma. After three years we found an exception in a case of bronchiectasis. That was the first exception, and I have since encountered one other. In the second place, this man had a wheeze, indicative of developing bronchial obstruction. My personal diagnosis, if I were about to operate, would be slowly growing sarcoma of the lung. I believe that sarcoma in the lung has occurred in this hospital only once.

DR. SWEET: That is correct.

DR. ROBBINS: How do you explain the erosion of the pedicle of the fourth thoracic vertebra if it is a primary lung tumor?

DR. ADAMS: I could not explain it as a primary lung tumor unless it were sarcoma of the lung. If it were a sarcoma arising in the mediastinum and invading the lung the explanation would be easy.

DR. GEORGE W. HOLMES: Is there anything to show why there was such a delay between the first roentgenologic examination and operation?

DR. CASTLEMAN: The patient refused operation.

CLINICAL DIAGNOSIS

Superior mediastinal tumor, with rupture into the pleural cavity.

DR. BRUES'S DIAGNOSIS

Teratoid tumor of mediastinum, with rupture into the pleural cavity.

ANATOMICAL DIAGNOSIS

Neurofibroma of lung, with cystic degeneration and rupture into the pleural cavity.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The material that Dr. Brown removed from the cyst or tumor was composed

of spindle-shaped cells, some in whorls, which strongly suggested a neurogenic benign tumor. In favor of this was the presence of huge numbers of so-called "foam cells," that is, large lipid-laden mononuclear cells. That is probably the reason why Dr. Robbins thought he saw fat in the tumor. Certainly a large part of the tumor was composed of cells filled with fat. Lipoid degeneration of a neurofibroma is not at all uncommon. We were fairly certain that the tumor was benign.

The autopsy specimen shows that this tumor was within the lung. It had broken down so much that it had become cystic. This cystic mass, which was about 7 or 8 cm. in diameter, communicated with the apical branch of the right upper lobe bronchus, and this certainly accounted for the long-standing hemoptysis. I believe that the tumor probably arose close to the bronchus, or perhaps in it, and degenerated slowly as it gradually increased in size. There was lung tissue surrounding the cyst on all sides except over the area where it had ruptured.

We have had 2 other cases of neurofibroma of the lung. One was in a man of thirty who had all the signs and symptoms of a bronchial adenoma, that is, bronchial obstruction with hemoptysis. Bronchoscopic biopsy showed it to be a neurofibroma, and Dr. Benedict removed the tumor via the bronchoscope in three operations.

DR. EDWARD B. BENEDICT: The patient was completely relieved by bronchoscopy. I have not seen him for three years. He had no apparent lung damage.

DR. CASTLEMAN: The other case was one in which Dr. Churchill performed a lobectomy for a well-circumscribed tumor that pressed on a bronchus but had not actually invaded its mucosa.

UNITED WAR FUND

No one knows better than physicians the valuable contribution to community life made by the two hundred and sixty-four hospitals, dispensaries, clinics and other health and social services that share in the Greater Boston Community Fund. Possibly no group of citizens gives more of itself to the 400,000 persons who depend on these agencies to help adjust themselves to life's problems. In either case, or perhaps because of both, physicians of Greater Boston are bound to be generous to the appeal now being made for these community services. But that's not all. The \$7,500,000 goes two ways. Whereas approximately \$5,500,000 is al-

located to Community Fund needs, \$2,000,000 goes directly to such war-related services as the USO, War Prisoners Aid, United Seamen's Service and relief of the stricken peoples of the Allies.

The physician must think twice when the solicitor asks for his gift this year. He will want, first of all, to do something for that bright-eyed little youngster whose parents have deserted him. Then, of course, he must help the USO, which is doing such a magnificent job everywhere, and he cannot resist the appeal to make a token gift for all the brave people overseas who are suffering unknown hardships in this war, while he and his family live safely and snugly at home. GIVE — BECAUSE YOU CARE.

SO LITTLE TIME

THE majority of us are so constantly confronted with the perplexing problem of fitting our commitments into an allotted daily twenty-four hours that we view with amazement and despair the activities of individuals like, let us say, Prime Minister Churchill. Writer of history and maker of history, he has found time in his abundant life to fight in one war and direct another, to make books and speeches, to lay bricks, to paint pictures and to save an empire.

John Buchan, later Lord Tweedsmuir, was a writer of note before he became a statesman and finally governor general of Canada; we are familiar with the dual activities of Disraeli, romantic novelist and statesman without peer, who presented Queen Victoria with the empire that Churchill has kept intact; Bulwer-Lytton was a novelist and statesman, if not pre-eminent as either; General Lew Wallace wrote one of our really outstanding historical novels; and General Patton, we are told, is a poet of no little merit! These men, whether satisfied with their achievements or not, have at least found time to make some contributions to the world in which they found themselves.

It is a common experience of those who are sensitive to life, who feel the need of some personal

fulfillment, some satisfying justification for their existence, to awaken rather late, and suddenly, to a realization of life's self limitation. The allotted years are never really enough, nor does anyone know the sum and extent of his allotment. We accumulate, as we go, a squirrel cage full of little duties and activities that may keep us moderately comfortable because of a real communion with our selves, but we seldom find time to realize the dreams of youth or to search out the various talents that may lie in each one of us. We use our work and our play, our recreations and our amusements, as anodynes to keep us from a full realization of our relative futility.

Some stern moral censor devised a comfortless motto for sundials. What could possibly be more effective than the ominous epigram, "It is later than you think," to destroy the pleasure of a sunny hour in a garden? John Marquand must have been deciphering this legend just before he developed the theme of middle aged frustration in his newest book, *So Little Time*. Middle age is a bit late to realize how little time there is, but it is the period of life at which we usually appreciate it—except, perhaps, for those happy extroverts who never realize it at all.

Time is an elusive commodity, and the greatest gift that man can have or develop is the ability to use it intelligently, if not industriously. Every individual is given the same amount of time in each twenty four hours—which sounds like a truism, but is really a fundamental and dimly appreciated truth. The only difference in this respect is that some of us are given more units to use than are others. Next in importance is a sense of values that will help us to see clearly those of our own qualities that can be developed and the wishes that can reasonably be fulfilled. If we wish to avoid frustrations, we must choose the goal that is within our reach, we must work steadily toward it, and we must start early enough. The only qualification that need apply to this goal is that it must satisfy the person who is seeking it.

MEDICAL EPONYM

KUMMELL'S DISEASE

Professor Hermann Kummell (1852-1937) described this condition in a paper, entitled "Die rarefiierende Ostitis der Wirbelkörper [Rarefactive Ostitis of the Vertebral Bodies]," published in the *Verhandlungen der Gesellschaft deutscher Naturforscher und Aerzte* (64: 282-285, 1892). A portion of the translation follows:

To sum up, we are dealing with an injury, often of trifling nature, that affects the vertebral column either directly or indirectly, and so far as the immediate effect is concerned leaves no sign of its occurrence. After months of complete health, there begins a rarefactive process in the vertebrae which finally results in atrophy of their substance. Suppuration does not occur in this pathologic process as in tuberculous spondylitis, nor is there any thickening of the bony mass, as in syphilitic processes, or bony deposition and change, as in arthritis deformans.

The diagnosis of the condition, after what has been said, offers no great difficulties and if we consider the most important factors—the effect of trauma in an otherwise healthy person, transitory pains and gibbus formation later, with the accompanying local and referred discomfort—confusion with tuberculous spondylitis or other disease of the vertebrae is easily avoided.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

CUSHMAN—HOWARD L. CUSHMAN, MD of Methuen died November 4. He was in his fifty-eighth year.

Dr Cushman received his degree from Boston University School of Medicine in 1908. Up to the time of his death he served as school physician in Methuen. He was a member of the Massachusetts Medical Society, the American Medical Association, the Lawrence Medical Association and the Lawrence Medical Club.

His widow and a brother survive.

DAVID—ERNEST J. DAVID, MD of Lowell died July 11. He was in his sixtieth year.

Dr David received his degree from Laval University Faculty of Medicine, Quebec, in 1915. He was a member of the Massachusetts Medical Society and the American Medical Association.

HALLORAN—ROD D. HALLORAN, MD of Walham died November 10. He was in his fiftieth year.

Dr Halloran received his degree from Columbia University College of Physicians and Surgeons, New York, in 1920. He served as an intern at the Newark (New Jersey) City Hospital from 1920 to 1922 and later as assistant physician at the New Hampshire State Hospital in Concord. He joined the staff of the Boston State Hospital in 1922 and served as assistant superintendent in 1928 and 1929. In 1925 he and Dr Abraham Myerson of Boston founded the hospital's research department. In

1933 Dr. Halloran was named the first superintendent of the Metropolitan State Hospital, a post that he held until he took leave of absence in July, 1942, to be commissioned a colonel in the Army Medical Corps. His job in the Army was to organize and co-ordinate the neuropsychiatric service in all Army branches, at home and overseas. He was a member of the American Psychiatric Association, New England Society of Psychiatry, Massachusetts Medical Society and American Medical Association, as well as professor of clinical psychiatry at Tufts College Medical School.

His widow, a daughter and a son survive.

KENNISON—**FREDERICK M. KENNISON, M.D.**, of Boston, died July 31. He was in his eighty-first year.

Dr. Kennison received his degree from Tufts College Medical School in 1905. He was a member of the Massachusetts Medical Society and the American Medical Association.

MILLER—**HOWARD S. MILLER, M.D.**, of Taunton, died September 6. He was in his fifty-sixth year.

Dr. Miller received his degree from Middlesex University School of Medicine, Waltham, in 1922. He was a member of the Massachusetts Medical Society and the American Medical Association.

THOMPSON—**CLARA L. THOMPSON, M.D.**, of Boston, died September 16. She was in her seventy-third year.

Dr. Thompson received her degree from the College of Physicians and Surgeons, Boston, in 1915. She was a member of the Massachusetts Medical Society and the American Medical Association.

WASHBURN—**FRANK H. WASHBURN, M.D.**, of Holden, died November 10. He was in his seventy-third year.

Dr. Washburn received his degree from Tufts College Medical School in 1899. Dean of physicians in Holden, he was a founder and chief surgeon at the district hospital and a fellow of the American College of Surgeons. He was consulting surgeon at the state sanatorium and the United States Veterans Hospital, both in Rutland Heights. He was a councilor of the Massachusetts Medical Society, past president of the Worcester District Medical Society, a member of the American Medical Association, American Urological Association, New England Urological Society, Trudeau Society, American Society of Regional Anaesthesia and the New England Roentgen Ray Society.

His widow, a daughter and two sons survive.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

GONOCOCCUS CULTURE SERVICE

The Massachusetts Department of Public Health announces a new service to physicians of Massachusetts. The superiority of cultural methods over smear methods in detecting gonococci in certain types of gonococcal infections is now well recognized, and the department is of the opinion that

utilization of cultural methods will be of aid in the control of such infections.

Mailing of specimens. Recent advances in methods of sending specimens through the mail for cultural studies indicate that such delayed cultures are less efficient than cultures planted immediately after obtaining the specimens, but considerably more efficient than the examination of stained smears. Any physician wishing to utilize this service should request mailing kits from the Bacteriological Laboratory, Room 527, State House, Boston. Instructions for obtaining specimens will accompany each mailing outfit.

Storage of mailing outfits. The fluid in which the specimens are placed for mailing will maintain its efficiency only if kept in the icebox, and for a period not to exceed six weeks. All containers will be stamped with an expiration date, and if not used by that time they should be returned to the laboratory, whereupon fresh outfits will be sent to the physician on request. It should be emphasized that mailing outfits kept at room temperature before being inoculated do not give satisfactory results.

Relative value of cultures. Cultures are but slightly more efficient than smears in detecting gonococci in male patients who have a purulent urethral discharge, but far more efficient than smears in detecting gonococci in prostatic secretions as a test of cure. Cultures are more efficient than smears in detecting gonococci in both adult and immature females in all stages of gonococcal infection.

Precautions to ensure satisfactory specimens. The efficiency of the cultural method depends greatly on the physician's care and expertness in obtaining satisfactory specimens. The instructions on the card in the outfit are brief but if followed in detail should ensure satisfactory specimens.

COMMUNICABLE DISEASES IN MASSACHUSETTS FOR OCTOBER, 1943

RÉSUMÉ

DISEASES	OCTOBER 1943	OCTOBER 1942	SEVEN-YEAR MEDIAN
Anterior poliomyelitis	57	5	11
Chicken pox	485	291	333

Whooping cough	322	731	555

*Pfeiffer-bacillus meningitis only other form reportable previous to 1941.

COMMENTS

The month of October has produced a long list of diseases more or less above the seven-year median. Anterior poliomyelitis is still at a point five times that of the seven-year median, but, on the other hand, the current

month's figure is less than half that of last month. Apparently the summer's outbreak is well on the wane.

Scarlet fever, which has been at an unusually high level all this year, seems to have begun again the usual seasonal upswing following the summer drop.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anterior poliomyelitis was reported from: Amherst, 1; Arlington, 1; Attleboro, 3; Beverly, 7; Boston, 2; Cambridge, 2; Danvers, 3; Fall River, 6; Fitchburg, 1; Hamilton, 1; Hopedale, 1; Ipswich, 1; Lee, 1; Lowell, 2; Lynn, 2; Medford, 3; Methuen, 1; Natick, 3; New Bedford, 2; North Attleboro, 1; North Reading, 1; Norwood, 1; Plymouth, 1; Quincy, 1; Saugus, 1; Seekonk, 1; Swansea, 2; Topsfield, 1; Waltham, 2; Walpole, 1; Watertown, 1; Weymouth, 1; total, 57.

Anthrax was reported from: Haverhill, 1; total, 1.

Diphtheria was reported from: Boston, 6; Bourne, 1; Chicopee, 1; Lowell, 3; Medford, 1; New Bedford, 2; Salem, 2; Somerville, 1; Taunton, 1; total, 18.

Dysentery, bacillary, was reported from: Beverly, 2; Boston, 3; Brockton, 1; Brookfield, 1; Cambridge, 1; Easthampton, 1; Malden, 11; Northampton, 1; Wellesley, 3; total, 24.

Encephalitis, infectious, was reported from: Worcester, 1; total, 1.

Malaria was reported from: Amherst, 2; Brookline, 1; Fort Banks, 11; Fort Devens, 2; total, 16.

Meningitis, meningococcal, was reported from: Arlington, 1; Beverly, 1; Boston, 12; Brookline, 1; Cambridge, 1; Chelsea, 2; Chelsea Naval Hospital, 3; Fall River, 1; Fort Devens, 2; Framingham, 1; Lowell, 1; Needham, 1; New Bedford, 1; Newburyport, 1; Newton, 1; North Brookfield, 1; Plymouth, 1; Salem, 1; Scituate, 1; Somerville, 1; Southbridge, 1; Waltham, 2; Wellesley, 1; Weymouth, 1; Winthrop, 1; Worcester, 4; total, 45.

Meningitis, other forms, was reported from: Boston, 3; Cambridge, 1; Haverhill, 1; Ipswich, 1; Marblehead, 1; Medford, 1; Methuen, 1; Northbridge, 1; Salem, 1; Springfield, 1; Waltham, 1; total, 13.

Meningitis, undetermined, was reported from: Boston, 4; Milton, 1; Palmer, 1; Quincy, 2; Springfield, 1; Worcester, 2; total, 11.

Salmonella infections were reported from: Boston, 1; Bridgewater, 1; Cambridge, 1; Chelsea, 1; Chicopee, 2; Leominster, 1; Lowell, 1; Lynn, 2; Medford, 1; Westboro, 1; Weymouth, 1; Worcester, 1; total, 14.

Septic sore throat was reported from: Boston, 6; Brockton, 1; Malden, 1; Natick, 1; Swampscott, 1; total, 10.

Tetanus was reported from: Springfield, 1; total, 1.

Trachoma was reported from: Medford, 1; total, 1.

Tularemia was reported from: Falmouth, 1; total, 1.

Typhoid fever was reported from: Brookfield, 1; Dartmouth, 1; Medford, 1; New Bedford, 1; total, 4.

Typhus fever was reported from: Chelsea, 1; total, 1.

Undulant fever was reported from: Adams, 1; Franklin, 1; Methuen, 1; Southbridge, 1; Southwick, 2; total, 6.

CONSULTATION CLINICS FOR CRIPPLED CHILDREN IN MASSACHUSETTS UNDER THE PROVISIONS OF THE SOCIAL SECURITY ACT

WAR ACTIVITIES

CIVILIAN DEFENSE

MANUAL ON EMERGENCY CARE OF INJURED

The immediate care that can be given to injured persons at the site of a disaster and the technics of transporting them to safety and medical attention are described in a new manual issued by the Medical Division, Office of Civilian Defense. The work is based on procedures and organization developed by the OCD and on careful study of three years of British and other air-raid experience. The 117-page book is divided into three parts: "Civilian Defense," "Emergency Field Care," and "Transportation of the Injured."

Part I describes the organization and operation of the field casualty service developed by the Medical Division, which includes mobile medical teams, based on hospitals wherever possible; express parties, made up of a medical team, a rescue squad, an ambulance, and a car for sitting cases, dispatched through the control center to a disaster for immediate action; casualty stations for the care of casualties with minor injuries; stretcher teams; and ambulances.

Part II includes a discussion of the injuries and conditions most frequently encountered in wartime disasters—namely, hemorrhage, shock, fractures, burns, suffocation and carbon monoxide poisoning. There are chapters on principles of bandaging, with detailed illustrations; marking of casualties and disposal of the dead; methods of blanketing a casualty; and methods of lashing a casualty to a stretcher.

Special attention is given to crush and blast injuries. Crushing wounds may result from falling masonry, girders, beams or whole floors dislodged by bomb explosions. Although these injuries may be immediately fatal, casualties often show little sign of injury when released, the manual points out. Their condition may appear good for a few hours and yet they may die of kidney failure several days later. Directions for first aid are included, and workers are warned that any person who has been trapped by debris which has pressed on any part of the body must be regarded as a serious casualty. The importance of administering by mouth abundant quantities of fluids and alkalis (sodium bicarbonate) is stressed. Persons exposed to blast from high explosives may also suffer serious internal injury without external evidence of it. The manual urges all persons concerned with the handling of casualties to suspect blast injuries in every person found near the site of a bomb explosion, especially those who have obviously suffered injury and yet show no external evidence of it. More extensive discussions of these two types of injury are included in the recent OCD publication, *Clinical Recognition and Treatment of Shock*.

Part III, devoted to transportation of the injured, describes regular and improvised stretchers and gives directions for stretcher bearing, with a separate section on types of injury that require special care in moving. Another chapter explains methods of carrying the injured without stretchers, and the final chapter explains the ambulance

service of the civilian-defense organization and presents specific instructions for loading and unloading ambulances. The latter instructions describe procedures required if war gases are encountered.

The manual is intended primarily for the training of rescue workers, medical auxiliaries, ambulance drivers and attendants, and stretcher bearers of the Emergency Medical Service. In the appendix are a schedule of training based on the manual; the OCD operations letters describing the work of stretcher teams, the Rescue Service and instructions on self-aid in case of exposure to war gas; and a section on electrical hazards.

MISCELLANY

GRANT TO PROMOTE MEDICAL INFORMATION

Dr. Ross G. Harrison, chairman of the National Research Council, has announced the acceptance by the Council of a grant from the Johnson and Johnson Research Foundation in the amount of \$75,000. The grant was made to enable the Division of Medical Sciences, under the chairmanship of Dr. Lewis H. Weed, to gather medical information pertaining to the war effort and to disseminate summaries. The program of the Division of Medical Sciences of the National Research Council contemplates coverage of the various medical reports and bulletins that emanate from civilian and military activities throughout the world. The enterprise should fill a much needed gap in the war effort in medicine, since one of the greatest difficulties encountered in medicine today lies in providing adequate up-to-date information to the medical officers of the armed services, both in this country and abroad, and in making the experience of war medicine available, so far as possible, to civilian physicians.

The Johnson and Johnson Research Foundation appropriation to the National Research Council becomes immediately available; in accordance with present plans it will be utilized in the period up to June 30, 1945. A central office will be established in Washington and reporters will be appointed in various foreign countries, so that a staff of special observers abroad will be working under the direction of the central office. The various theaters of operation present medical problems in which climate, season of year, distribution of insects and distribution of disease, all play different roles. Reports from widely separated parts of the world will be of the greatest medical importance and it is hoped that with the combined effort much of significance will be achieved.

AMA MEETING IN 1944

The Board of Trustees have recently announced that the 1944 annual session of the American Medical Association will be held in Chicago, June 12 to 16. The scheduled meeting place, St. Louis, had to be given up, owing to lack of adequate accommodations. The meetings of the House of Delegates will be held at the Palmer House, which will also house the Scientific Exhibit. The Technical Exposition will be installed at the Stevens Hotel.

The Scientific Exhibit will cover all phases of medicine and the medical sciences with particular emphasis on graduate medical instruction for the physician in

general practice. Application blanks for space in the exhibit are now available and may be obtained by communicating with the Director, Scientific Exhibit, American Medical Association, 535 North Dearborn Street, Chicago 10.

BOOK REVIEWS

Air-Borne Infection: Some observations on its decline. By Dwight O'Hara, M.D. 8°, cloth, 114 pp., with 11 charts. New York: The Commonwealth Fund, 1943. \$150.

The author challengingly but plausibly includes in this series of essays on air-borne infection not only a consideration of the scope of preventive medicine but also chapters on smallpox, streptococcal infections, rheumatic fever and the aging process, in addition to his discussion of upper respiratory infections and tuberculosis. He suggests that preventive medicine has enjoyed over the years the company of a silent partner, and attempts to analyze the spontaneous or indirect factors that have influenced the results of man's conscious effort at control of infection. Health—the physiologic integrity of the tissues—must not be confused with the mere control of conditions prejudicial to health.

This book will wear well because it thoughtfully interprets some rather striking factual data. The contributions of some investigators rust out because their squeaking metallic facts are not sufficiently oiled with interpretive thought. This little volume is well lubricated. It is also well written, and in this respect, as well as in thought and content, it follows in the tradition of such contributions as that of Bigelow on self-limited diseases. It will be read with pleasure and profit by all who are concerned with the problem of keeping men alive and well.

Biochemistry and Morphogenesis. By Joseph Needham. F.R.S. 4°, cloth, 787 pp., with 328 illustrations. Cambridge, England: University Press, 1942. \$1250.

No laboratory should be without this most important work, which deals with one of the fundamental problems of biology by a distinguished investigator. The purpose of the author is to show that the disciplines of chemistry and morphology are closely related. This object is achieved by bringing together the experimental evidence that shows that levels of organization are not alone anatomical but molecular, colloidal, paracrystalline, protein structural and fibrous macromolecular. All these orders are the natural consequence of the properties of matter.

The present study considers the chemical changes that go on during embryonic development. In 1931 the first successful embryonic inductions were obtained; this opened the way to the biochemical investigation of morphogenetic hormones. These substances are discussed in Part 1 under the heading of "The Morphogenetic Substratum," Part 2 deals with "The Morphogenetic Stimuli," that is, the isolation of the inductor substances. Part 3 discusses "The Morphogenetic Mechanisms."

There is a valuable glossary of 8 pages, and an excellent bibliography covers 70 pages. In addition there is a general index, as well as an index of animals, plants and genes. Every student of biology will find this book invaluable.

BLOOD-PRESSURE DETERMINATIONS IN PATIENTS WITH ESSENTIAL HYPERTENSION*

III. Evaluation of Sympathectomy over a Three-Year to Five-Year Period

DAVID AYMAN, M.D.,† AND ARCHIE D. GOLDSHINE, M.D.‡

BOSTON

THE treatment of essential hypertension is far from established. The hope of successful therapy by renal extract has not materialized. Sympathectomy by one method or another has been performed in the past eighteen years in about 3000 cases, and the reports of results are also becoming numerous. The literature, however, indicates widely varying opinions concerning the effect of the different operations on the levels of blood pressure and the course of the disease. The present paper reports some preoperative and postoperative observations made during the past six years in an unusually controlled group of patients with essential hypertension. The observations of blood pressure were made not only by the usual clinic methods, but in addition by readings taken at the start of, during and after twenty-minute clinic rest periods¹ and the determination of the blood-pressure levels, made at home by the patients themselves both before and after operations.² In some cases, the data have been obtained continuously over periods as long as five years.

LITERATURE

Sympathectomy as a therapeutic measure for hypertension was apparently first suggested by Daniélopou³ in 1923. The first operation seems to have been done by Rowntree and Adson⁴ in 1925. The second, third and fourth lumbar ganglions were removed without significant effect in a patient with malignant hypertension. In 1927, Pieri⁵ described his technic of splanchnicectomy for hypertension, but did not mention his results.

These initial efforts have undergone much elaboration and modification. The first change was by Adson⁶ himself, who cut the sympathetic nerves by resection of the anterior root.⁶ This operation, requiring laminectomy, was apparently effective but has been given up because of its difficulty and high mortality. In 1934, Craig and Brown⁷ carried out unilateral and bilateral infradiaphragmatic splanchnicectomy, in a few cases with resection of the first and second lumbar ganglions. In 1935, Peet⁸ reported his initial studies of supra diaphragmatic bilateral splanchnicectomy. In 1937, Allen and Adson⁹ described subdiaphragmatic splanchnicectomy with lumbar ganglionectomy, adding, in some cases, partial adrenalectomy. In 1938, we¹⁰ had a case subjected to a seven-stage, almost total, bilateral sympathectomy. In 1940, Smithwick¹¹ combining the Pieri-Peet and Allen-Adson methods, described a two-stage bilateral transdiaphragmatic operation by which he removes the entire great splanchnic nerves, their aortic branches and the sympathetic ganglions—the ninth, tenth, eleventh and twelfth dorsal ganglions, the first lumbar and occasionally the second lumbar ganglion. Finally, Grimson¹² has reported a group of almost total, bilaterally sympathectomized cases.

The results in these and many other studies are widely divergent; they are not analyzed here.

METHODS USED IN THIS STUDY

Most therapeutic studies of hypertension are seriously marred by unscientific methods of control: the studies of surgical therapy thus far reported are no exception. In a previous paper, one of us (D. A.) indicated pitfalls to be avoided and outlined suggestions for proper controls in evaluating such therapy. The present paper is a report of findings made by these methods, includ-

ing blood-pressure determinations at each clinic visit during a twenty-minute rest period, placebo treatment and, in addition, the method of having the blood pressure taken at home by an adequately instructed person or by the patient himself. In most cases, home observations were made both before and after operation. Postoperative observations were made almost continuously in some cases over a three- to five-year period. All blood-pressure readings, unless otherwise indicated, were made with the patient seated, the arm resting on a table.

Further standard methods of study included intravenous pyelography, sedative tests, pressor tests (breath-holding¹³ and ice water¹⁴), electrocardiograms, seven-foot roentgenograms, observations of the ocular fundi, postural tests^{9,15} and renal-function tests (nonprotein nitrogen, phenol-sulfonephthalein and dilution-concentration). Most of these tests were repeated postoperatively, usually once a year.

DETAILS OF CASES STUDIED

Fourteen cases were studied before and after sympathectomy. In Table 1 are listed the preoperative and some of the postoperative findings in each case. In Case 14, death occurred a few days after operation. Cases 1, 5 and 6 were not studied preoperatively by the home method but have been evaluated by the usual clinical methods and in addition twenty-minute rest periods. This table also shows that observations were detailed and were made over a long period. The patients represent all stages of hypertension, including 2 cases with papilledema. The heart was either normal in size or only slightly enlarged. The electrocardiograms varied from normal to the usual signs of left-ventricular strain. The patients in Cases 10 and 11 had attacks of angina pectoris on exertion; those in Cases 1, 7, 11 and 12 had cerebral hemorrhages during the preoperative period. The patient in Case 6 was the only one with renal failure. All the patients were under the age of fifty years at the time of operation.

NUMBER AND TYPES OF OPERATIONS EMPLOYED

In Tables 2 and 4, it is seen that sympathectomy was performed in every degree of extensiveness. At the outset of the study, bilateral, two-stage supradiaphragmatic splanchnicectomy with resections of the tenth, eleventh and twelfth dorsal sympathetic ganglions was performed in 10 cases. In Case 4, an interval of four months with home and clinic study elapsed between the first and second stages, permitting evaluation of the unilateral operation. In 6 of these 10 cases, after adequate evaluation of the initial bilateral operation, further sympathectomy was done: a two-stage bi-

lateral infradiaphragmatic resection of the first, second and third lumbar ganglions. In Case 7, this was followed by three more operations, in which the stellate ganglion and the dorsal ganglions through the eighth were removed on the right side, and the lower inferior cervical and first, second, sixth, seventh, eighth and ninth dorsal ganglions on the left side. This represented an almost total sympathectomy. In Case 10, a left supradiaphragmatic splanchnicectomy and a right dorsolumbar transdiaphragmatic splanchnicectomy were done. The latter consisted of the removal of the ninth, tenth, eleventh and twelfth dorsal ganglions, the first lumbar ganglion and the splanchnic nerves.¹¹ Finally, in Cases 12 and 13, a bilateral dorsolumbar transdiaphragmatic resection was done, an interval of seven weeks of home and clinic study elapsing between the two stages in Case 12. We are greatly indebted to Dr. Reginald H. Smithwick for the performance of all the operations.

RESULTS OF SYMPATHECTOMY

Blood-Pressure Levels

The chart (Fig. 1) of a successful case (Case 11) will first be discussed, and the details of our preoperative and postoperative methods and findings will be explained. This forty-four-year-old woman was first studied in our clinic from December, 1937, to April, 1938. At each clinic visit, she was seated in a quiet room, and blood-pressure readings were taken by one of us at the start of and during a twenty-minute rest period. Between readings, the patient was left alone. During these four months of study, the blood pressure varied markedly, but it can be seen that it averaged 240/124 (240 systolic, 124 diastolic). During the next two-and-a-half-month period of study, the twenty-minute rest periods were continued, placebo treatment was given, and the home blood-pressure method was started. A friend of the patient was taught to take her blood pressure and did so at morning and night. At each sitting, three or four readings were taken during a five-to-ten-minute period. During this time, the clinic readings, indicated by the vertical heavy columns, averaged 224/124; the home readings, shown by the continuous wavy lines, averaged 200/114. During this period, the patient had a mild cerebral hemorrhage with hemiplegia.

The first set of operations was a two-stage bilateral supradiaphragmatic splanchnicectomy consisting of resection of the greater splanchnic nerves and the tenth, eleventh and twelfth dorsal sympathetic ganglions. The patient was followed postoperatively for three months, during which the average clinic readings were 214/124 and the average home readings 184/114. It is clear that

the operations had little effect on the level of the blood pressure. The patient was then subjected to a two-stage bilateral lumbar sympathectomy in which the first and second lumbar ganglions were removed. Following this step, there was a dramatic drop in all readings, so that the average clinic readings became 156/100 and the average home readings 124/80. This change has persisted

blood pressure was only slightly lower than before operation, running in the clinic at an average of 216/108 and at home at an average of 194/104. After a left dorsolumbar sympathectomy was done, a striking drop occurred; the average clinic levels became 140/84 and the average home levels 110/70. These levels have persisted up to the time of writing, a period of three and a quarter years

FIGURE 1. Case 11.

This chart shows five and a half years of preoperative and postoperative blood-pressure observations. The jagged continuous lines represent the home levels of blood pressure. The vertical columns, hatched or solid, indicate the clinic blood-pressure readings over a twenty-minute rest period. The end of the chart shows the last two months of 1943. The period between 1939 and 1943 is omitted for the sake of space, but the levels were unchanged.

to the present time. The end of the chart shows the readings during the last two months (April and May, 1943). The areas between 1939 and 1943, not charted, show exactly the same levels. The patient has continued taking her home readings, and has estimated that about eleven thousand readings have been made in the past five years; we have taken about one hundred and fifty clinic readings since the operation. This patient, unable to work more than four months a year prior to operation, is now working full time at the Boston Navy Yard.

Figure 2 presents the record of Case 12. The average levels of blood pressure rather than all the readings available have been plotted. The patient was a forty-eight-year-old woman who, prior to the beginning of this study, had a cerebral hemorrhage with good recovery. During one year of observation in the clinic with twenty-minute rest periods, the average blood-pressure levels were 220/120. Then, home readings taken by the patient were instituted, and over a four-month period the clinic levels averaged 250/120 and the home readings averaged 220/114. A right dorsolumbar sympathectomy was done and resulted in a pneumothorax. The patient convalesced for seven weeks. During this period, the

after the last operation. The patient now performs all the duties of an active housewife.

Figures 1 and 2 indicate how most of the patients were studied so far as the levels of blood pressure are concerned. Table 2 lists the results in the remaining cases, using the average levels or trends of blood pressure. This table indicates that, in the majority of the cases observed, the results were unsatisfactory. It also shows the different types of operations done in each case. The numbers to the left of each blood-pressure reading indicate the length of observation in weeks, months or years that the average reading covers, and applies to both the clinic and the home readings during this period. Thus, in Case 3, the blood pressures taken for seven weeks in the clinic with twenty-minute rest periods averaged 230/146; for the next six weeks, the average readings in the clinic were 228/138 and the average home readings 222/136. After completion of the two-stage splanchnicectomy, the patient was followed for seven months up to his death, and during this period the clinic blood pressures averaged 236/144 and the home readings about the same, 226/136. It is clear, therefore, that this patient was not benefited by the operation so far as the blood-pressure levels are concerned, and

his death seven months after the operation indicates that the sympathectomy did not have any discernible effect on the progress of the disease. This case was one of Group 4 (Keith-Wagener¹⁰)

The patient had a pneumothorax and so was allowed home for four months before the other side was done. It is seen that the unilateral operation had little or no effect on the blood-pressure levels,

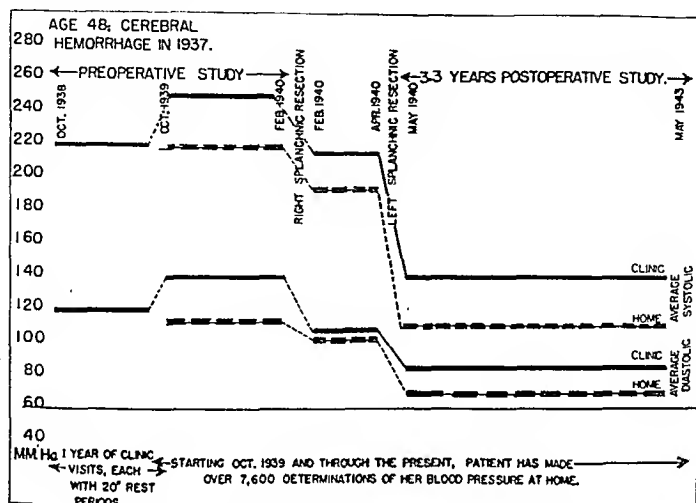

FIGURE 2. Case 12.

This chart shows the preoperative and postoperative average levels of blood pressure. The clinic levels are indicated by the solid black lines, and the home levels by the broken black lines. A period of seven weeks at home elapsed between the first and second stages of operation. The operation performed was the transdiaphragmatic dorsolumbar sympathectomy (Smithwick type).

hypertension with papilledema; headaches were improved after operation.

Efficacy of Type of Operation

Suprardiaphragmatic splanchnicectomy. Of the 10 cases in which bilateral suprardiaphragmatic splanchnicectomy was done as a first attempt to lower the blood pressure (Cases 1, 2, 3, 4, 5, 6, 7, 8, 9 and 11), only 1 case (Case 8) showed a significant drop in the clinic blood-pressure readings. We have arbitrarily chosen a minimum drop of 30 mm. systolic and 14 mm. diastolic as minimum evidence of any effect of the operation on the levels of blood pressure in the clinic or home. Turning to the home levels of blood pressure in these 10 cases, it is noted that Cases 4, 7, 8 and 9 showed significant drops in blood pressure. However, in only 1 case (Case 9) did the average blood-pressure level drop to normal. Case 4 in Table 2 is worth noting with reference to the findings after only one side of the splanchnicectomy was done.

but that when the left side was operated on, there was a definite drop in the home levels, persisting for the next five years. If these cases are analyzed to compare the relation of effect of operation to grade of hypertension, it is found (Table 3) that the only case with a significant effect in the clinic level of blood pressure was of Grade 2. By the home method, 3 additional cases were found to have a drop, and these were Grade 2 or 3. It is unfortunate that in 2 of the 3 cases of Grade 4, there was no opportunity to have home observations made. In Case 5, which is labeled in Table 3 as having a questionable result, there was a brief period of home readings a year after operation. The home readings in this case were much lower than the clinic readings. As evidence of possible effect of operation, this case showed a marked postoperative change in the electrocardiogram: a deeply inverted T wave in Lead I gradually changed to an erect T wave, depressed ST in-

tervals in Leads 1 and 2 became normal, and an inverted T wave in Lead 4 became erect.

Supradiaphragmatic splanchnicectomy followed by lumbar sympathectomy. Table 2 indicates that of the 10 cases first subjected to splanchnicectomy,

and 8). Of these 6 cases, only 1 (Case 11) had a drop in clinic level and a drop to a normal level by the home observations, lasting four and a half years to the present. Case 8 continued to maintain the improvement in clinic readings produced

FIGURE 3. Case 5.

Three sets of electrocardiograms, taken in June, 1937, in March, 1938, and in May, 1943, respectively. During this period, although the T waves in Lead 1 became normal, there was no improvement in the blood-pressure levels obtained at the clinic.

6 (Cases 1, 4, 6, 7, 8 and 11) later underwent more extensive sympathectomy. In these cases, the further operations were two-stage bilateral infradiaphragmatic lumbar resections in which the first and second and occasionally the third lumbar ganglions and the sympathetic trunks were removed. These lumbar operations were performed at intervals varying from four weeks to one and a half years after the original splanchnicectomies. They were done because of failure of the original operations (Cases 1, 6, 7 and 11) and to observe whether more extensive removal of the sympathetic system would be more effective (Cases 4

by splanchnicectomy, and also showed a further drop in the home readings after the lumbar operations. On the whole, therefore, the addition of the lumbar operations in these 6 cases produced a beneficial effect in 2 cases (Grade 2 and 3). Table 3 shows that of the 4 unbenefited cases, 2 were Grade 4 and 2 were Grade 3.

Total sympathectomy. Total sympathectomy was carried out in only 1 case (Case 7). This patient was subjected first to supradiaphragmatic splanchnicectomy, then to resection of the lumbar ganglions, and then to three more stages in which the stellate ganglions down through the eighth

In each column of blood pressure readings the upper set is the clinic reading and the lower set the home reading.

dorsal ganglion on the right and the inferior cervical and first, second, sixth, seventh, eighth and ninth dorsal ganglions on the left were removed — an almost total sympathectomy. A small area of sweating over the left anterior chest confirms the readings, the full drop did not appear until three weeks after hospital discharge. The delay in drop seemed related to pain about the operative scars. In the unsuccessful cases, followed up to five years, there has been no evidence of any tendency toward

TABLE 3. Results of Different Operations Compared with the Severity of the Hypertension (Keith-Wagener¹⁶).

persistence of the third, fourth and fifth dorsal ganglions. Table 2 shows that for the past four and a half years since completion of this extensive denervation, the blood pressure has been somewhat lower, both in the clinic and the home, but nowhere near normal. Further details of this unusual case will be published elsewhere.

Transdiaphragmatic lumbodorsal splanchnicectomy. This was done in Cases 10, 12 and 13 by the

lowering or elevation of the blood pressure. In the successful cases followed postoperatively as long as four and three quarter years, there has been no tendency of the blood pressure to rise in either home or clinic readings.

The correlation of postoperative effect with preoperative sedative test with Sodium Amytal has not been good. The patient in Case 7, on whom the total sympathectomy was performed, had a

Smithwick method. Case 10 had a left supra-diaphragmatic splanchnicectomy and a right trans-diaphragmatic operation. The patients have been followed postoperatively from one and a half to four and a half years. All had a marked drop in clinic levels close to normal, and a complete drop to normal in their home readings taken daily up to the present. Two of these cases were Group 3 and one was Group 2.

Additional Points Regarding Blood-Pressure Levels
In all cases in which a marked drop in blood pressure occurred, the fall in the clinic readings appeared immediately after operation. This rapid drop also occurred in the home readings in all cases but 1 (Case 9). In this patient, although there was some drop at the outset in the home

sedative drop in blood pressure to 96/66, but had little postoperative drop.

We should like to emphasize the constant instability of the preoperative and postoperative blood pressure levels in our cases. Although the figures in Table 2 report the averages of thousands of home readings and hundreds of clinic readings, such average figures merely represent trends. The actual facts are illustrated in Figure 1. In this case, although the average clinic readings after operation are 156/100, in reality they varied from 180/112 to 128/80 and the home readings, which averaged 124/80, varied from 140/94 to 92/58. Similar fluctuation at higher levels is evident preoperatively in this chart. There were, therefore, swings in blood pressure postoperatively amounting to as much as 88 systolic and 54 diastolic. The lower

levels usually occurred after sitting and resting a few minutes or were found oftener in the morning. If our cases were reported on the basis of readings after resting only, it is evident that the selected level would be much lower. The higher clinic and home levels were usually related to environmental or emotional stimuli. Finally, in only 1 patient (Case 12) was the blood pressure often normal as soon as she entered the clinic and sat down. Even in this case, elevated readings were frequent when she first sat down, and dropping to or near normal after twenty minutes of rest.

Postoperative Complications

Pneumothorax due to inadvertent nicking of the pleura occurred in 3 cases, but had only a brief effect on complete rapid recovery from the operation. In Case 14, death resulted three days after the first stage of a supradiaphragmatic splanchnicectomy from an overwhelming streptococcal infection of the mediastinum. In Case 10, unusual spells, apparently unrelated to the operation, developed eight months after operation. These episodes consisted of generalized shaking either when the patient was asleep or, less often, awake, with twitching of the face and inability to talk. The diagnosis has been the subject of debate by several neurologists; hysteria and diencephalic epilepsy have been considered. Electroencephalograms were within normal range, and spells did not respond to Dilantin Sodium or to phenobarbital. The fact that they developed eight months after operation and that the blood pressure was lowered makes it unlikely that they were related. Reactions of this nature have not been reported in papers on sympathectomy. Sterility in men due to inability to empty the seminal vesicles may occur when the lumbar ganglions are removed. Our own data on this point are inadequate.

Postural Changes in Blood Pressure and Pulse

As noted by Roth¹² and Allen and Adson,⁹ extensive denervation is associated with a marked drop in blood pressure and with tachycardia when the patient stands. This occurred in marked degree in Cases 11, 12 and 13, and in a mild degree in Cases 7, 8 and 10. In Case 7, however, a moderate postural effect on blood pressure was unassociated with any pulse rise; in fact, the pulse remained around 50. In all cases, the postural effect wore off in two or three months. It is of significance, however, that in patients whose home readings while seated at times have been as low as 76 systolic, there has been no tachycardia or faintness even four years after operation.

Changes in Heart Size and in Electrocardiograms

Table 1 shows that in only 4 of the 13 cases (Cases 5, 6, 11 and 12) was there any cardiac en-

largement before operation, and this was of only slight degree. In Case 6, death from renal failure occurred. The remaining 3 patients are still living. In Case 5, the enlargement has remained unchanged over the five and a quarter years of postoperative observation. During this period, the electrocardiogram has become normal. In Cases 11 and 12, which originally showed slight enlargement, the heart has returned to normal size. Even in some of the cases showing normal heart size before operation, serial x-ray films have revealed postoperatively a definite decrease in size. There have been no cases with increase in heart size postoperatively.

Table 1 also shows which cases had preoperative and postoperative electrocardiographic abnormalities. In Cases 5 and 10 the T waves in Lead 1, inverted before operation, postoperatively became erect (Fig. 1). In Case 5, this was unassociated with any evidence of improvement of blood-pressure level in the clinic. In this case, home readings were available over only a brief period postoperatively; they were moderately lower than the clinic readings. In Case 12, the T waves in Lead 1, inverted to a depth of 7 mm. preoperatively, showed after operation inversion to a depth of 2 mm.; in Lead 2, the T waves, previously inverted, became erect. In both Cases 10 and 12, the changes were also associated with the development of deep Q waves in Lead 3. Case 10 had angina pectoris preoperatively on exertion; it has not recurred in the four and three-quarter years since operation. The ST intervals were depressed preoperatively in Leads 1 and 2 in Cases 5, 10 and 12, becoming normal after operation. In Cases 10 and 12, the clinical result was excellent. Left-axis deviation did not change more than slightly following operation, but any expected decrease was probably prevented by a gain in weight of twenty to thirty pounds in these two cases.

Changes in Eyegrounds

In 2 cases (Cases 1 and 3), there was edema of the optic disks. In Case 1, the edema disappeared postoperatively and did not recur in the two and a half years that elapsed before the patient's death. In Case 3, death occurred seven months after operation; unfortunately, the postoperative records of the fundi were lost. In the other cases, no definite change in any direction was noted after operation. The ophthalmologist was occasionally of the opinion that the vessels seemed wider after operation (Case 13). Arteriovenous nicking and changes in caliber have not improved. No evidence of progress is present in the patients who are still alive.

Changes in Renal Function and Albuminuria

The renal function was normal in all cases except 1 (Case 6). The latter showed preoperatively an elevated nonprotein nitrogen, with a fixed specific gravity of the urine and constant albuminuria. Of the 4 patients with constant albuminuria preoperatively (Cases 1, 3, 6 and 8), 2 (Cases 1 and 3) died of cerebral hemorrhage, 1 (Case 6) died of renal failure, and 1 (Case 8) is still living. The last patient has had a good operative result. Of 3 patients with inconstant albuminuria, all are living, and only 1 has had a strikingly successful result.

Intravenous pyelograms were normal in all but 2 cases (Cases 8 and 11). In Case 8, there was a history of pyelitis of pregnancy in 1929, with a kink of the right ureter straightened by operation. A pyelogram taken before the sympathectomies showed some blunting of the calyces and slight enlargement of the pelvis of the right kidney. In Case 11, pyelograms and flat plates revealed a small right kidney with only slight function. It is striking that in both these cases with abnormal pyelograms, sympathectomy produced excellent results lasting up to the present. In Case 11, two years after sympathectomy, the right kidney was removed because of pain; it was found to be hypoplastic and atrophic, with chronic pyelitis. The blood pressure, normal before nephrectomy, remained unchanged after nephrectomy.

In general, no improvement was noted in the concentrating ability of our cases.

Symptoms before and after Operation

Table 1 indicates apparent symptomatic improvement in many cases. The chief symptom relieved was headache. This occurred even when there was no apparent improvement in blood pressure. Only 1 case (Case 7) was free of symptoms before and after operation. In 1 case (Case 2), symptoms were more marked after operation. The patients in Cases 8, 11, 12 and 13, almost wholly incapacitated before operation, have returned to full activity since operation. The other cases did not show any striking improvement in capacity for work.

Pressor Tests before and after Operation

We have carried out many pressor tests, using the breath-holding and ice-water methods. They have not been of any aid preoperatively and have added little to our findings postoperatively. Whether or not the operation is successful, the pressor test may show no change in range—the range meaning the amount of rise in blood pressure produced by the test. Some successful cases,

however, may have a postoperative decrease in range. The top level to which the blood pressure rises after the pressor tests is called the ceiling; this is lower in benefited cases, but the success of operation is easily seen in the top clinic readings themselves. On the other hand, the pressor-test ceiling after the operation and occasionally preoperatively may be much less than the actual height at which the blood pressure is frequently found in the clinic without pressor-test stimulation. Case 12 is an example. Although this patient has become a so-called "hyporeactor" to the tests,—that is, a normal range,—the readings in the clinic varied markedly: at one visit she might have a top blood pressure of 196/104 and at another visit a top reading of 130/80. These top readings in the clinic were much higher than the ceilings obtained by the pressor tests. It is clear, therefore, that the pressor tests do not indicate the degree to which the blood pressure in some of these patients fluctuates. In other words, the range of blood pressure after pressor stimuli of breath-holding or cold is much less in such cases than the range produced by environmental stimuli

COMMENT

Regardless of how skeptically and critically we have viewed less well-controlled studies of sympathectomy, our own data, viewed just as critically, have convinced us that no medical therapy has ever equaled the results obtained in 5 of our 13 cases. Certainly, the blood pressure can be lowered to a marked degree by potassium thiocyanate in large, somewhat toxic doses, and kept down for prolonged periods, but constant attention must be given to such patients, and their activity becomes greatly depressed by the marked effects of the drug.^{17, 18} A patient can be ordered to bed and given large doses of sedatives with a similarly good effect on the blood pressure. It is clearly recognized that but little has been accomplished in the medical treatment of this disease. No one can point to a single well-controlled case in which medical treatment has brought the size of the heart, the electrocardiogram and the blood pressure back to normal. In our experience, sympathectomy has accomplished this in some cases with persistence of success for five years to the time of writing.

The optimism and enthusiasm rising out of our findings have been tempered by some provoking facts and queries. First, the operation, no matter how extensive, has not, even in our most successful case (Case 12), abolished rises in blood pressure produced by excitement. Almost one hundred thousand home readings of the blood pressure show rises associated with arguments, great

physical or emotional strain, markedly cold rooms and so forth. The average home existence of these patients does not often produce such rises, and the blood pressure may be as low as 80/64. In the clinic, the initial readings taken immediately after the patient enters the examining room are oftenest in the abnormal levels, even if on resting they drop to or close to normal. These marked variations of blood pressure indicate that large underventilated areas are left and that the hypertensive tendency still exists. The fluctuations in blood pressure in these patients resemble those seen in many young, early hypertensive patients who used to be dismissed with the diagnosis of emotional hypertension.

The promising picture presented in this paper must be viewed in the light of this question: Does the operation increase the life expectancy in the successful case? Our own data do not, of course, contribute an answer. Other reports are strikingly conflicting. Woods and Peet,¹⁹ on the one hand, state that splanchnicectomy does increase life expectancy, and Flaxman²⁰ on the other, after comparing Woods and Peet's results with medically treated cases, concludes that there is little difference in mortality between the two groups. Even if the latter theory proves to be correct, results like those in Cases 10, 11, 12 and 13 justify the operation merely on the ground that it makes possible for the patient such long periods of normal activity and well-being.

We must also take cognizance of the argument raised by Volini and Flaxman²¹; namely, that hypertensive patients often have a drop in blood pressure after any major operation. This is reasonable if one remembers that great inactivity and some asthenia after major operations do cause a lowering of the blood pressure. The present study, however, clearly indicates that this is not the reason for the drop in blood pressure in our cases. First, the drops in blood pressure were not transitory, but have persisted up to five years. Secondly, in Cases 4, 11 and 12, intervals of months elapsed between stages, and the precipitous drop in blood pressure did not occur after the first stages while the patients were up and about convalescing. Finally, there is evidence that extensive sympathectomy carried out in patients with normal blood pressure has practically no effect on the readings, even in the upright position.¹⁶ In this sense, the effect of sympathectomy on the blood pressure of essential arterial hypertension is a specific one and not comparable to the effect of transitory asthenia and inactivity following operations in general.

Another disturbing fact is that 5 of our 13 cases failed to respond successfully. Since our patients were operated on by a surgeon highly skilled in

sympathetic-nerve surgery, we are certain that the amount of sympathetic resection planned preoperatively was carried out. This leaves, therefore, two explanations of failure: first, the cases with extremely severe forms of the disease did not respond, or secondly, the operation was not sufficiently extensive. Certainly, the newer operation — transdiaphragmatic splanchnicectomy — has had a more constant degree of success. On the other hand, the slight response to an almost total sympathectomy in a Grade 3 hypertensive patient indicates that there are other as yet undiscovered reasons for failure.

So far as the failures reported in the literature are concerned, our studies indicate an additional important reason for some of the apparently poor results. We believe that, as in Cases 4, 7, 8 and 9, some of the cases reported in the literature have had a much better result than the clinic readings of the blood pressure indicate. We feel certain that, as in our own cases just cited, there are many cases in which the home blood-pressure readings have been lowered greatly since operation, although the clinic readings have been lowered little or not at all. This is a probable explanation for the change of the electrocardiogram to normal in Case 5. It seems also a likely explanation for the report of Bordley et al.²² that in one of their cases there was a decrease in the size of the heart, the electrocardiogram lost its left-axis deviation for two years, and there was no improvement of the blood pressure after operation. It may also explain why many cases have improved symptomatically without any apparent change in blood pressure.

Several more questions will inevitably be raised. First, what is the value of the home blood-pressure method? As stated in previous papers, we believe that it is invaluable for the true interpretation of any therapy in hypertension. In no cases have we seen any psychic harm from the use of the method. A second question that may be raised is, If the patients who have normal blood-pressure readings at home also have rises on excitement, what do the normal home readings really represent? We think that the home readings represent the usual level of blood pressure during the patient's normal life at home. Otherwise, we should have found hundreds of high home readings among the thousands taken in a given case if the levels were raised by merely slight happenings at home. The clinic or office high readings, therefore, represent the excitement associated with a visit to the doctor. It is provocative to note and emphasize that this excitement may produce after operation a rise in blood pressure much greater than that produced by the pressor tests.

The question of the effectiveness of surgery in relieving symptoms must be considered separately, since so much of the subjective factor enters into the picture. The evaluation of symptom relief is most difficult. We² have already shown that any strong form of suggestion treatment is markedly effective in relieving symptoms. This should be kept in mind in cases where relief of symptoms has occurred in the absence of any demonstrable effect on the levels of blood pressure. We disagree strongly with the statement that the operation is justified merely for the relief of distressing symptoms, even if the good results last only several months, and that the criteria for operation are incapacitating symptoms.

We now believe that the criteria for operation are severe or progressive disease in which there is no renal or cardiac failure, and the development of any of the following: cardiac enlargement, electrocardiographic evidence of left-ventricular strain, inconstant or constant albuminuria and marked changes in the ocular fundi. The age factor is a matter not yet settled; it seems to us that as time goes on, one must seriously consider those people over fifty-five years of age who now receive no attention. Chronic unilateral renal disease is not a contraindication (Cases 8 and 11). Time may prove the same to be true for bilateral renal disease.

Three final points are as follows. The preoperative and postoperative evaluation of such cases should be the primary concern of the internist. The decision to operate should rest on the opinions of the internist and surgeon and the patient as well. In suggesting surgery to such patients, the experimental nature and uncertainty of success should be made clear. Finally, the operation should be performed only by surgeons who are properly trained in this field.

SUMMARY AND CONCLUSIONS

There have been presented a small series of patients with essential hypertension who have undergone a variety of sympathetic denervations and who have had the advantage of unusually detailed controlled study. This type of controlled study with sympathectomy has not been secured or reported before. The controls consisted of special clinic study of the blood pressure, together with home blood-pressure determinations by the patients themselves.

The data so gathered lead inevitably to the conclusion that sympathectomy, regardless of its rationale, is the first therapy of essential hypertension that has been shown to produce in some cases a marked, prolonged, nontoxic lowering of the blood pressure. With this improvement in blood pres-

sure, the heart may gradually decrease in size, the electrocardiogram return to normal, the symptoms disappear, and the incapacity be replaced by completely normal activity lasting at least as long as five years. Angina pectoris may disappear. Successful sympathectomy did not result in constantly normal blood-pressure levels in any case.

Our study does not completely clarify the reasons for failure but does offer some explanations. First, regardless of the extent of sympathectomy, Grade 4 patients did not respond. Secondly, success in general was more constant in those patients subjected to extensive denervation. The transdiaphragmatic type of splanchnicectomy with dorsolumbar ganglionectomy was the most effective type of operation. Finally, some failures are only apparently so when judged by the standard clinic readings of the blood pressure, whereas the home blood-pressure method reveals real improvement.

Therapy by sympathectomy should be considered in patients with essential hypertension in whom progressive elevation of the blood pressure is found after long and careful study or in whom any evidence of beginning vascular damage is demonstrated. Proper control figures of blood pressure levels and variations should be secured, preferably in the ambulatory state. Brief periods of preoperative hospitalization do not afford proper data with which to compare postoperative results, no matter how many intricate or detailed studies are carried out during such periods. In a disease that has usually existed for some years, there is only rarely an excuse for brief preoperative studies or emergency decisions. Such studies and decisions are the primary concern of the internist.

SOCIOECONOMIC ASPECTS OF DISEASE*

A Community Study of Pulmonary Tuberculosis in Selectees

MAJOR ROBERT W. HYDE, M.C., A.U.S.,† AND DAVID ZACKS, M.D.‡

WITH THE ASSISTANCE OF SERGEANT LOWELL V. KINGSLEY, A.U.S.

BOSTON

ALTHOUGH it has long been recognized that the incidence of pulmonary tuberculosis is especially high in crowded slums, and that certain races apparently have greater susceptibility than others to this disease, the exact effect of these factors has never been properly weighed and differentiated. As our examination of selectees before induction into the armed forces includes routine chest roentgenograms, an unparalleled opportunity has been offered for studying the incidence of pulmonary tuberculosis in men of military age coming from communities of different types. The purpose of this study is to correlate the prevalence of pulmonary tuberculosis in selectees with the factors of the socioeconomic level, population density, nationality and industries of the communities from which they came.

One of the best determinations of the relation of tuberculosis to economic level was that of the National Health Survey,¹ which showed that the rate of disability from tuberculosis is nine times as high for those on welfare as that for persons in the upper income group of \$3000 per year and over, and almost four times as high for those with annual incomes of less than \$1000 as for those with incomes of \$3000 and over. Hart and Wright² in their studies in England, in addition to pointing out the similarity between the curves of pulmonary tuberculosis and of real earnings, noted the effect of differences in average closeness of personal contact between the inhabitants in one county borough and those in another. Other studies of the relation of tuberculosis to popula-

tion density consist largely of the comparison of urban and rural rates. Parkhurst³ in 1933 found the total rural rate to be 15 per cent lower than the urban rate, and Sydenstricker⁴ during the period of 1900-1915 found the urban rate maintained at double the rural rate. Whitney⁵ reported that the death rate from tuberculosis is more than twice as high in laboring classes and factory and mill workers as in business and professional people and farmers. Dauer⁶ states that numerous reports have demonstrated that immigrants from certain countries to the United States have higher tuberculosis death rates than do the offspring of native-born parents. The Irish have had especially high rates, whereas the Italians, Russians and Jews have had relatively low rates.

No paper has appeared that differentiates the effects of low economic status and crowded housing. Although it is obvious that these two factors are often found together, their relation is not constant, and a differentiation of them is important in the establishment of mass preventive methods. In this paper an attempt will be made to differentiate the effect of population density and that of the socioeconomic level.

Although it has been stated that the high incidence of tuberculosis in the foreign born and their children and in certain races may have been influenced by their low economic status and the crowded housing of immigrant communities, it has not been shown that the latter are not the prime causative factors rather than racial susceptibility, to which the high incidence was attributed. Our consideration of the relation of economic status and population density to the prevalence of tuberculosis in certain nationalities is far from complete, but it does suggest a method for

*From Headquarters Boston Armed Forces Induction District presented at a meeting of the Massachusetts Trudeau Society Boston May 14, 1943.

isolating the various factors contributory to the incidence of tuberculosis.

At this time it is possible to review the findings for almost the entire period of Induction Board examinations from December, 1940, until early in 1943. Of the selectees who received chest roentgenograms at the Boston Armed Forces Induction Station during this long period, 0.9 per cent were found to have pulmonary tuberculosis. Sixty-six per cent of these did not know that they had the disease. Of the cases that it has been possible to follow, 60 per cent have shown pulmonary tuberculosis in an active stage.

METHOD OF STUDY

Every selectee as a part of his examination has a routine chest photoroentgenogram at the Induction Station. Only the cases classified as pulmonary tuberculosis, reinfection type, are considered here. The diagnosis is made by an accredited radiologist on x-ray evidence, in most cases on the basis of four-by-five-inch stereoscopic photoroentgenograms, except occasionally when the radiologist desires single or stereoscopic fourteen-by-seventeen-inch films for verification. Rarely has this been found necessary, and then only in cases in which there were lesions of minimal extent of doubtful stability or in which measurement of the extent was necessary. Occasionally, the clinical history was inquired into, and this assisted in the diagnosis of doubtful cases. Before cases were classified as pulmonary tuberculosis, the films were reviewed by one of us (D. Z.). Tuberculosis suspects were not included as cases unless they were later proved to be tuberculous.

The men examined during most of the period were selectees between the ages of twenty-one and thirty-eight, some in the eighteen to twenty-one and thirty-eight to forty-five age groups were examined during part of the period. Because of its youth, the former age group is not presented as representative of the population in general, but it does form an excellent cross section of the male population of draft age without dependents, not engaged in essential industry, and not possessing obvious disqualifying defects evident on inspection by local-board examiners. Two groups not submitted as selectees and hence not included are those men who passed the physical examination for enlistment as volunteers in the armed forces and did not have tuberculosis, and those undergoing sanatorium treatment for tuberculosis, or, in rare cases, rejected by local boards because of proved tuberculosis. These two groups, one with, and the other without tuberculosis, tend to balance each other.

The source of the registrants was the eastern segment of Massachusetts at no point more distant than thirty miles from the coast line. The diversity of population represented was exceptional, ranging from high population densities, at their greatest in Boston proper and including four other cities of over 100,000 population and fourteen with more than 25,000, to such low densities as are represented in more than fifty towns and villages with a population of less than 2000. Industries of all types are found in the cities and large towns. Many semirural areas where the chief occupations are farming and fishing are represented. Many diversified nationalities are present, with the foreign population of Irish, Italian, Jewish and many mixed foreign groups concentrated especially in the urban areas, and with other communities still of almost purely English stock, now in the sixth and seventh generations in this country.

A social study was made of the area with the use of such available statistics as Lambie's *Experiments in Methods of Municipal Analysis*⁷ and *Social Statistics*⁸ of the Boston Council of Social Agencies, which together give detailed information on population densities, tax rates, welfare rates, industries, wages and a variety of other factors influencing the economy of the area. Surveys of the communities made by interrogation of many persons from each of them gave an evaluation of the utilization by the subject of the social and economic assets of his community and a subjective evaluation of the statistical data on the community. From these data a classification of each community was made covering the following factors: socioeconomic level (desirability), density of population per square mile, dominant nationality, and dominant occupations and industries.

The principle of our assessment of socioeconomic level of the community was based on Lynd's *Middletown*,⁹ wherein the social structure of an American community is intensively studied. The following factors were evaluated to obtain an index of socioeconomic level: medical care, educational facilities, density of housing, social class, recreational facilities, public works and welfare. These were chosen because, except for welfare, they represent those factors in a community that either influence or characterize its socioeconomic level. Welfare was used because it was the most objective figure available of economic level. This method of measuring community socioeconomic levels is considered superior to others because it is more universally applicable, is obtainable by a comparatively easy survey, and should be more consistently correct than an evaluation of any single factor such as basic wage, a figure that is

both difficult to obtain in certain areas and invalid at this time because of such special circumstances as high wartime wages.

The local board was used throughout as the community unit, and it fortunately is a satisfactory one, being comparable to a city ward, a large town or several adjacent small towns.

All communities were rated according to the above socioeconomic factors and placed in one of six groupings according to their socioeconomic level, ranging from A, the finest communities, to F, the slum areas. The tuberculosis rate on examination was found for each community and the total rate for the group was calculated.

In the separate consideration of correlation of tuberculosis with community welfare rates, the rates of 1936 to 1939 were used because they were considered more representative than any rates of today would be. All the communities were divided into four groups according to the welfare rates given by Lambie; namely, less than twenty, twenty to twenty-nine, thirty to thirty-nine and forty dollars or more per capita. Tuberculosis rates in these groups were calculated and compared.

Population density based on the number of inhabitants per square mile was found for each community sending selectees to this station. Communities were placed in seven groups according to population density, ranging from less than 500 to over 20,000 per square mile. In this way a complete study was made possible of the relation of tuberculosis incidence to population density. As the desirability rating previously described for every community was known, it was possible by considering the rating of any one density group to see what extent desirability influenced tuberculosis incidence in different population densities.

Because of the mixed nationalities that made up most of the communities, it was possible to consider only a small part of them in comparing various nationalities; hence, only those communities with a dominant nationality were grouped by nationality. The tuberculosis incidences in selectees from these groups were compared. Here the factors of the socioeconomic level and population density can be evaluated to see whether or not they explain the difference in incidence found.

A like consideration was made of those communities with a dominant industry, in an effort to show to what extent socioeconomic factors are related to the differences in the incidences of tuberculosis found in different industries.

All the communities studied were ranked according to their tuberculosis incidence. Seventeen communities were found to have especially high and seventeen especially low rates for tuberculosis. The characteristics of the seventeen com-

munities with the highest rates were compared with those of the seventeen with the lowest rates.

RESULTS

Tuberculosis Rate and Community Desirability

The correlation of tuberculosis incidence in selectees with the desirability rates of the communities from which they came is shown in Figure 1.

FIGURE 1. Incidence of Pulmonary Tuberculosis at Different Levels of Community Desirability, from A, the Best, to F, the Poorest.

Here the incidence of tuberculosis in selectees increased from 0.7 per cent in the best (A) communities to 1.4 per cent in the poorest (F). This doubling of the incidence of tuberculosis tends to confirm the findings of the National Health Survey¹ and the study of Hart and Wright² in England on the relation of tuberculosis to income. Their studies, however, were on an individual basis, correlating tuberculosis incidence with income, whereas this study rests on a community basis wherein a much poorer correlation would be expected.

To see if the same correlation was found with mortality as that with morbidity, the death rates for the years 1937-1941 for the same communities were compared. As good a correlation was shown as that for incidence, with the death rate ascending from 24 per 100,000 population in the most desirable (A) communities to 60 per 100,000 in the poorest (F).

The importance of this relation of pulmonary tuberculosis to socioeconomic level can in no way be minimized, especially in view of the fact that without doubt the public-health attack on tub-

culosis has not been neglected in those communities with the lowest socioeconomic level. For this reason it cannot be considered, as it might be in certain other diseases, simply as indicative of medical neglect, but must be associated more with low standards of living found in the undesirable areas. The fact that there was an incidence of pulmonary tuberculosis of 0.7 per cent in the finest communities is also notable, for such a

FIGURE 2. Incidence of Pulmonary Tuberculosis in Different Population Densities, Classified according to People per Square Mile.

high incidence here demonstrates that even the best environment is far from good enough, and that efforts must be directed not only at the community of low socioeconomic level but also at the entire range of society. Of the twelve communities in the highest desirability bracket, only one presented an outstandingly high incidence of tuberculosis. Of the eight communities with the lowest desirability rating, only one presented a low incidence.

Tuberculosis Rate and Population Density

As shown in Figure 2, in which all communities are grouped under like population densities, the four least dense groupings, those with densities of less than 5000 per square mile, presented similar averages of tuberculosis incidence. This suggests that insofar as can be determined from this study, population densities up to 5000 per square mile do not exert an unfavorable influence on the rate of pulmonary tuberculosis. Of the forty-six

communities with populations less than 5000 per square mile, only five presented rates for pulmonary tuberculosis higher than the average. Communities of a great variety of types and qualities are represented among these forty-six communities, and the fact that only five had tuberculosis rates above the average indicates the extent to which low population density is associated with low tuberculosis incidence.

From population densities of 5000 per square mile up to those of over 20,000 per square mile, there was an ascending rate of pulmonary tuberculosis from 0.6 to 1.4 per cent. All but two of the fourteen communities with population density over 20,000 per square mile presented a tuberculosis rate above the average. This serves to illustrate what is considered to be the effect of crowded housing in a contagious disease such as tuberculosis, where close contact with active cases is conducive to its spread. These findings are in agreement with the work of Hart and Wright,² Parkhurst³ and Sydenstricker.⁴

A similar study of mortality made by comparing the tuberculosis death rates for five years in the various population densities yielded similar results. The death rates rose from 28 per 100,000 population in densities of under 2000 to 54 per 100,000 in those of over 20,000 per square mile.

It is to be expected that the relation of tuberculosis to crowded living would be even more strongly emphasized if a study could be added of the number of people per dwelling room as well as population per square mile, for even in the density groups of less than 5000 per square mile, many areas exist where a small crowded urban district is balanced by a sparsely populated surrounding semirural area, producing a low population-density figure for the community, not truly representative of the situation. Even in entirely rural areas, people of low economic level are often crowded together into too few rooms.

It is apparent that the densely populated areas also include more poor tenement districts of low socioeconomic level. Hence, without investigation it is impossible to say that the increase in tuberculosis in the high-population densities is not due so much to their low economic level as to crowding per se.

It is of the greatest importance to differentiate the effect of low socioeconomic level from that of population density. The average desirability level of those communities in the 2000 to 5000 population-density group proved to be C, whereas the desirability level in the highest density group proved to be E. By referring to the previously charted relation of tuberculosis to desirability, the rates to be expected for these two groups on the basis of

desirability alone are shown to be 0.8 and 0.9 per cent, respectively. But since the rates that were found on the basis of population density were 0.6 and 1.4 per cent, it can be seen that the factor of population density was largely responsible for the increased prevalence in the crowded areas. Hence, increased population density above a certain level produces more tuberculosis even independently of socioeconomic level.

To distinguish further between the effect of density and that of desirability, the tuberculosis rates for those communities of the same desirability level were plotted against the various population densities of the communities included in each group. Only desirability groups C and D were used, for not enough communities were represented in any one other group to be broken down into a satisfactory variety of population densities. A good correlation was shown of pulmonary tuberculosis rates with population density in communities classified in the same socioeconomic level. Hence, the tuberculosis rates ascend in increased population densities, even independently of the socioeconomic level of the communities considered. On the other hand, the correlation between pulmonary tuberculosis and community desirability in the same population density is poor, but this may be due to the small number of communities in each population-density group rather than to the weakness of the influence of socioeconomic level independent of density that would be suggested.

Although this attempt to distinguish between population density and socioeconomic level is difficult, and the extent of this study is not sufficient for the final evaluation of such an intricate relation, it does suggest strongly that population density in itself is perhaps the most important consideration in the incidence of pulmonary tuberculosis.

Tuberculosis Rate and Community Welfare Rate

Welfare rates based on the period of 1936-1939, as recorded by Lambie,⁷ were used because they were judged to be more representative of the community than would any rate based on the present time. No uniform relation existed throughout the four divisions of welfare rates, but the communities with the highest welfare rates had 1.0 per cent tuberculosis against an average of 0.8 per cent in the communities with lower welfare rates. This is hardly worthy of note, but since it is based on a single purely objective factor, it is considered for the sake of completeness.

Tuberculosis Rate and Community Nationality

Only those communities where a dominant nationality was considered as contributory to

community homogeneity were included in this study, approximately 50 per cent or more being of the same general nationality. Nationality was determined by the birthplace of the subject or his parents in a foreign country. It must be noted that this is not a study of incidence of tuberculosis in persons of different nationalities but in communities of the same nationality.

In each group of communities of the same nationality there was a decided variation between its members, suggesting that nationality does not influence tuberculosis incidence to a sufficient degree to overcome all the other factors in the community that affect this rate. Furthermore, the desirability rating and population density of the community served to explain for the most part any difference in nationality that did exist.

It may be mentioned for completeness, however, that the average percentages of pulmonary tuberculosis for each community group by nationality were as follows: Irish, 1.3 per cent; Jewish, 1.0 per cent; Italian, 0.9 per cent; and Portuguese, 0.6 per cent. The crowded housing and low socioeconomic level of the Irish communities were the likely causative factors, since a consideration of these communities on the basis of a desirability rating of F and a population density greater than 20,000 alone would lead to the same incidence of tuberculosis irrespective of nationality.

The fact that Italian communities all happened to be of very different population density offers an opportunity for comparing incidence of tuberculosis in communities of the same nationality but with different population densities (Table 1).

TABLE 1. *Tuberculosis Incidences in Four Italian Communities Compared to Their Population Densities.*

COMMUNITY	POPULATION DENSITY	NO. OF INDICES EXAMINED	INDICES WITH PULMONARY TUBERCULOSIS	
			%	
C 51	60,000	2,498	1.2	
C 21	25,000	2,779	0.9	
C 89	7,000	990	0.7	
C 201	1,500	743	0.4	

From the table it is evident that whatever influence nationality may have on tuberculosis incidence is eclipsed by other factors—in this case, population density.

Tuberculosis Rate and Community Occupation

A consideration similar to that made of nationalities was made of pulmonary tuberculosis by community occupation, considering only those communities wherein a dominant type of occupation was represented. The average rates for communities grouped by each occupation were

as follows: urban office-workers (chiefly employees) 1.1 per cent; fishing, 1.0 per cent; leather and shoe manufacturing, 0.8 per cent; textile manufacturing, 0.6 per cent; suburban office-workers (chiefly employers), 0.6 per cent and farming, 0.4 per cent. There was such a variation in tuberculosis incidence between different communities within the same occupational group that it seems apparent that the community's major occupation itself has little or nothing to do with tuberculosis incidence, insofar as those occupations here considered are concerned. The only occupational group with uniform incidence throughout the several communities constituting the group was that of farming, with the low rate of 0.4 per cent. This is consistent with, although in excess of, the low incidence previously demonstrated in the low population densities, and hence can be partly attributed to decreased contact from uncrowded living. One might go farther and attribute it, in part, to outdoor work and freedom from the stress of urban life.

Although the textile (0.6 per cent) and shoe-manufacturing communities (0.8 per cent) do not form homogeneous groups, the fact that their average rates for tuberculosis are below the general average is worthy of note, since some authors have considered that industrial communities have a very high tuberculosis rate.

Comparison of Communities with Highest and Lowest Tuberculosis Rates

The one hundred and thirteen communities sending registrants to this induction station were listed in rank order according to the incidence of pulmonary tuberculosis found in selectees from each. The range covered was from the high rate of 2.4 per cent found in the most crowded area under consideration, composed of Italian and a mixed foreign population including Chinese, to 0.05 per cent in a small jewelry-manufacturing city with an outlying area devoted to farming, composed mainly of an old-line native population with a small mixed foreign element.

A comparison was made of the seventeen communities with the highest tuberculosis incidence with the seventeen with the lowest incidence to check the previous findings and if possible to furnish information on the socioeconomic aspects of pulmonary tuberculosis. Of the seventeen communities with the highest tuberculosis rates, eleven were of high population density with a low socioeconomic level. Of the seventeen communities with the lowest tuberculosis rates, twelve were of low population density with moderate or high desirability.

In a comparison of nationalities, eleven of the seventeen communities with a high incidence of

tuberculosis contained a major element of population of foreign birth or first-generation American born, whereas the same foreign element was predominant in only six of the seventeen communities with the lowest incidence of tuberculosis. No community with the lowest desirability rating and only one with high population density was represented among the communities with a low tuberculosis rate.

A comparison of the size of the cities in the two groups is interesting, for none of the communities with a low incidence of tuberculosis were in Boston, whereas thirteen of the seventeen communities with the highest incidence were in that city.

SUMMARY

Of the selectees examined at the Boston Armed Forces Induction Station from December, 1940, to early in 1943, 0.9 per cent were found by x-ray examination to have pulmonary tuberculosis.

There was progressively more pulmonary tuberculosis in selectees from communities of low socioeconomic level than in those from the better communities, with 1.4 per cent in the poorest and 0.7 per cent in the best communities.

The incidence of pulmonary tuberculosis was uninfluenced by variations in population densities under 5000 per square mile, but in greater densities it increased progressively from 0.6 per cent at population densities of 5000 to 1.4 per cent at population densities of over 20,000 per square mile.

The association of a higher rate of tuberculosis with the higher densities of population appears to be due to population density per se and not merely to the lower socioeconomic level of the congested areas. There is some evidence that the effect of socioeconomic level is secondary to population density.

The correlation of tuberculosis death rates of five years, 1937-1941, with both community socioeconomic level and population density gave results similar to those of the correlation of tuberculosis incidence, showing the close relation of morbidity and mortality studies of this disease.

Of communities with a dominant nationality the Irish communities presented the highest tuberculosis rates, with an average of 1.3 per cent. This incidence was no greater than would be expected on the basis of their high population density and low desirability irrespective of nationality. The tuberculosis rates in Italian communities varied with population density; hence, nationality was not shown to be a factor in the incidence of pulmonary tuberculosis.

No specific relation between community occupation and tuberculosis could be found. In 13

trial communities presented average and below-average rates. Farming communities had the least tuberculosis—an incidence of 0.4 per cent.

This study of tuberculosis on a community socioeconomic basis points to a sufficiently close relation between tuberculosis incidence and both population density and socioeconomic level to demonstrate the need for future extensive investigation of these factors.

MEDICAL PROGRESS

THE TREATMENT OF THERMAL BURNS

I. General Outline

NATIONAL RESEARCH COUNCIL*

WASHINGTON, D. C.

THE treatment of thermal burns is one of the most acute problems of war surgery; it has been the subject of many publications, and many discussions have been devoted to it. The abundance of details and the frequently contradictory character of the evidence, however, sometimes make it difficult to see the main trends of the development. For this reason, the present general outline sketched on a historical background has been prepared. It goes back to the introduction of the tannic acid treatment by Davidson in 1925, without, however, in any way attempting to be exhaustive or to provide a comprehensive bibliography of the subject. The existing monographs by Pack and Davis, Hilgenfeldt, and Harkins, as well as Volume V of *Military Surgical Manuals*, entitled *Burns, Shock, Wound Healing and Vascular Injuries*, which has just been published, make such an undertaking unnecessary. It should be noted, moreover, that in preparing this outline abstracts published in the *Bulletin of War Medicine* and in *War Medicine* were often relied on.

PREWAR PERIOD

For many centuries the chief aim in the treatment of burns was the promotion of good healing. Consciously or unconsciously, this included the prevention of dangerous sepsis. It was no-

ticed, moreover, that the blood of patients suffering from burns often showed increased viscosity, and the infusion of saline solutions had become popular before World War I.¹ But on the whole, the treatment was local and very often purely empirical. From the time of Hippocrates, a host of drugs has been applied, and the so-called "Hippocratic Collection" itself lists several prescriptions, one of them employing oak root (*Quercus ilex*), which supposedly contains tannic acid and may have had an astringent or even tanning effect.²

In the course of World War I and its aftermath, increasing attention was paid to the phenomenon of shock. Burns presented themselves more clearly as a thermal trauma that was often followed by shock, was easily open to infection, and might lead to disfiguring scars and contractures. The pathology and treatment of burns, therefore, became special problems in such wider surgical provinces as shock, wound infection and plastic surgery.

These various aspects are reflected in the classification of burns. The classic grouping since Dupuytren³ was a histologic one—that is, according to the depth of skin involved.³ His distinction of six degrees proved, however, less practical than a classification into three degrees. The latter might be based on the clinical aspects—that is, erythema, blistering and charring⁴—or on a direct appraisal of the layers destroyed—that is, superficial destruction, deep destruction and

*The articles in the medical progress series of 1941 have been published in book form (*Medical Progress Annual*, Volume III. 678 pp. Springfield, Illinois: Charles C. Thomas, 1941. \$5.00).

*Prepared by the Office of Medical Information and released under the date of February 17, 1943.

complete destruction of skin.³ Apart from expressing the severity of the burn, it also made it possible to distinguish between burns where the skin would regenerate and those where skin grafting was required. Later on this point of view was even more strongly emphasized by Hall, Cade and McIndoe who proposed a distinction between "partial skin loss" (first and second degrees) and "complete skin loss" (third degree).³

Since, however, the severity of a burn and the extent of the subsequent shock were even more dependent on the extent of the burned area, an estimate of the latter was of prime importance. Such an estimate was provided by the Berkow⁴ method in 1924. The general attention this scheme has received and its usefulness for the estimate of plasma protein loss and plasma transfusion required,⁵ are in themselves a testimony to the increasing emphasis laid on shock.

Likewise, it was the problem of shock that in 1925 led Davidson⁶ to the introduction of the tannic acid treatment of burns. Reviewing the various explanations of the clinical picture commonly described by such a term as "shock" or "exhaustion," Davidson concluded that the constitutional reaction is probably due to absorption of some toxic substance or substances from the burned area. Such absorption, he thought, might be prevented, and he chose tannic acid to precipitate the poisonous materials in burned tissue. It is interesting to note that Davidson was also influenced by the work of Bardeen,⁷ who in 1898 had observed damage of the liver and other organs following burns.

Although the precipitation of toxic substances was the key point for Davidson, he believed that the treatment had several additional advantages. He emphasized the analgesic effect, the minimal trauma and general comfort of the patient, the prevention of loss of body fluid, the limitation of secondary infection, the less marked scar-tissue formation and the scaffold offered for the growth of young epithelial cells.

The fact that Davidson considered the prevention of loss of body fluid forms a link between his work and that of Underhill.⁸ While engaged in the study of poisoning by war gases, particularly phosgene, during the last war, Underhill paid increasing attention to changes in blood concentration. Extending his studies to the problem of burns, he was later on followed by Blalock and others.^{1,9} These workers elaborated a theory of burn shock as a result of injury to the capillaries, anhydremia, fluid shift and anoxia. It was, moreover, shown that the fluid shifting toward the burned area had the character of blood plasma, and that the circulating blood was relatively

rich in blood corpuscles but poor in plasma proteins. These results had in the main been arrived at before the outbreak of the present war, but many points are still disputed. The process as it is now usually pictured has, however, been summed up as follows: "The local thermal trauma produces a local capillary injury with regional loss of plasma-like fluid both into the burned tissues and from the skin by means of 'weeping.' Later there may be generalized infiltration of plasma into tissues remote from the region of the burn. The quantitative aspect of the loss of plasma is of especial significance; the loss may exceed several liters."⁵

Although this theory of shock differed widely from Davidson's ideas, it did not oppose the tannic acid treatment. It had become doubtful whether tannic acid acted by precipitating toxic agents, but as Blalock¹⁰ stated in 1931, "It is entirely possible that such agencies as tannic acid and epinephrin exert their beneficial effects by preventing loss of fluid rather than by stopping the absorption of toxins."

An attack on the theory of toxemia and the use of tannic acid came from a different direction. Aldrich,¹¹ in 1933, denied the existence of non-bacterial toxemia in burns; in his opinion the toxemia was due to sepsis. His view ran parallel to the observation that in many cases where coagulation with tannic acid had been practiced, infection had developed underneath the eschar. Bancroft and Rogers,¹² who had remarked on the latter fact as early as 1928, had adopted—for certain cases, at least—the treatment with acriflavine. Aldrich employed gentian violet, the bactericidal and bacteriostatic properties of which had been made known by Churchman¹³ in 1912, for the treatment of burns, claiming that it was particularly effective in combating *Streptococcus hemolyticus*. Subsequently, Aldrich¹⁴ used triple dye—that is, a mixture of brilliant green and acriviolet (acriflavine and crystal violet). Brilliant green had been in use as an antiseptic for quite a number of years, and in a 1 per cent solution Koritkin-Nowikow had employed it for burns and scalds in 1934.¹

Other criticisms voiced before the present war against the use (or sole use) of tannic acid may be mentioned. Bettman,¹⁵ in treating an extensive burn of the arm of a five-month-old child, had observed a progressively increasing edema with subsequent pressure and impediment of the circulation that led to a sloughing of the hand. In order to obviate the slowness of tanning and the rigidity of the eschar by tannic acid, he preferred the tannic acid-silver nitrate method that he had proposed in 1935. Here again a much older thera-

peutic agent had been reintroduced in a new combination, silver nitrate having been used in burns as early as 1858 by Kalt.¹

In Germany, Löhr, in 1934, introduced the cod-liver oil treatment of burns.¹⁰ He pointed out that tannic acid did not prevent shock and sometimes led to infections under the scab. Cod-liver oil, which he used in the form of *Unguentolan*,—that is, mixed with other ointments,—prevented infections and helped the healing of the burns. Taylor in 1936 remarked that tannic acid hindered the growth of epithelium.⁹

Under this two-sided assault the existence of toxemia due to burns became questionable. In 1938, Wilson, MacGregor and Stewart¹⁷ wrote: "The present trend of opinion seems to be towards Underhill's view that increased concentration of the blood is the main, even the sole, cause of symptoms in the stage of toxæmia; some support, however, is given to Aldrich's belief in the predominating influence of hæmolytic streptococcus infection. An attitude of scepticism or reserve towards a specific burn toxin has become fashionable."

But Wilson and his co-workers thought that they could prove the existence of a separate stage of acute toxemia as distinguished from shock on the one hand and septic toxemia on the other. They differentiated five stages in the course of burns: initial shock (the first two hours after the burn); secondary shock (two or more hours after injury); acute toxemia (six to fifty hours after injury); septic toxemia (approximately from the fourth day on); and healing. The stage of acute toxemia, in their opinion, was marked not only by clinical symptoms but by liver damage as well. Although they used tannic acid, which has recently been found to have a toxic effect of its own, they believed that the liver lesion furnished the strongest indication of a nonbacterial toxin circulating during the first few days after a burn.

This outline of the possible course of a severe burn has become the basis for much subsequent discussion. As will be seen later, their evidence for the existence of nonbacterial toxemia has lost much of its strength, although the question has not yet been finally decided. At the time, however, it gave renewed impetus to the belief in a toxic agent.¹⁸ Moreover, it vindicated the original rationale for the use of tannic acid, if indeed such a vindication was necessary. For in spite of the criticism by Aldrich and a few others, tannic acid, possibly in combination with silver nitrate or antiseptics, remained the local medication of choice for the hospital treatment of burns. Besides, chemotherapy in the form of sulfonamide drugs used orally or locally had come into use. Here, then, was a new, powerful remedy to ob-

viate the danger of sepsis that tannic acid alone might not always prevent.

PERIOD FROM OUTBREAK OF WAR UNTIL PEARL HARBOR

At the outbreak of war, the treatment of burns was relatively uniform. In first-aid treatment, picric acid was given preference in Great Britain as well as in this country. *The Memorandum for the Guidance of Medical Officers and Other Personnel at First Aid Posts* of the British Emergency Medical Services,¹⁹ issued in 1939, states: "No attempt should be made at cleaning these [burns]. They should simply be covered with a suitable dressing. The burn dressing (picric acid) should be moistened before application. Picric acid does not interfere with the efficiency of tannic acid dressing applied later. Morphia will probably be required." The American Red Cross *First Aid Textbook*²⁰ similarly placed picric acid first, and so did the War Department field manual, *Military Sanitation and First Aid*,²¹ published in 1940, although in the two latter publications tannic acid was given an almost equal place. Due stress was placed on combating shock by keeping the patient warm and providing him with fluids.

In the hospital, treatment with tannic acid alone or in combination with silver nitrate or antiseptics predominated. An example is the procedure recommended by McClure,¹⁸ of the Henry Ford Hospital, Detroit. Measures to control shock came first. The patient was given sedatives, heat externally, fluids (5 per cent dextrose and a physiologic solution of sodium chloride) and transfusions of blood plasma. The local treatment consisted in removing the clothing, superficial débridement and application of a 5 per cent freshly prepared solution of tannic acid with an atomizer or power spray. Collections of pus under the tan were liberated, skin grafting was employed early, and blood transfusions were given in late stages of secondary anemia. McClure emphasized the need for strict aseptic precautions during the surgical procedures, since the burned area should be regarded as a large open surgical wound.

This method represented one of the most advanced patterns of treatment, particularly as regards asepsis, which was too often neglected in routine practice. Other surgeons preferred silver nitrate in combination with the tannic acid or the addition of resorcinol. Still others painted the edges of the tan with antiseptics.²² It must also be remembered that gentian violet and triple dye had their advocates, but on the whole, coagulation with tannic acid in one form or another was the treatment of choice.

Before entering on the changes brought about by the experience of the war, two points that

later on became important in the treatment of shock should be mentioned. Early in 1940, Elkinton, Wolff and Lee²³ showed that the restoration of lost plasma proteins depends on the time when capillary impermeability is restored and on the amount of protein needed. In their opinion, loss of plasma continues for thirty to forty hours, and during this time repeated small plasma transfusions will prevent hemoconcentration. After forty hours a large plasma transfusion is given to make up the plasma deficit. They also proposed a formula for calculating the deficit, and various other methods for calculation were suggested by other authors.⁵ The work of Elkinton and his associates made it particularly clear that transfusions had to be given in the very early period after the injury. Estimates of the amount of plasma required, based on the extent of the burn, on hematocrit and hemoglobin readings and on calculations of the plasma deficit, assumed an important place in subsequent outlines of the treatment of burns.⁵ The quest for plasma and serum substitutes, on the other hand, did not meet with unequivocal success.²⁴ Secondly, it was realized that the administration of saline solutions was dangerous since it tended to increase the edema²⁵—unless vomiting had led to a serious loss of chlorides.³

In anticipating these points it can be shown that the general treatment of shock followed a gradual development. Although many theoretical points remain debatable, no completely new aspects have been introduced during the war,^{*} as in the case of the local treatment.

The fall of France, the evacuation of Dunkirk and the subsequent battle of Britain changed the perspective as well as many details of the treatment of burns. The British soldiers returning from France, the personnel of the R.A.F. and the civilians bombed in the British Isles suffered heavily from burns. From the spring of 1940 until the spring of the following year, the British had to cope with new and unforeseen conditions. Large numbers of burned persons had to be treated at first-aid posts or under first-aid conditions, treatment on board ship also falling into this category.^{28, 29} Often considerable time passed before patients were transferred to the hospitals, where facilities were overtaxed and work had to be performed under most difficult circumstances. Under the impact of the emergency, the need for certain adjustments made itself felt. Cohen,³⁰ who treated men evacuated from Dunkirk in a hospital of the Emergency Medical Service, remarked, "Many lessons were gathered, but one lesson stood

out clearly from it all—the necessity for and the value of a prepared routine of treatment [in hospitals]." The demands on doctors, nurses and hospital facilities were so heavy that makeshift arrangements were quite inadequate. Again and again in following years, the need for co-operating teams, including experienced general surgeons, plastic surgeons and even pathologists, as well as the desirability of burn centers, has been stressed.^{31, 32} Only recently, the disadvantages of lack of prepared routine were demonstrated when a fire broke out in a Knights of Columbus leave center in St. Johns, Newfoundland.³³ Seventy-seven patients had to be taken to various hospitals that, as can easily be understood, were not adequately prepared for such a disaster. As a result, many necessary materials were lacking and many different forms of treatment were employed by the staffs of the various hospitals.

Another lesson that was learned in Britain was the need for proper instruction of first-aid personnel. It was necessary to distinguish between those cases that might receive preliminary or definitive treatment by first-aiders and those that had to be transported to a hospital as soon as possible. This led to an increasing emphasis on a short, practical classification, as for instance into "minor" and "major" burns.³⁴ Regarding the latter class, it also led to restrictions in the local first-aid treatment, that many authorities kept to an absolute minimum, simply covering a severely burned part with clean towels, cloth or *tulle gras* or first powdering them with sulfanilamide.³⁴ Still others consented to more active measures, particularly if transport was delayed, as for instance in naval action.^{32, 34} The instructions of Emergency Medical Services,³⁵ dated June, 1941, advise: "*Serious burns* requiring admission to hospital should be treated by the application of sterile vaseline on gauze or lint to cover the exposed portions of the burn. Provided the patient is shortly to be transferred to a nearby hospital, no attempt should be made to remove clothing in order to expose the entire burn area. Serious burns always require injections of morphine for pain, in full doses ($\frac{1}{3}$ to $\frac{1}{2}$ gr. for adults)."

Although the points mentioned so far chiefly concerned organization and instruction for the treatment of burns, the very soundness of the prewar local treatment began to be questioned. To meet the danger of contractures under tannic acid treatment, the extremities, particularly the fingers, had been splinted³⁶ or extension apparatus used,¹⁸ but such measures were not sufficient. The fact that a great many war burns had affected the face and hands led to an early recommendation to substitute saline packs or baths on

*Recent research has made the traditional therapy of shock by external heat questionable, and it has also detracted from the value of oxygen inhalations.^{26, 27} These new aspects, however, have as yet hardly made an impact on the treatment of burns.

the so-called "critical areas." This recommendation did not, however, meet with general approval,³⁷ particularly since it was understood as a general rejection of the tannic acid treatment altogether. Whereas the majority of physicians followed the new directions and avoided tannic acid on the face and the hands, others defended the treatment and stated either that its condemnation was not at all justified or that there was not yet sufficient evidence for the rejection. A conference on the treatment of war wounds, organized by the War Wounds Committee of the British Medical Research Council on November 29, 1940, showed how vigorous was the defense.³⁸⁻⁴¹ Finally, there was a third group⁴² that tended to avoid tannic acid altogether.

Reviewing briefly the discussion for and against tannic acid treatment, the following trend is apparent. Those defending it pointed to the decrease in the mortality rate following the introduction of tannic acid. They maintained that the saving of life held precedence over the saving of function.^{43, 44} The opposition largely argued on the basis of the Hippocratic principle, *Nil nocere*. Saline baths and packs, which were so favorably received in Great Britain, owed some of their popularity to the advantages they offered to early skin grafting.⁴⁵ Most authorities agreed on the following point: burns that did not epithelialize promptly needed grafting, and sepsis was one of the major obstacles to the early performance of this operation. But among those who stressed the deleterious effects of sepsis were also advocates of triple dye therapy,³² which, as has been seen, had been devised for the prevention of infection.

Besides the use of saline baths, silver nitrate, triple dye, gentian violet and other drugs already mentioned, there emerged a host of different therapeutic procedures. The use of trypsin to clear up the burned surface was envisaged,³⁸ Euglamide⁴⁶ and the closed plaster treatment⁴⁷ were recommended, and Bunyan,^{48, 49} followed by other workers, suggested the envelope method with irrigations.* The latter method was recently illustrated in a popular American magazine,⁵¹ after Budyne ointment had also received publicity.⁶² These are but a few items from a long list.⁵³ By the middle of 1941, the local treatment of burns had become so confused that even the reintroduction of the much abused carron oil seemed possible, and anything might be good if, in addition, sulfonamide drugs were prescribed.^{54, 55}

The local application of sulfonamide, which at the outbreak of the war appeared to have great

promise, also had its ups and downs. Omitted by some⁴⁰ and cautiously used over small areas, usually in combination with coagulants, by others,⁵⁶ it was employed by still others as *the* local treatment. Best known among the latter methods was the one announced in August, 1941, by Pickrell,⁶⁷ who sprayed the burned area with 3 per cent sulfadiazine in 8 per cent triethanolamine. The Pickrell method was criticized by H. S. Allen and Koch,⁶⁸ who, however, conceded that sulfathiazole ointment, introduced by J. G. Allen, Owens and others⁶⁹ in May, 1942, might be useful in first aid. In Canada, Skinner and Waud⁶⁰ were working with plastic films of polyvinyl alcohol containing sulfonamide drugs. Among the other local applications of these drugs mentioned in the literature hydrated films containing 10 per cent sulfanilamide and buffer, with and without quantities of azochloramide,^{61, 62} may be cited as one of the most recent proposals.

PERIOD AFTER PEARL HARBOR

The disaster at Pearl Harbor on December 7, 1941, resulted in a great number of burns, and the treatment given shows some decisive differences as compared with the British procedure in 1940. Whereas in Great Britain shock had been mainly combated by keeping the patients warm and giving them large quantities of fluids orally at Pearl Harbor, in addition, blood plasma, supplemented by glucose and saline solution, was used in most cases. The local medication too varied considerably, at the United States Naval Hospital, for instance, it included sulfanilamide powder, sulfanilamide in mineral oil spray, sulfathiazole suspension, gentian violet spray and boric acid wet dressings.⁶³ At the dispensary of the Naval Air Station, on the other hand, the treatment was divided between tannic acid and sulfonamides.⁶⁴

But in spite of all the criticism and the many alternative remedies suggested, coagulation with tannic acid still predominated in the first half of 1942. In England, it is true, it had been removed from the schedule of first aid posts by March, 1942 and dressings of soft paraffin ointment had been advised instead.⁶⁵ It had also generally been recognized by this time that tannic acid should not be used on critical areas. For the rest, the state of affairs is approximately characterized by the recommendations of the National Research Council formulated in January, 1942.⁶⁶ Regarding first aid treatment it is here stated: "All burned surfaces except the face, hands and genitalia should be liberally coated with a water soluble jelly containing 10 per cent tannic acid and 5 per cent sulfadiazine. Burns of the face, hands and gen-

*Kilner recently advocated the first aid Bunyan bag filled with sulfonamide.⁵⁰

italia should be covered with a water-soluble emulsion containing 5 per cent of sulfadiazine." The definitive treatment of other areas envisaged tannic acid, 10 per cent, and silver nitrate, 10 per cent. Sulfadiazine was given orally as a routine measure. These recommendations of the National Research Council are echoed in the booklet of the Office of Civilian Defense⁶⁷ and represent opinions also found in the *Guides to Therapy* of the War Department⁶⁸ and in other publications of the time. *Treatment of Thermal Burns* issued by the National Research Council of Canada³ on August 6, 1942, although much more detailed regarding the pathology as well as the treatment of burns, also makes recommendations that are in basic agreement with those of the American National Research Council. In spite of all criticisms, qualifications and alternatives suggested, tannic acid by the middle of last year had not been superseded by any other single medication.

The recommendations of the research councils of the United States and Canada mention a point that indicates the further development. For burns on the hands, they suggest a firm-pressure bandage. This was an early recognition of a method that was soon to have a much wider application. Impressed by the inconclusive search for a burn toxin, some American physicians proposed to regard a burn simply as a large, open wound.⁶⁹ From this principle they deduced a simple technic. The burned area had to be examined, cleansed, and covered under strictly aseptic safeguards. The covering had to be nonirritant and had to protect the surface and prevent loss of fluid. "A large pressure dressing similar to that applied over skin graft seems to be advantageous in that it helps to immobilize the part and minimize the loss of fluid into the tissues about the burn." From January 1, 1939, on, the mortality rate at the Cook County Hospital in Chicago was considerably reduced by thorough cleansing and a pressure dressing over vaseline gauze. This treatment, first detailed for burns of the hand,⁷⁰ became more widely known through a paper by Allen and Koch⁶⁸ concerning the treatment of patients with severe burns.

Discarding the existence of burn toxins, Allen and Koch still had to account for the liver damage in certain cases. They attributed it to the use of general anesthesia, the danger of which, particularly in patients suffering from shock, had also been pointed out by others.³ But it was just the existence of liver necrosis, used as evidence for burn toxemia by Wilson, that led to a much more decisive argument against tannic acid than any advanced before. The studies by Wilson and his co-workers had been followed up by other observers. In April, 1941, Buis and Hartman⁷¹ found

that shock with plasma loss and hemoconcentration occurs in experimental burns and produces acute congestion of the tissues, especially the liver. Without excluding the possible existence of a burn toxin, they suggested that anoxia resulted from the shock, plasma loss, hemoconcentration and acute congestion as contributing causes of the liver necrosis. But a few months later Wells, Humphrey and Coll,⁷² at a meeting of the New England Surgical Society, gave a different interpretation of the liver damage. They claimed that the central necrosis of the liver was the result of treatment with tannic acid solution, tannic acid jelly or tannic acid and silver nitrate solutions. The dangers of the tannic acid treatment in turn enhanced the advantages of the Koch method, both being brought to the attention of a wider public in an editorial published in May, 1942, in the *Journal of the American Medical Association*.⁷³

Studies by Siler and Reid⁷⁴ presented experimental evidence suggesting that primary pressure dressings may reduce the loss of plasma at the site of, and into the surrounding tissues of, burned areas. On the other hand, the practical possibilities of the pressure method, which presupposes the strictest aseptic technic, were regarded with some skepticism by the armed forces. At the present moment, it cannot be said that any single method has been accepted to the exclusion of all others. The local treatment chosen depends on the site of the burn as well as on its degree, and Volume V of the *Military Surgical Manuals*⁷⁵ lists a considerable variety of medications including tannic acid, sulfonamide drugs, saline baths, boric ointment, the Bunyan-Stannard envelope and triple dye, as well as the pressure dressing. But the last-named method stands in the foreground of the debate. At the Coconut Grove fire on November 28, 1942, it underwent a favorable test,⁷⁶ and is now recommended by the National Research Council. In *Circular Letter No. 15*, dated January 11, 1943, from the Surgeon General's Office,⁷⁷ the treatment of burns with boric acid ointment is given first place, and the importance of firm pressure is stressed, especially in burns of the hands and face.

MASSACHUSETTS MEDICAL SOCIETY

PROCEEDINGS OF THE COUNCIL

Stated Meeting, October 6, 1943

A STATED meeting of the Council of the Massachusetts Medical Society was called to order by the president, Dr. Roger I. Lee, Suffolk, in John Ware Hall, 8 Fenway, Boston, at 10:00 a.m., on Wednesday, October 6, 1943. There were 215 councilors present (Appendix No. 1).

On a motion by Dr. Reginald Fitz, Suffolk, and a second by Dr. David Cheever, Suffolk, the record of the last meeting of the Council (May 24, 1943), as published in the *New England Journal of Medicine*, issue of July 8, 1943, was approved.

Dr. Lee, in commenting on the death of Dr. Halbert G. Stetson, spoke as follows:

It is the sad duty of the President to announce that Dr. Halbert G. Stetson, of Greenfield, a former president of the Massachusetts Medical Society, died on September 15, 1943. Dr. Stetson was probably known to everybody in the room. He was in his seventy-sixth year.

He received his degree in medicine from the College of Physicians and Surgeons of Baltimore in 1895.

Dr. Stetson had been a prominent member of the Massachusetts Medical Society, giving freely of his time and energy to his activities. He was president of the Society from 1931-1933. He was a delegate from the Massachusetts Medical Society to the House of Delegates of the American Medical Association for twenty years—1912-1932. He had been a member of the Council for many years. He likewise served as nominating councilor for many years. He was a member of the Committee on Public Relations from 1935 to 1943. He was president of the Franklin District Medical Society from 1901-1903. He also served as secretary-treasurer of this district society for many years.

From 1921 to his death he served as medical examiner for the Eastern District of Franklin County.

He had served as chairman of the Greenfield school board and president of the Franklin County Public Hospital Corporation. He was formerly president of the New York and New England Association of Railway Surgeons and the Connecticut Valley Medical Association.

Dr. Stetson was a member of the Scientific Assembly of the American Medical Association.

It was moved by Dr. Walter G. Phippen, Essex South, and seconded by Dr. Cheever that this memorial be placed upon the records. It was so ordered by vote of the Council.

REPORT OF EXECUTIVE COMMITTEE

The Secretary reported as follows:

The Executive Committee of the Council, at its meeting held on August 25, 1943, discussed the advisability of calling a conference of those who might be expected to represent the point of view of the ma-

jority of the physicians of New England anent the Wagner-Murray-Dingell Bill.

It was voted by the committee to empower the president, Dr. Roger I. Lee, to appoint a committee looking toward this end. Pursuant to this action, the following committee was appointed by Dr. Lee: Dr. Walter G. Phippen, chairman, Dr. Frank R. Ober, Dr. Brainard F. Conley and Dr. Michael A. Tighe. This committee will report its activities later in this meeting.

The committee regarded this matter as an emergency inasmuch as Congress was to reconvene in a few days and inasmuch as the committee was given to understand that hearings on this bill were to begin immediately after the Congressional recess.

(The Secretary moved that the Council approve this action of the Executive Committee. This motion was seconded by a councilor and it was so ordered by vote of the Council.)

The committee reviewed the reports of the following committees: Membership, Postwar Loan Fund, Public Relations and War Participation, and approved of their respective recommendations.

In relation to that part of the report of the Committee on Public Relations that deals with the operation in Massachusetts of the plan of the Children's Bureau for the maternity care of wives and infants of enlisted men, the committee expressed its approval in principle and so notified Dr. Vlado A. Getting, Massachusetts commissioner of public health. The Council has received advance information on this matter.

The War Participation Committee, under a directive of the Council, studied a plan organized by the staff of the Beth Israel Hospital for the care of the patients of those of their members who had entered the various services of the United States. In this directive the Council ordered the War Participation Committee to report on the matter to the Executive Committee of the Council.

In accordance with the recommendation of the War Participation Committee, the Executive Committee expresses its sympathy with the ideology involved but does not recommend approval by the Society of the plan as outlined in the protocol.

(The Secretary moved the adoption of this recommendation. This motion was seconded by a councilor. Dr. George L. Schadt, Hampden, asked if, by the Secretary's motion, the Council was being asked to approve the administrative setup in Massachusetts of the plan of the Children's Bureau for the maternal and infant care of soldiers' dependents. The Secretary replied that the Committee was offering no motion with regard to this plan and that the debate on this particular matter would come when the report of the Committee on Public Relations was offered. The motion before the house, he continued, had to do with the plan of the staff of the Beth Israel Hospital for the care of the patients of those of their members who had entered the United States service. The motion was adopted by vote of the Council.)

The Committee, under a directive of the Council, reconsidered the matter of sending gratis one hundred subscriptions of the *New England Journal of Medicine* for one year to the United States Navy and now so recommends

(The Secretary moved the adoption of this recommendation. This motion was seconded by a councilor. Dr Carl Bearse, Norfolk, expressed the fear that if this recommendation were adopted we would be put in the position of being partial to the Navy. He said that the Army had agreed to buy about six hundred subscriptions. If the Navy were to get these subscriptions free so should the Army. Dr Richard M Smith, Suffolk, favored the recommendation because he thought that it would be to the advantage of the *Journal* and that this organ would not particularly suffer because of the expense involved. The motion was adopted by vote of the Council.)

The by laws of the Massachusetts Medical Service Corporation require that the board of directors of that organization be approved by the Massachusetts Medical Society, which means the Council. The committee was in receipt of a communication from Mr Twomey, clerk of the Massachusetts Medical Service Corporation, urging an amendment to these by laws whereby this approval may be given by the Executive Committee of the Council in the name of the Massachusetts Medical Society. This amendment is urged as a matter of convenience, and is approved by the committee.

(The Secretary moved the adoption of this recommendation. This motion was seconded by Dr Fitz, and it was so ordered by vote of the Council.)

The committee acknowledges the receipt of two letters addressed to the Secretary—one from Dr Stephen Rushmore, dean of Middlesex University Medical School and the other from Mr Samuel H Wragg, president of this university. These letters in substance ask the help of the Massachusetts Medical Society in obtaining clinical teaching facilities for this Medical School. The committee took no action on these letters.

The committee approved certain ad interim appointments made by the President. Dr Lee will ask for the approval of these appointments later in this meeting.

(The Secretary moved the adoption of this report as a whole. This motion was seconded by a councilor. Dr Hyman Morrison, Norfolk, asked why the committee did not take any action on the letters of Dr Rushmore and Mr Wragg. At the direction of the President the Secretary replied that he could answer the question only from the standpoint of the discussion and debate that took place in the committee when this matter was presented to it. This debate seemed to indicate that it was the feeling of the majority of the committee that the granting of requests contained in these letters would involve the Massachusetts Medical Society in a type of activity in which it should not engage. Dr Morrison expressed the thought that he had no intention of advocating substandard medical education. He felt, however, that there is an honest effort in this case to improve the teaching and make the school a standard school. He added that he felt that it is along the tradition of the Massachusetts Medical Society to aid this effort. Dr Harold L. Musgrave, Suffolk, announced that he was a member of the Board of Trustees of Middlesex University Medical School, that this board had been reorganized

and that it now was made up of honest men who were trying to do a good job. He said that the preclinical needs of the school had been vastly improved. The inability to meet clinical needs of the school, however, results in failure in an important way. He added that the two letters spoken of in the report of the Executive Committee were prompted by the fact that a committee was appointed by the Society seven or eight years ago to help the school. He pointed out that the school was no longer a proprietary school and that the real motive behind the letters was an appeal for advisory counsel and nothing more. Dr Musgrave was advised by the President that any motion which he might have in mind in this matter would more properly come under the heading of new business. The report of the Executive Committee as a whole was adopted by vote of the Council.)

REPORTS OF COMMITTEES

Committee on Publications—Dr Richard M Smith, Suffolk, chairman

This report, which is as follows, was offered by Dr Smith

The committee has secured Dr Alfred Blalock, professor of surgery at Johns Hopkins University School of Medicine and surgeon in chief at the Johns Hopkins Hospital, Baltimore, to deliver the Shattuck Lecture at the annual meeting of the Society in 1944.

There are no important matters in connection with the supervision of the publication of the *New England Journal of Medicine* that need to be brought to the attention of the Council at this time. A full report will be made at the February meeting of the Council.

Dr Smith moved the adoption of the report. This motion was seconded by a councilor and it was so ordered by vote of the Council.

Committee on Arrangements—Dr Gordon M Morrison, Middlesex South, chairman

Dr Roy J Heffernan, Norfolk, reported for the committee as follows

Last year your committee looked forward to the 1943 meeting of the Society with some uncertainty. Owing to the absence of so many members in the service, to gasoline restrictions and to other wartime conditions we anticipated a small meeting. Fortunately our fears were groundless the attendance was only slightly less than the previous year, and the presence of a great number of Army and Navy medical officers made us feel that the meeting was justified. At the present time, the treasurer's books show a profit from that meeting of \$1863.42.

Your committee has voted that the 1944 annual meeting of the Society be held at the Hotel Statler, Boston, on Tuesday and Wednesday, May 23 and 24, 1944, and that the annual meeting of the Council be held at the same place on Monday evening, May 22, 1944.

Dr Heffernan moved that the report be accepted. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Committee on Ethics and Discipline—Dr. Ralph R. Stratton, Middlesex East, chairman.

The report (Appendix No. 2), which was offered by Dr. Stratton, spoke of two all-day meetings that the committee had held. Many of the cases coming before the committee were of minor importance and were settled by letter. Many others required the committee to conduct hearings.

Many of the complaints had to do with the fees charged by doctors. The committee believes that ordinarily it is not within its province to be involved in disputes of this kind.

The report spoke of three specific cases. One concerned an attempt on the part of a member to injure the professional reputation of certain of his professional brethren. The proof was insufficient and the matter was placed on file. The second case concerned a member who was charged with an active attempt to belittle the professional reputation of two other members. The charge in this case was substantiated and the member in question was asked to resign, which he did. The third case was concerned with the personal conduct of a member who was warned by the committee that his habits must improve.

Dr. Stratton moved the acceptance of this report. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Committee on Medical Education—Dr. Robert T. Monroe, Norfolk, chairman.

No report.

Committee on Membership—Dr. Harlan F. Newton, Suffolk, chairman.

This report, which was presented by Dr. Newton, is as follows:

The Committee on Membership, meeting with the supervising censors and the Committee on Ethics and Discipline, recommends that the application for reinstatement of Dr. Anthony P. Carogana, of 672 Broadway, Chelsea, this former fellow's resignation having been requested by the Committee on Ethics and Discipline, under the provisions of Chapter I, Section 11, of the by-laws, be approved.

Dr. Newton moved the adoption of the report. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Committee on Public Health—Dr. Francis P. Denny, Norfolk, chairman.

No report.

Committee on Medical Defense—Dr. Arthur W. Allen, Suffolk, chairman.

No report.

Committee on Society Headquarters—Dr. William H. Robey, Suffolk, chairman.

No response.

Committee on Finance—Dr. Francis C. Hall, Suffolk, chairman.

No report.

Committee on Industrial Health—Dr. Dwight O'Hara, Middlesex South, chairman.

No response.

Report of the Activities of the House of Delegates—Dr. Charles E. Mongan, Middlesex South, senior delegate from Massachusetts.

This report (Appendix No. 3) was offered by Dr. Mongan. At the conclusion of the report Dr. Lee complimented Dr. Mongan on its completeness and ordered it to be made a part of the record.

Massachusetts Committee on Procurement and Assignment—Dr. Reginald Fitz, chairman, reporting through courtesy of the committee.

At the outset, in offering the report (Appendix No. 4) Dr. Fitz said that it was his understanding that his committee was a committee of the Massachusetts Medical Society.

Dr. Lee ruled otherwise pointing out that Procurement and Assignment Service is an agency of the government operating under the War Manpower Commission.

Dr. Fitz moved the adoption of the report. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Committee on Public Relations—Dr. Albert A. Hornor, Suffolk, chairman.

This report, which was offered by Dr. Hornor, is as follows:

The committee met on August 18, 1943, at the Harvard Club and all were present except the representatives of two districts. President Lee presided, and I have the honor to report the following business as transacted:

1. The resignation of Dr. Elmer S. Bagnall, because he had become *ex officio* vice-chairman, and the election of myself as secretary of the committee.

2. The Committee on Public Relations endorsed in principle the plan of the Children's Bureau, as presented to the committee by Dr. Vlado A. Getting, for the care of wives and infants of men in the armed forces. This is the plan referred to in the advance information for the Council sent out by the secretary of the Massachusetts Medical Society. In the September 16, 1943 issue of the *New England Journal of Medicine* the plan is well described.

3. Dr. Bagnall asked that the members of the Committee on Public Relations submit to him the names of persons from their respective districts who would further the bank plan for postpayment of medical indebtedness, and this has been done.

4. A committee, consisting of Dr. Bagnall, Dr. Hornor and Dr. Tighe, was appointed by Dr. Lee to

confer with the Council on Employment Security. The first meeting will be held October 7.

Dr. Hornor moved the acceptance of this report. The motion was seconded by a councillor.

Dr. Schadt took issue with that part of the report as it refers to the last paragraph on page 3 of the sheets of advance information supplied the councillors, which reads as follows:

The Committee on Public Relations met in conference with Dr. Vlado A. Getting, state commissioner of public health, who discussed the administration of this plan in Massachusetts. In this state all deliveries will be in a hospital. All deliveries will be by graduates of Grade A schools or by those approved by a technical committee, the latter committee for the most part is identical with the Committee on Maternal Welfare of the Massachusetts Medical Society.

He pointed out that there are among the members of the Massachusetts Medical Society many who are graduates of unapproved schools. Under this plan, he continued, these gentlemen will not be permitted to take part in this plan.

Dr. Schadt was informed in this connection that the Massachusetts Department of Public Health had set up a technical committee, the personnel of which is largely made up from the Massachusetts Medical Society's Committee on Maternal Welfare and, when a graduate of a non-approved school applies to practice under this plan, his ability to do so will be assayed by this committee.

Dr. Schadt said that it was important that we understand that certain of our members could not practice under this plan unless they had received the approval of a committee.

Dr. Brainard F. Conley, Middlesex South 1, asked if it were not true that, when the law was passed in Washington, it was specified that there could be no discrimination as to the qualifications of men provided that they were within their rights to practice in the state in which they lived.

Dr. Lee said that the Attorney General of the United States had ruled that the Children's Bureau could not discriminate in the manner mentioned by Dr. Conley but this ruling was not binding on the states.

The Secretary pointed out that each state had its own administrative setup and that, when Dr. Getting met with the Committee on Public Relations, he said that he had a ruling from the Attorney General of Massachusetts to the effect that the Department of Public Health was within its rights, under the law, in setting up the conditions under which this plan should be operated in Massachusetts.

Dr. Mongan said he would not ask the Attorney General of Massachusetts, no matter how emi-

nent he might be, to decide a question of federal law.

Dr. Hornor said that there are two points at issue. In the first place, it is clear that federal boards cannot discriminate. On the other hand, in the actual administration of the plan in the several states, the health departments of those states are within their rights in designating those who will give their services under the plan. At least this is true in Massachusetts, Dr. Getting having the word of the Attorney General of Massachusetts to this effect.

Dr. Smith, a member of the Public Health Council, confirmed the latter statement in response to a question put by Dr. Schadt.

Dr. Donald Munro, Suffolk, was recognized by the chair. He said he would like to discuss certain other objections to this paragraph in the report of the committee:

As I understand it the recommendation of the committee is that this law be approved in principle. It seems to me that is wrong. I refer to the financial relation between the patient and his doctor. As I understand this law, there is a provision whereby the doctor is paid directly from the federal government or its representative, and there is no financial agreement between the patient and his doctor. A set fee is paid for certain services and that is given directly to the doctor without any intervention or consent on the part of the patient. Is that correct?

Dr. Hornor replied, 'The consent of the patient and the doctor must be agreed to; they must be in agreement before they make any application, and in making the application, they both sign a definite agreement as to that particular fee.'

Dr. Munro continued:

Nevertheless, the fee is paid directly to the physician by the Government and not by the patient. It seems to me that this violates a principle that we have supported for a great many years. I do not think that any member of the Massachusetts Medical Society will raise his hand to stop the law, but I do think it opens up that phase or aspect of the problem and I think for that reason that this law should not be approved in principle by this body. Furthermore, it seems that this is the opening wedge looking toward the establishment of state or federal medicine. Here we are now advocating in principle the payment by the federal government of money to the doctor without any formal agreement between the doctor and his patient. I think that is bad and it should be opposed by this society as a group. I am informed that practically every state society throughout the country has also taken that same attitude. They felt that this is a law which violates our principles. I recognize that regardless of any action of the Society the payment of these moneys and the putting into effect of this law will take place. But I think that this society should raise its objection to the violation of the principle involved. I hope that paragraph 2 of Dr. Hornor's report will not be accepted.

Dr. Hornor said that every member of the Committee on Public Relations felt the same way as Dr. Munro did. He said the committee was also aware that Dr. Munro's stand was the stand of the House of Delegates of the American Medical Association but that there did not seem to be any other way in which to put this proposal into effect.

Dr. H. Quimby Gallupe, Middlesex South, secretary of the State Board of Registration in Medicine, said he was instructed by his board to state that it would offer no objections to the plan proposed by Dr. Getting. He called attention, however, to the fact that there were a very large number of registered physicians in the Commonwealth who are graduates of unapproved schools and that there are many thousands of families being cared for by such graduates. He added that these families have within their numbers many citizens who contribute to the federal funds that support this plan. He thought that this matter would be better organized if the plan would indicate that all registered physicians in the Commonwealth could participate if they initially could prove to the Technical Committee their ability to do satisfactory obstetrics. An alternative to this, he continued, would be to have the plan open to all members of the Massachusetts Medical Society who could prove to the Technical Committee their ability to do satisfactory obstetrics.

Dr. Paul J. Jakmauh, Norfolk, was recognized by the chair. He said that the program under discussion was presented while he was commissioner of health of Massachusetts and that, as a result of a survey that he had made, he found that there was no need of it. He said that the plan would go on anyway whether we approved it or not and intimated that the Society should commit itself only after a free and thorough discussion of it.

Dr. Norman A. Welch, Norfolk, said that at the time the Massachusetts plan was first presented to the Committee on Public Relations, it had already gone to Washington for the approval of the Children's Bureau and that the reason for the haste in getting the Society's approval of it was a desire on the part of the Commissioner of Health to be able to say that the physicians of Massachusetts approved. He added that the plan, as outlined, did discriminate against certain physicians and in this respect we should move cautiously. We cannot, however, he continued, be in the position of failing to co-operate with the federal government in a plan that provides for the maternal and infant care of soldiers' dependents.

Dr. Smith explained that the haste mentioned by Dr. Welch was due to the fact that, under the law, the plan had to be in effect by September 1.

Dr. Conley expressed the thought that there are many principles involved in the plan and he wanted to know which of those we were accepting.

Dr. James C. McCann, Worcester, thought we might favor the program and leave the question of principles for another time.

Dr. Charles C. Lund, Suffolk, expressed himself as being in accord with many of the criticisms of the plan already mentioned. He thought, however, that it would be harmful to our public relations if the word went out that the doctors of the Commonwealth refused to play ball. He added that public relations might be further improved if we should ask the Children's Bureau and Dr. Getting to remove the apparent discrimination against certain doctors.

Dr. Richard Dutton, Middlesex East, asked whether the State Department of Public Health, in operating this plan, would act as a state body or as a federal body.

At the request of the chair, Dr. Smith answered by saying that the state department was merely distributing certain federal funds under regulations set up by this department. Dr. Hornor added that these regulations must be approved by the Children's Bureau, to which Dr. Smith agreed.

Dr. Leroy E. Parkins, Suffolk, said he was opposed to approving this thing officially. He added that he would like to co-operate but the way suggested did not appeal to him.

Dr. Elmer S. Bagnall, Essex North, president-elect, thought that this matter should for the moment be tabled until such time as action could be properly worded. He favored the appointment of a committee of the Council which would consider this matter, such a committee to report later in the meeting. Dr. Bagnall offered this as an amendment to Dr. Hornor's motion to accept the report. This amendment was seconded by a councilor.

There was much discussion at this point, principally as to procedure. Participating in the discussion were Dr. Lund, Dr. Philemon E. Truesdale (Bristol South), Dr. Schadt, Dr. McCann, Dr. Fitz, Dr. Nathaniel W. Faxon (Suffolk), Dr. Edward F. Timmins (Suffolk), Dr. Hornor and Dr. Mongan.

The chair called for a show of hands as to the advisability of receiving the report of the Committee on Public Relations without adopting what might be termed the recommendation contained therein. The vote was overwhelming in favor of such a procedure.

Dr. Lee declared the report received.

Dr. Hornor moved that the question of the care of the wives and children of men in uniform be

referred back to the Committee on Public Relations and that in the meantime the Society co-operate with the Commissioner of Public Health in the execution of the plan as now developed. This motion was seconded by a councilor.

Dr. Bagnall again reiterated his original thought that it would be much better if a committee of five of the Council were appointed by the President to bring in a report on this matter later in the meeting, such a committee to have in mind the discussion which has already taken place.

At the suggestion of the chair Dr. Bagnall acquiesced in offering this as a substitute motion. This substitute motion was seconded, and it was so ordered by vote of the Council.

The chair appointed Dr. Hornor, Dr. Smith, Dr. Bagnall, Dr. Welch and Dr. Gallupe. (These gentlemen retired.)

Committee on Legislation—Dr. Brainard F. Conley, Middlesex South, chairman.

No report.

Committee on New England Conference Anent Senate Bill 1161 (Wagner-Murray Bill)—Dr. Walter G. Phippen, Essex South, chairman.

Dr. Phippen reported as follows:

The Executive Committee of the Council of the Massachusetts Medical Society empowered the President to appoint a committee to consult with representatives of the New England state medical societies regarding a joint conference between doctors and legislators of New England on the subject of the Wagner-Murray-Dingell Bill, with power to proceed with such a meeting if they so decided. The President appointed to that committee Dr. Walter G. Phippen, chairman, Dr. Frank R. Ober, Dr. Brainard F. Conley and Dr. Michael A. Tighe.

The committee met and decided to invite the New England state medical societies to send representatives to an informal meeting to discuss what steps if any should be taken, to influence the New England senators and representatives. In response to this invitation nine members of the medical societies of Maine, New Hampshire, Rhode Island and Connecticut met with your committee and the President of the Massachusetts Medical Society on Wednesday, September 22, 1943. While this conference was purely informal it was very satisfactory. Various angles of the situation were discussed and the viewpoints of the other states were well presented. It was the unanimous opinion of this group that it would be unwise, for various reasons, to try to hold a joint meeting of New England doctors and congressmen. It was, however, thought wise to consider the organization of an informal New England group to study and analyze the Wagner-Murray-Dingell Bill, and to distribute information and criticisms, possibly advice, as to the proper approach to senators and representatives, and send this to various members of the profession throughout New England with the idea that personal contact might do more good than large

conferences. With this end in view the meeting adjourned to meet again on October 20.

On a motion by Dr. Phippen and a second by a councilor the report was accepted as a report of progress.

Committee on War Participation—Dr. William B. Breed, Suffolk, chairman.

This report (Appendix No. 5) spoke in terms of appreciation of the work done by the district reviewing committees. It said that 321 names were submitted to these committees and 298 had been reported on; 102 were declared available, 31 were already in the service and 32 had already submitted their applications. Twenty-nine were declared essential, and 104 were not available.

The report recommended that the present reviewing committees in the several districts be not discharged, but be retained with the same personnel and organization (chairmen and secretaries) as district committees on war participation, subcommittees, so to speak, of this committee.

Dr. Breed moved the adoption of the recommendation. This motion was seconded by Dr. Mongan, and it was so ordered by vote of the Council.

The report further recommended that an appropriation of \$300 be made to this committee for past and future expenses, largely clerical, from the time of its appointment to January 1, 1944.

Dr. Breed moved the adoption of this recommendation. The motion was seconded by a councilor.

The Secretary announced that the Committee on Finance approved, and it was so ordered by vote of the Council.

Committee on Postwar Loan Fund—Dr. George Leonard Schadt, Hampden, chairman.

This report (Appendix No. 6) was offered by the chairman who moved its acceptance as a report of progress. This motion was seconded by a councilor and it was so ordered by vote of the Council.

Committee on Public Relations (continued)

Dr. Hornor, in reporting for the committee of five appointed earlier in the meeting, made the following motion:

The Council of the Massachusetts Medical Society pledges full co-operation with the Massachusetts Department of Public Health in the procurement of adequate care for the wives and infants of men in the armed forces. The Council respectfully requests that the Commissioner of Public Health modify the regulations with reference to "Standards of Medical Care," paragraph 2, as printed in the *New England Journal of*

Medicine for September 16, 1943, so that the physician who is to be paid for maternal or infant care must be registered in Massachusetts and must be found qualified by training or experience in obstetrics or pediatrics and approved by the technical committees appointed by the Commissioner of Public Health.

Dr. Hornor moved the adoption of this motion. The motion was seconded by a councilor, and it was so ordered by vote of the Council.

Committee to Meet With the Medical Advisory Committee of the Industrial Accident Board — Dr. Daniel J. Ellison, Middlesex North, chairman.

No report.

Subcommittee on Tax-Supported Medical Care — Dr. Elmer S. Bagnall, Essex North, chairman.

This report, which was offered by the chairman, is as follows:

The State Department of Public Welfare has, with the approval of its advisory board, adopted a formulary of approved drugs. This is based on pharmacopoeal rather than more expensive proprietary remedies.

The druggists are co-operating effectively.

We recommend that the Council of the Massachusetts Medical Society approve the formulary in principle and that physicians treating old-age and state-welfare patients be urged to accept the initial minor inconveniences as a public service in the interest of proper economies.

Dr. Bagnall moved the adoption of the recommendation. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Subcommittee on Postpayment Medical Care (Bank Plan) — Dr. Elmer S. Bagnall, Essex North, chairman.

Dr. Bagnall said that the committee was to have a meeting at the close of the Council meeting and that a vice-president of the National Shawmut Bank is endeavoring to obtain material for the committee from the National Bank Association. Dr. Bagnall moved that this report be adopted as a report of progress. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Subcommittee on Prepayment Medical-Care Costs Insurance — Dr. James C. McCann, Worcester, chairman.

Dr. McCann reported as follows:

When I reported in June there were about 2000 members enrolled. The early period of organization was necessarily given over to approaching industrial groups, and I can say that our enrollment now in the first year will be 10,000. That compares very favorably with all the states except one. New Jersey in the

first year had about 7000, and Colorado in about the same period had 10,000 and is concerned with whether it can go much beyond that. Pennsylvania in three years has approximately 10,000 enrollments. Michigan must be looked on as most unusual because of its huge organized industries. Its enrollment is running up to 500,000.

With regard to the financial condition of the organization, last June the subscriptions were \$6000. Today they stand at \$30,000. The operating expenses are about \$11,000 and the payments to members to date about \$10,000, which, other than that initial cost of \$4000 for organization expense, leaves the Massachusetts Medical Service Corporation with a balance of \$1200. That takes care of the \$300 required for the premium and the 25 per cent reserve required by the Commissioner of Insurance. It may possibly be that the reserve will be waived for the first year, which would allow us to remove the obligation of the \$4000, probably about \$4000 surplus, without having to use any of the \$25,000 that the Council so generously donated. So that we have our program rolling along at about the average rate, and rolling along with every prospect of success.

Dr. McCann's complete report (Appendix No. 7) was read by title only.

Dr. McCann moved that the report be accepted as a report of progress. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Military Postgraduate Committee — Dr. W. Richard Ohler, Norfolk, chairman.

No report.

Committee to Aid the District Rationing Administrator — Dr. Joseph Garland, Suffolk, chairman.

Dr. Garland reported as follows:

Your committee, since notification of its appointment on June 21, has met four times with the district rationing officer; Mr. John M. Deely, and Miss Elizabeth Golden, of the Food Rationing Division. About 730 persons, up to October 1, have applied for unusual allotments of rationed foods on Doctors' Certificates of Patients' Necessity, of which 240 have been reviewed in detail by the members of the committee. The remainder were passed on at the district office under instructions laid down by the committee. Between 20 and 30 certificates were rejected. In addition to these requests, several thousand certificates have been approved by the local war price and rationing boards according to directions furnished by the committee.

At the present time, certificates are coming in at the rate of approximately 150 per month, which perhaps is not an unusual number to come from an area with over 3,000,000 inhabitants, and would seem to indicate that the medical profession as a whole is co-operating well with the rationing officials. There will probably be a sharp increase from now on, however, as the district has been enlarged, as of October 1, to cover the entire state, adding some 2,000,000 individuals to the program.

It seemed desirable at the start to establish certain reasonable maximums of rationed foods that would apply to the majority of cases, regardless of the medical diagnosis, and your committee, after consulting with various competent authorities, accepted the standards established by Joslin and others for diabetics, namely, 32 pounds of processed foods and 40 of meats and fats for each two-month period. Local rationing boards have been advised that they may grant up to these maximums on certificates properly executed by registered physicians. All requests in excess of these maximums are forwarded to the district office for review.

It is obviously not the function of this committee to decide in what manner and by what method medicine is to be practiced in Massachusetts, but only to prevent abuse of the privilege of prescribing extra rations, so that a limited supply of certain foods may be fairly distributed.

So far as local district rationing officials have been able to discover, Massachusetts is the only state that has made the effort to handle the requests for extra food rations in this manner.

Dr Garland moved the adoption of the report. This motion was seconded by a councilor and it was so ordered by vote of the Council.

Committee to Aid the Boston Medical Library—
Dr William H. Robey, Suffolk, chairman

Dr Robey reported that the work of the committee had been finished. He moved that it be discharged. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Committee on Cancer—Dr Ernest L. Hunt, Worcester, chairman

No report

Committee on Postgraduate Instruction—Dr Reginald Fitz, Suffolk, chairman

No report

Committee on Physical Therapy—Dr Arthur L. Watkins, Middlesex South, chairman

No response

Committee on Expert Testimony—Dr Frank R. Ober, Suffolk, chairman

No report

Committee on Automobile Insurance Claims—
Dr Henry C. Marble, Suffolk, chairman

No response

Committee on Convalescent Care—Dr T. Duckett Jones, Norfolk, chairman

No response

Committee to Study the Practice of Medicine by Unregistered Persons—Dr Richard Dut

ton, Middlesex East, chairman

No report.

Committee to Meet With the Massachusetts Hospital Association—Dr. Walter G. Phippen, Essex South, chairman.

No report.

Committee on Maternal Welfare—Dr Judson A. Smith, Suffolk, chairman

No response

Committee on Rehabilitation—Dr William E. Browne, Suffolk, chairman

The report which was offered by Dr Browne is as follows:

This communication is obviously not a report from the Committee on Rehabilitation. Even though quite frequently in the daily press and various professional, including medical, journals the need for rehabilitation is being stressed more and more, no meeting of your committee has been held since the last meeting of the Council of the Massachusetts Medical Society.

Curtis M. Hilliard, director of the Subdivision of Health, Massachusetts Committee of Public Safety, called a meeting of his fairly large committee on September 14, 1943. Only four members of his committee, however, answered his call. He has again notified all members of his committee that an important meeting will be held October 8. Shortly after this meeting the members of your committee will get together and try to arrange a program that may be of some help in this important work of rehabilitation.

It may be of interest herein to state that already it seems apparent that the members of the Massachusetts Medical Society can be of real assistance with the formation of a group of physicians in each district who may review, when called on to do so, the medical problem of anyone discharged from service because of some form of disability. At the present time it does not seem that the members of the Massachusetts Medical Society can do very much in the matter of aiding those discharged, even when rehabilitated in getting a job. With information at hand it is not entirely clear what the federal government will do in this matter. Certain states have gone ahead with tentative programs, but no very definite program has been worked out thus far.

I repeat that following the meeting on October 5 the Committee on Rehabilitation will meet and, if necessary, send a communication to the Executive Committee of the Council of the Massachusetts Medical Society before the next general meeting of the Council.

On a motion by Dr Browne and a second by a councilor the report was accepted as a report of progress.

Committee on Ways and Means to Conserve Physicians' Energies—Dr Elmer S. Bagnall, Essex North, chairman

No report

APPOINTMENTS

Dr Lee named Dr Fritz B. Talbot, Suffolk, chairman of the Auditing Committee for 1943 and

Dr. Harry Linenthal, Norfolk, as the second member of this committee. These nominations were confirmed by vote of the Council.

The following ad-interim appointments, made by the President, were confirmed by vote of the Council:

To the Council:

- Dr. John T. Batal, Essex North, replacing Dr. Elmer S. Bagnall, who has become a member *ex officio*.
- Dr. John E. Burns, Norfolk, replacing Dr. Norman A. Welch, who has become a member *ex officio*.
- Dr. Joseph H. Carey, Norfolk, replacing Dr. Louis F. Curran, deceased.
- Dr. Henry M. Landesman, Norfolk, replacing Dr. Morris Frank, deceased.
- Dr. Nahum R. Pillsbury, Norfolk South, replacing Dr. Daniel B. Reardon, who has become a member *ex officio*.

To the Committee on Finance:

- Dr. Francis C. Hall, chairman, replacing Dr. John Homans, resigned.

To the Committee on Legislation:

- Dr. William E. Browne, Suffolk, replacing Dr. William B. Breed, resigned.
- Dr. John J. McNamara—representative from Plymouth District.
- Dr. Henry Wardle—representative from Bristol South District.

To the Military Postgraduate Committee:

- Dr. Gordon M. Morrison.

To the Committee on Postpayment Medical Care (Bank Plan):

- Barnstable: Dr. Harold F. Rowley
- Berkshire: Dr. Charles F. Fasce
- Bristol North: Dr. James H. Brewster
- Bristol South: Dr. Harold E. Perry
- Essex North: Dr. Elmer S. Bagnall, chairman (already a member of committee)
- Essex South: Dr. Loring Grimes
- Franklin: Dr. Howard M. Kemp
- Hampden: Dr. Patrick E. Gear
- Hampshire: Dr. Alfred J. Bonneville
- Middlesex East: Dr. Wilfred L. McKenzie
- Middlesex North: Dr. Daniel J. Ellison (already a member)
- Middlesex South: Dr. Egon E. Kattwinkel
- Norfolk: Dr. Norman A. Welch
- Norfolk South: Dr. Walter L. Sargent
- Plymouth: Dr. Michael F. Barrett
- Suffolk: Dr. Francis T. Jantzen
- Worcester: Dr. James T. Brosnan
- Worcester North: Dr. William G. LeBrecht

To the Postwar Loan Fund Committee:

- Drs. George L. Schadt, chairman, Edward P. Bagge, C. Sidney Burwell, John Homans, Eliot Hubbard, Jr., Peirce H. Leavitt, Herbert L. Lombard, Hyman Morrison, Walter G. Phippen, William F. Ryan, David D. Scannell, Charles A. Sparrow, Ralph R. Stratton, Michael A. Tighe, Charles F. Wilinsky.

To the Committee Concerned with Prepayment Medical Care Costs Insurance:

- Dr. Joseph C. Merriam, replacing Dr. William B. Breed, resigned.

To the Committee on Public Education:

- Dr. Joseph Garland, replacing Dr. Richard M. Smith, resigned.

To the Committee on Public Relations:

- Dr. Harold R. Kurth, replacing Dr. Elmer S. Bagnall, who has become a member *ex officio*.

To the Committee to Aid the District Rationing Administrator:

- Dr. Joseph Garland, chairman, Dr. F. Gorham Brigham, Dr. Franklin W. White.

To the Committee to Arrange Conference with New England Physicians Anent the Wagner-Murray-Dingell Bill:

- Dr. Walter G. Phippen, chairman, Dr. Frank R. Ober, Dr. Brainard F. Conley, Dr. Michael A. Tighe.

To Massachusetts Hospital Service, Incorporated (voting member):

- Dr. Joseph C. Merriam, replacing Dr. David L. Halbersleben, resigned.

NEW BUSINESS

The chair recognized Dr. Harold L. Musgrave, Suffolk. The latter asked that the letters from Dr. Ru. hmore and Mr. Wragg, referred to in the report of the Executive Committee, be read.

These letters were read by the Secretary. They are as follows:

MIDDLESEX UNIVERSITY SCHOOL OF MEDICINE
May 25, 1943.

Dr. Michael A. Tighe, Secretary
Massachusetts Medical Society
8 The Fenway
Boston, Massachusetts

Dear Dr. Tighe:

The Massachusetts Medical Society has from time to time formally directed its attention to the School of Medicine of Middlesex University, and it is the opinion of the school that the time has come for the Society to do so again. The grounds for this opinion are set forth below, after reviewing some of the past occasions.

In 1936, a law was passed in Massachusetts establishing an approving authority for medical schools, and in accordance with this statute, no graduate of a medical school not approved by this authority should after a certain time, be admitted to examination for license to practice medicine in this Commonwealth. The effect of this law on Middlesex Medical School was to stimulate the efforts at improvement which had previously seemed to be rather desultory and separated by rather long intervals of time. In that same year a letter was written to the Massachusetts Medical Society by Middlesex College in which it was indicated that the good offices of the Society in plans for improving the school would be appreciated.

The Committee on Medical Education and Medical Diplomas, of which Dr. Reginald Fitz was chairman, presented as part of its report to the Council at its stated meeting held October 7, 1936, the following recommendations: "That the Massachusetts Medical Society inform the Trustees of Middlesex College that the Society is deeply interested in the improvement of all conditions which have to do with the giving of medical education in Massachusetts; that the Society is anxious to do all that it can to help Middlesex College develop in an approved manner. The Society suggests that the Trustees of Middlesex College lay before the president of the Society suggestions as to how the Massachusetts Medical Society might be of help to Middlesex College."

The proceedings of the Council read further as follows: "In addition to the foregoing formal recommendation the committee offered the suggestion that the President be empowered to appoint a committee of fellows of the Massachusetts Medical Society to act on behalf of the Society of the Massachusetts Medical Society in an advisory capacity to any medical school or college in helping direct such institution's efforts to develop and improve its facilities for teaching. The report of the committee was accepted by vote. The Council next adopted the formal recommendation of the committee and voted approval of the suggestion that the President appoint an advisory committee recommended by the Committee on Medical Education and Medical Diplomas."

In June, 1939 Dr. Elliott Joslin, recognizing that the Society had an important interest in all efforts directed toward the education of physicians within the Commonwealth, and therefore had some obligation in the matter and being aware of a certain expressed willingness on the part of the school to accelerate its progress devoted a considerable part of his annual discourse before the Society to the discussion of the problem presented by Middlesex School of Medicine and he made a number of suggestions noting some steps to be taken by the college.

Actually so little seemed to be done following the action of the Council in 1935 and following the suggestions made by Dr. Joslin in 1939 that the general impression on has been that nothing was accomplished. But it was important that the problems should have been brought to the attention of the medical profession and be discussed frankly and freely. It became more evident that here was a problem in which the medical profession had a great interest and since the law said in substance that the school would within a comparatively short time have to be salvaged or closed more serious attention was given to the question of whether the school should be salvaged and if not why not.

Without going into the details of a rather complicated situation it may be summarized by saying that the impression spread that the school was willing to be salvaged by the efforts of others rather than by its own efforts and many persons raised the question "Why bother about the school if it was not willing to help itself?"

It is because this impression was not quite correct that the school would like to bring to the attention of the Society the condition in which it actually now is so that the Society may become aware of how much has been accomplished by the school in transforming itself and in making progress on the way to deserving approval.

The basic criticism of the school was its proprietary character. Assurance can be given that in this respect the change has been radical and complete. The proprietary features have been removed and will not be permitted to return.

Another criticism was that the standards of admission were low. For a number of years until the present war emergency, the requirements were a baccalaureate degree and the generally accepted minimum requirements in science as set by the Council on Education of the American Medical Association. The quality of the students at judged by scholastic standards in college has been steadily improving.

Another criticism was that Middlesex accepted students who had failed elsewhere. For a number of years no student who failed in another medical school has been admitted to advanced standing. Occasionally a student from this group has been admitted to the first year class but no credit is given for any work done in another medical school if the candidate has been dropped on account of poor scholarship.

Another criticism has been that graduates of schools of osteopathy were admitted to advanced standing and were given their degrees in medicine after one year of attendance. This practice was especially objectionable because to few osteopathic physicians had fulfilled the usual minimum premedical requirements. For a number of years no credit toward the medical degree has been given by Middlesex for work done in a school of osteopathy.

The status of the graduates has been improved as they are now eligible for commissions in the armed forces and over two hundred have actually been commissioned. The students and the faculty have been given deferment and over \$18,000 of the War Loan Fund has been given to Middlesex students.

Certain much needed improvements it has been impossible to complete under wartime conditions but plans are in the making for rapid development as soon as conditions permit. The demand for medical education has not diminished and the school is still overcrowded but the institution in the first and second years is good. It is in the third and fourth years that serious deficiencies persist due to lack of clinical facilities.

There has been expressed a fear that hospitals approved by the Council on Medical Education of the American Medical Association would lose their standing with this body if they permitted the use of their clinical facilities for the teaching of the students of Middlesex. The secretary of the council, Dr. Herman G. Weinkotten has stated explicitly that as far as the rating by the council is concerned such teaching of students would have no effect. Thus this difficulty has now been removed.

One of the great obstacles to the progress of the school has been the adverse sentiment of the medical profession largely due to the just criticism based on the points which have been noted above but the grounds for which are now things of the past.

The school is prepared and will be very glad to enter into conference with the Massachusetts Medical Society along the lines suggested by the Committee on Medical Education and Medical Diplomacy in 1936 or in any other way that seems appropriate to the officers of the Society and we hope that the Society is as willing now as it was in 1936 to assist the school in such ways as may seem practicable.

Yours sincerely,

Stephen Rushmore (signed)

STEPHEN RUSHMORE, M.D., Dean

MIDDLESEX UNIVERSITY

August 16, 1943

Dr. Michael A. Tighe, Secretary
Massachusetts Medical Society
9 The Fenway
Boston, Massachusetts

Dear Dr. Tighe

Several times in the past the Massachusetts Medical Society has expressed its willingness to be of assistance to Middlesex University School of Medicine. We believe

now that the time has come when your society may aid us in a very material way.

The Executive Committee of the Board of Trustees, as at present constituted, has during the past year made considerable improvement in the medical school, and is now much in need of the assistance which the Executive Committee believes the Massachusetts Medical Society may give. This point of view, I believe, has been presented to your society by our dean, Dr. Stephen Rushmore, on May 25, 1943, and since time is important we should now greatly appreciate your appointing a small committee to meet with a similar committee of the university at an early date.

The School of Medicine is training several hundred students for eventual service as commissioned officers in the United States Army Medical Corps. It is greatly handicapped in its efforts by the lack of adequate clinical teaching facilities. The trustees of the university ask the Massachusetts Medical Society for assistance in order that the university may provide a better training for these prospective physicians, whose services are so vitally needed, as indicated by the leading editorial, entitled "More Doctors Needed for the Armed Forces," in the August 7 issue of the *Journal of the American Medical Association*.

Very truly yours,

Samuel H. Wragg (signed)

SAMUEL H. WRAGG, President

The Secretary said for the information of the Council that on October 7, 1936, the following motion was passed by the Council:

That the Massachusetts Medical Society inform the Trustees of Middlesex College that the Society is deeply interested in the improvement of all conditions which have to do with the giving of medical education in Massachusetts, that the Society is anxious to do all that it can to help Middlesex College develop in an approved manner. The Society suggests that the Trustees of Middlesex College lay before the president of the Society suggestions as to how the Massachusetts Medical Society may be of help to Middlesex College.

He continued that, under this motion, the following committee was appointed. Dr. Reginald Fitz, chairman, Boston; Dr. Fresenius Van Nuys, Weston; Dr. James F. Donaldson, Salem; Dr. William F. Lynch, Worcester; Dr. William T. Frawley, Pittsfield. He added that there is no record that this committee has ever reported.

Dr. Musgrave spoke of the radical changes which had taken place in the personnel of the trustees of Middlesex University Medical School. He said that the old order is gone forever, that this school has ceased to be a proprietary school and that it is now in the hands of honest and earnest men who want to do and who are doing a good job. He added that facilities for clinical teaching represents the school's greatest need. He pointed out that the graduates of this school are being commissioned in the Medical Corps of the United States Army.

Dr. Musgrave moved that the committee, heretofore referred to as appointed in 1936, be dis-

solved. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Dr. Musgrave moved that a committee be appointed to discuss with the trustees of Middlesex University their problems in their attempted improvement of the school. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Dr. Earle M. Chapman, Suffolk, was recognized by the chair. He spoke as follows:

At the May meeting of the Council many of you applauded the report of the Committee on Legislation in which we were advised that only \$50 was spent on legal aid. It is unfortunate that you who applauded did not also hear Dr. Quimby Gallupe, secretary of the Board of Registration in Medicine, expose the shocking inadequacies of our legislative committee in the May 27 meeting. In this year's session, a relatively inactive year, two bills of great importance to the Massachusetts Medical Society went through without either the support or opposition of our society.

First, the Antivivisection Bill reached the Governor's desk, where it fortunately was stopped by him. This bill was not opposed.

Second, a vital bill to improve the standards of practice in this state was defeated. This was a bill which would limit to the number of three the times that a man could appear before the Board for re-examination. This bill received no support from the Committee on Legislation and, as Dr. Gallupe expressed it, he likes to feel that the Board of Registration functions in the State House for the Massachusetts Medical Society. In closing his address at that time Dr. Gallupe made two specific recommendations to the Society: that we employ adequate legislative counsel, and that, in order to improve the standards of practice, we favor the annual registration of physicians.

Dr. Chapman moved that the Council of the Massachusetts Medical Society recommend employment of adequate legislative counsel to aid legislation favorable to the medical profession and to oppose legislation that is considered unwise. This motion was seconded by a councilor.

Dr. Welch asked if this motion were passed would it compel the Committee on Legislation to employ counsel irrespective of its judgment as to the necessity for such employment. Dr. Lee replied that such was his understanding of the motion.

Dr. Lester M. Felton, Worcester, asked what was the meaning of the words "adequate counsel" as they appear in the motion. Dr. Chapman replied that these terms refer to a lawyer who makes the serving of our interests a full-time job or mostly a full-time job, who will make it his business to be up at the State House and work in our interests as a lawyer.

Dr. Cyril M. Lydon, Norfolk, asked if the problem had not in the past been cared for by the committee which handles our legislative matters.

Dr. Lee asked Dr. Brainard F. Conley, chairman of the Committee on Legislation, to come forward and be heard. He further asked that Dr. Conley say something about the historical development of the present committee. Dr. Conley spoke as follows:

I thought that the day had come when all reverberations of dissension and personal feelings had gone. I thought the day had come when the Massachusetts Medical Society was being represented by men who had at heart only the interests of the public in general and that of their fellow practitioners. I thought that this laudable object was accomplished this past year. It was accomplished by and as the result of a new setup—a committee which is now no longer a junior committee but a committee which is appointed as truly representative, a democratic group of men—one man from each district who is elected by each district, and they together elect a chairman and a clerk. That committee met and elected as chairman myself, and elected as secretary Dr. Lester M. Felton, of Worcester—and a no more conscientious man is in this society than Dr. Felton.

We have the full co-operation of every member of your committee. We had unanimous action on every bill that was discussed. It is one of the most pleasant assignments that I have ever had on any committee. And as a result of our work we returned to this Society a goodly portion of the amount of money which we asked for at the beginning.

The reason for that return of money was that we did not need to spend it. We were not spending it for any purpose other than actual need. We were not giving away the money of the Society. We were not seeking any outside assistance unless that assistance was needed; and when that assistance was needed, we consulted an attorney in a firm in Boston. Now, it is in the by-laws that in order to have counsel or engage the services of legal counsel it is necessary for the Committee on Legislation to get permission from the President. That was done. I know it was done because I did it myself by calling Dr. Schadt, your president, at his home in Springfield and told him the point had come when we needed the services or the opinion of legal counsel, and Dr. Schadt immediately gave me permission to engage counsel, which we as a committee felt we needed. And he gave me permission to engage counsel who had been agreed upon by the five working members of the committee, namely, Dr. William Breed, Dr. John Fisher, Dr. Lester Felton, Dr. Charles McCann and myself. That was the working committee.

Now, then, \$1500 was the price which was proposed. We did not feel that it was necessary to spend \$1500 for legal assistance, and I discussed with our committee of five the possibility of needing an attorney or legal counsel. We decided to ask legal counsel from the firm of Powers and Hall, attorneys in Boston—attorneys who handle, perhaps, 70 per cent of all malpractice cases. Mr. Leland Powers has appeared before many district societies as a speaker on medical aspects of laws and legislation; and I believe there is no more competent legal concern in Boston to give aid to us. That firm of attorneys was asked for counsel, with the limitation that we would pay

them for what advice we got or needed and not on any established yearly basis or fee

I spent one afternoon in the office of Powers and Hall and went over every bill which seemed to require legal counsel or legal advice. I spent from 2 30 until 6 15 in that office with Mr James M Clark, a graduate of Harvard University in the Class of 1904 and Harvard Law School later, and a man who graduated with honors and is regarded by the legal profession of the United States as an authority. That cost us \$50. It necessary, your committee would have spent the entire amount the Council had given us if we needed it—but we did not need it.

Now, then, regarding the matter of the three bills of the Board of Registration in Medicine, I have been beside the secretary of the State Board of Registration in Medicine at this meeting. At the request of Dr Quimby Gallupe, the secretary of the State Board of Registration in Medicine, I personally appeared at the State House at the hearing given by the Committee on Public Health on those bills, and I personally—and Dr Gallupe is present and will bear me out—put the Massachusetts Medical Society on record favoring those three bills.

Now, on the antivivisection bill, that bill was heard before the Committee on Public Health. I was present at that hearing and I listened to the arguments pro and con, and I put the Massachusetts Medical Society on record as opposing that antivivisection bill.

Your Committee on Legislation has had a recording on every bill that came before the Committee on Public Health. That is a matter of record with the clerk Norman F. Wells, of Marlboro. On every bill that pertained to medicine there was an appearance or a recording of the Massachusetts Medical Society.

I have no apologies to make for my committee or for myself for any bit of our conduct in representing you during the past legislative year.

Dr Chapman's motion was put by the chair and defeated by vote of the Council.

Dr Chapman moved that the Council of the Massachusetts Medical Society favor the annual registration of physicians in order to further maintain the standards of practice. This motion was seconded by a councilor.

Dr Welch asked to be recorded as opposed to this motion.

Dr Chapman expressed a desire to hear Dr Gallupe on the motion. At the invitation of the chair, Dr Gallupe came forward and spoke as follows:

For the second time I am here but I did not come until asked to do so. The Board of Registration in Medicine has felt that it would be of some help to have in annual registration or reregistration of physicians because it was found that it has been of some help for nurses and dentists. It has seemed to us that there was not in our office at the State House sufficient information about physicians who have registered to practice in the Commonwealth. We register a physician once and he is forever registered unless he does something wrong and after we register him we have no further information about him of any nature. We do not know whether he has continued to practice

medicine or not. We have no information about him. We do not know anything more except that he has registered to practice and none of the doctors in his city or town know much more about him.

Now, recently because of the war, we have corresponded with the Red Cross, the FBI and the Army and Navy about physicians and we cannot give them any information. All we can give them is the name and nothing more for the past twenty or thirty years. And so we thought that an annual registration on the doctor's birthday would be of some help. It might be of help in tracking down some physician who is practicing illegally. We do not know how many there are and you do not know because you have no means of ascertaining. If you had a list on your desk of registered physicians, you could readily tell who was not registered. It might be some help in tracking down these men who practice illegally in the Commonwealth. That is of some value, I think. We think it would be of value to the Society as it would enable it to know who is registered to practice. It is just a suggestion but, as Dr Rushmore said last spring, we do not want to do anything that the Society does not want to have us do or does not like to have us do. We want to do whatever is most helpful. We are your agents. We, as members of your Society, wish to do what you would like to have us do. If you do not want the annual registration, we do not want it. If you do want it, we will help to get it for you. That is all.

Dr Carl Bearse, Norfolk, thought this was an inappropriate time to bring up a matter of this kind. He moved that the motion be tabled. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

At 2 15 p.m., Dr Parkins moved that the meeting be adjourned. This motion was seconded by a councilor and it was so ordered by vote of the Council.

MICHAEL A. TIGHE, Secretary

APPENDIX NO. 2

REPORT OF THE COMMITTEE ON ETHICS AND DISCIPLINE

During the past four months, the committee has held two all-day meetings on June 30 and on September 15, with a special meeting on August 16. During this time, numerous cases have come to the attention of the committee. Some of these were of very minor importance and were settled by letter. Several others required considerable investigating, hearings being given to both complainant and defendant. These complaints were settled amicably by the committee.

A number of communications from laymen complaining of the amounts of doctors' charges, mostly for small amounts, have been received and have been answered invariably that it was not within the province of this committee to decide matters of professional fees, which should be settled satisfactorily between doctor and patient.

Three charges by laymen against doctors for alleged breach of ethics, after exhaustive investigation, were decided unanimously for the defendants.

There were three other cases of such a serious nature that a brief résumé at this time is justified.

Case 1. A charge of breach of ethics in an attempt to discredit and injure the professional reputation of some of his confreres was brought against a fellow. Accompanying this complaint were several items on which the complaint was based. Thorough investigation was given

o this charge and every possible avenue of approach was explored, but no actual proof which would stand the scrutiny of a board of trial or of a court of law could be verified, and the committee was forced, therefore, to place the case on file. The complainants were notified.

Case 2 There was a complaint by two fellows against a third charging active attempts to belittle their reputations and their professional standing in the community by active participation in the preparation of and unfair and vicious testimony during a court case for malpractice. Following a period of investigation covering two months, including scrutiny of court records, hospital records and hearings given to both the complainants and the defendant, an overwhelming mass of proof was accumulated resulting in a unanimous vote by the committee of 'guilty,' and the fellow was requested to resign from the Society. His resignation was received and accepted.

Case 3 This case is the first of its kind that has been brought to the attention of the committee during the past eight years. A complaint was received from a layman in good standing and of excellent reputation in the community in which he lives, against a fellow practicing in the same community, charging violation of Chapter III, Article I, Sections 1 and 3, of the *Principles of Medical Ethics* of the American Medical Association. It is not the duty of the Committee on Ethics and Discipline to intrude itself on the private life of any member. That is a matter between himself and his conscience and his self respect. But when that private life becomes a public reproach on the Society sufficiently grave to be complained about by laymen, then it is our duty to investigate. Inquiries and conversations with the defendant and corroboratory evidence given unwillingly by his confreres, in writing, and the fact that on account of his action he was dropped from the staff of a hospital in high standing in his community, compelled the committee to acknowledge the truth of the allegation and to find the fellow guilty as charged. However, as the fellow later admitted his indiscretion and promised to change his manner of living and also by reason of affidavits of his intimates that such an attempt was being made, the committee felt that an opportunity should be given him to rehabilitate himself, and the case was placed on file pending further complaints.

Every case heard has been settled only after the accumulation of evidence which we as a committee know would substantiate the committee's findings before a board of trial and we believe likewise, before a court of law.

ALLEN G. RICE
FRED R. JOUETT
ARCHIBALD R. GARDNER
RALPH R. STRATTON *Chairman*

APPENDIX NO 3

SOME COMMENTS ON THE PROCEEDINGS OF THE MEETING OF THE HOUSE OF DELEGATES OF THE AMERICAN MEDICAL ASSOCIATION HELD IN CHICAGO, JUNE 7 TO JUNE 9 1943

The House of Delegates was called to order promptly at 10 a.m., Monday morning June 7, 1943. The report of the Committee on Credentials showed that 144 delegates were present. A supplementary report given on Tuesday morning June 8, showed that 170 members of the

House of Delegates had been registered. All states, all sections and three government services had complete representation. The only delegates not in attendance were those from Alaska, the Isthmian Canal Zone, the Philippines and Puerto Rico. This was a most remarkable record, showing the interest and sincerity of individual members. Rarely has there been shown so much interest, so much seriousness in conducting the proceedings of the House of Delegates as was shown at this meeting.

The whole atmosphere seemed to be surcharged with the importance of the business under consideration. The reference committees appointed by the Speaker were regionally well balanced. The hearings were exceptionally well attended. The attention of the Council of the Massachusetts Medical Society is especially called to the addresses of Dr. H. H. Shoulders, speaker of the House of Delegates, of President Frederick W. Rankin, of President Elect James C. Paullin, of Surgeon General Norman T. Kirk, of George M. Morris, president of the American Bar Association, of Dr. J. C. Routley, secretary of the Canadian Medical Association, and Brigadier General David N. W. Grant.

General David N. W. Grant is a flight surgeon of the United States Army. On taking over the department of flight surgeons a year and a half ago, he found that there were in the Army 97 flight surgeons. Today there are 9300 Army flight surgeons. When we consider these figures, we are greatly astonished at the amount of work accomplished by General Grant.

It would seem as if it were the bounden duty of every member of this council to read these addresses carefully. In short, terse and plain language they contain the aims, the duties and the responsibilities of the American Medical Association. The inspiring address of the Speaker of the House, Dr. H. H. Shoulders, merits special attention.

The most important subject under discussion was the proposition that the American Medical Association establish in Washington, D. C. a council on medical care. Resolutions were presented from the state medical societies of Minnesota, Indiana, New Jersey, Nebraska, Oklahoma, and Ohio, and from the Section of Radiology, supporting such a general proposition. A proposal called for a council of nine members, from nine geographic subdivisions of the United States. Among the recommendations was one proposing the establishment and maintenance in Washington, D. C., of a full time executive director, who would act as secretary of the council and whose duties would be specified by them. Another proposal suggested that such an executive director be a physician who has been actively engaged in the private practice of medicine for not less than five years during the previous ten years. Another proposal recommended that the council be further authorized to hire such legal and administrative help as it deemed necessary. Still another suggested that the Council on Medical Service submit a budget for its fiscal year to the Board of Trustees of the American Medical Association. All the resolutions asking for the establishment of a council on medical service were referred to the Committee on Legislation and Public Relations for consideration. At a stated time, this committee held a hearing on the subject. The hearing was very well attended by delegates to the session. All persons who wished to discuss the question of establishing a council on medical service were given time and ample opportunity to present their views.

The Reference Committee on Legislation and Public Relations reported as follows: All the resolutions submitted as well as the opinions expressed at the open meeting of your reference committee have been given

full, earnest consideration. There appears to be one objective in all of them."

The reference committee reported in favor of such a council. Before this report could be enacted into a law of the Association, it was necessary for the Board of Trustees to consider the matter and give its approval. The Board of Trustees met with the Committee on Public Relations and recommended the creation of a Council on Medical Service and Public Relations.

It was finally determined after conferences and certain recommendations for change of by-laws that the Council on Medical Service and Public Relations be created by the House of Delegates of the American Medical Association. It was agreed that the membership of this council shall consist of six members, selected according to geographic distributions, and the president, the immediate past-president, the secretary and a member of the Board of Trustees of the American Medical Association. Their functions shall be as follows:

The functions of the Council on Medical Service and Public Relations shall be (1) to make available facts, data and medical opinion with respect to timely and adequate rendition of medical care to the American people; (2) to inform constituent associations and component societies of proposed changes affecting medical care in the nation; (3) to inform constituent associations and component societies regarding the activities of the Council; (4) to investigate matters pertaining to the economic, social and similar aspects of medical care of all the people; (5) to study and suggest means for the distribution of the medical service to the public consistent with the principles adopted by the House of Delegates; (6) to develop and assist committees on medical service and public relations originating within the constituent associations and component societies of the American Medical Association. In the exercise of its functions this Council with the co-operation of the Board of Trustees, shall utilize the functions and personnel of the Bureau of Legal Medicine and Legislation, the Bureau of Medical Economics and the Department of Public Relations in the headquarters office.

The names of the following men were selected to act as the Council on Medical Service and Public Relations: Louis H. Bauer, chairman, Hampstead, New York; A. W. Adson, Rochester, Minnesota; John H. Fitzgibbon, Portland, Oregon; W. S. Leathers, Nashville, Tennessee; E. J. McCormick, Toledo, Ohio; James R. McVay, Kansas City, Missouri; Olin West, Chicago, Illinois; Roger I. Lee, Boston, Massachusetts; James E. Paullin, Atlanta, Georgia; and Fred W. Rankin, Washington, D. C.

Your attention should also be called to the work of the Board of Trustees of the American Medical Association. The report of the Board covers 115 pages of the handbook which is a book distributed to the members of the House of Delegates as a guide. The main report is very exhaustive. It represents a prodigious amount of work. Besides this main report there was submitted to the House of Delegates, a supplementary report entitled *Supplementary Report of Board of Trustees Dealing with Report of Proceedings of the Joint Committee Meeting of National Hospital Associations and Representatives of the Board of Trustees of the American Medical Association*.

In reading these reports there is one thing to keep in mind constantly, namely, that the House of Delegates of the American Medical Association defines the policy of the Association and the Board of Trustees carries out this

policy. It is not the purpose of your commentator to go into the details of the reports. Your commentator, however, would advise every member to read the reports and to study them carefully. The complete reports will be found in June 19, 1943, issue of the *Journal of the American Medical Association*, which also contains the report of the Council of Medical Education and Hospitals. A valued member of the latter council is Dr. Reginald Fitz, of the Massachusetts Medical Society.

One of the subjects treated by the Council of Medical Education and Hospitals is entitled "Essentials of an Acceptable School for Clinical Laboratory Technicians." Your commentator will close his comments on the accomplishment of the Board of Trustees by quoting the reference committee's remarks regarding the work of the Board of Trustees.

Your reference committee is aware of frequent criticisms of the Board of Trustees because the Board does not do this or that, and, although it should be well known by the medical profession at large, it is worth repeating that the Board of Trustees is bound by the mandates of the House and the House is responsible for the Board's activities. Your reference committee feels that the House should express its appreciation of the tremendous amount of work carried on throughout the year by the Trustees, an amount of work which has been gradually increased by the war. It recommends, therefore, that the House express its heartfelt thanks to the members of the Board for their efficient work.

Remember also, we are all members of a very large and influential nonprofit educational institution. The membership is 122,741. Its net worth is \$4,711,215.32. It has a payroll of over 500. It maintains suitable and comfortable headquarters, from which plant many publications are issued besides those of the *Journal of the American Medical Association* and *Hygeia*.

A pleasant and notable incident took place at the meeting in Chicago. A fellow-member of the Massachusetts Medical Society, Dr. Elliott P. Joslin, was honored with the bestowal of the Distinguished Service Award of the American Medical Association. The selection of Dr. Joslin as the recipient of the award gave joy and delight to every member of the Massachusetts Medical Society. The award consisted of a medal properly inscribed, which was formally presented to Dr. Joslin at the meeting of the House of Delegates on Tuesday evening, June 8. The recipients of former awards are as follows: Dr. Rudolph Matas, 1938; Dr. James B. Herrick, 1939; Dr. Chevalier Jackson, 1940; Dr. James Ewing, 1941; and Dr. Ludwig Hektoen, 1942.

The Massachusetts Delegates in attendance were as follows: David D. Scannell, Boston; Ernest L. Hunt, Worcester; Charles E. Mongan, Somerville; Walter G. Phippen, Salem; Allen G. Rice, Springfield; and Richard H. Miller, Boston. Dr. Walter G. Phippen served as a member of the Reference Committee on Medical Education. Dr. David D. Scannell served as a member of the Reference Committee on Reapportionment. Dr. Michael A. Tighe, secretary of the Massachusetts Medical Society, who was present as an observer at the meeting of the House of Delegates, was voted the privilege of attending the executive session of the House of Delegates.

Dr. Herman L. Kretschmer, of Chicago, was selected as president-elect. Dr. Kretschmer is not unfamiliar with the administration of the American Medical Association affairs as he served ten years as treasurer. He

comes well equipped assuming the responsibilities attached to the office of president elect of the American Medical Association

COMMENT

Your commentator wishes to bring the attention of the Council of the Massachusetts Medical Society to the great part that Massachusetts influence bears in the conduct of the affairs of the American Medical Association. The chairman of the Board of Trustees, Roger I. Lee, the president of the Massachusetts Medical Society has an enormous responsibility. One cannot overestimate the demands on his time and on his strength which the heavy responsibilities of his office exact. I wish to testify that I think he is one of the ablest chairmen of the Board of Trustees that the American Medical Association has ever had. There is another member of the Massachusetts Medical Society who works very quietly and very effectively. The members of the American Medical Association need never worry concerning the kind and quality of medical service and medical education which is promoted by the American Medical Association while Dr. Reginald Iitz is a member of the Council of Medical Education and Hospitals.

Last but not least is the part that Dr. Frank H. Lahey has taken in the affairs of the Procurement and Assignment Service in bringing about the enlistment of 45,000 doctors in the American armed services.

CHARLES E. MORGAN, *Senior Delegate*

APPENDIX NO. 4

REPORT OF THE MASSACHUSETTS STATE COMMITTEE OF THE PROCUREMENT AND ASSIGNMENT SERVICE FOR PHYSICIANS

On August 26 the *New England Journal of Medicine* printed an editorial entitled — or Else. Here in bold faced type, was stated that the armed forces need medical officers so urgently that in order to increase enrollments a directive already had gone to the commanding officers of several Service Commands authorizing them if necessary, to induct into service physicians up to forty-five years of age who had been declared available by the Procurement and Assignment Service. The editorial went on to warn physicians in this age group who had been declared available, and who had failed to offer their services, to apply for commissions at once. Unless they did this it seemed probable that they might soon be inducted into the Army as privates eventually to receive commissions of minimal rank rather than ones which took into consideration age and experience.

The justification for this editorial is now clear. The state director of Selective Service has recently informed your committee of two important directives under which he will be guided in the future. The War Manpower Commission has authorized Selective Service to induct pre Pearl Harbor fathers after October 1, 1943 in the sequence of their order number and as fast as needed after the induction of single men and childless married men. The War Department has authorized the commanding generals of Service Commands to waive age limitations for induction in the case of physicians between the ages of thirty-eight and forty-five when they are declared available for military duty by the Procurement and Assignment Service and when waivers are requested by state directors of Selective Service.

These two statements make it plain that dependency need no longer play a part in determining Selective

Service deferments for doctors and that age, also within the limits specified, can be discounted. Thus Selective Service and Procurement and Assignment now appear to have considerably stronger authority over physicians than ever before.

As a result of this the problem of the graduate of the substandard school promises to be more baffling than ever. Consider as a typical illustration the City of — which happens to have a population of about 110,000 people. In it are 70 doctors born between 1879 and 1898, all too old for military service. In addition there are 2 younger men who have been declared essential and 7 who have applied for commission and have been rejected on physical grounds. These 79 men are able to cover the medical needs of this city in a satisfactory manner, but in addition there are 6 graduates of standard schools who have been declared available without doing anything about it and 14 who are licensed to practice in Massachusetts but are ineligible for commission because they are foreigners or graduates of schools not recognized by the Surgeons General.

If the men who are graduates of standard schools are reported to Selective Service they may be discriminated against in favor of men whose competency is less certain. Heretofore the latter group has been protected on the ground that any doctor with a license to practice in Massachusetts was better than none. Now that doctors are liable to induction, the situation has changed. In future to be as fair as possible your committee proposes to report to Selective Service when necessary two groups of physicians declared available: one comprising physicians who have not applied for commissions though asked to do so, and the other, physicians ineligible for commission whose services are not essential to the health and welfare of the community. If any physicians must be inducted both these categories should be subjected to equal scrutiny.

On August 26 there began what has been called the third phase of procurement. This consists in the appraisal of men under forty-five years of age who are called essential. The supposition has been made that the longer the war lasts the greater is the likelihood that a number of doctors will be inducted out of the Army or Navy and that they may be able to resume work in the various communities to which they belong. As such men return it may be possible little by little for them to replace men now held as essential.

The essential men therefore have been asked to apply for commissions and to have physical examinations by the Army or Navy so as to make it a matter of record that they are not objectors that they have applied for commissions when asked to and what the state of their physical fitness is. The directive regarding this matter says that *no such man will receive a commission until he has been declared available* by Procurement and Assignment and Procurement and Assignment has been ordered not to declare any such man available until a satisfactory replacement for him has been found.

The Corps Area chairman and the state committee have agreed to accept as definition for the word *satisfactory* that used in the *Concise Oxford Dictionary* of 1931 leaving no room for complaint causing satisfaction adequate.

A certain degree of suspicion has become manifest on the part of the essential men who so far have been approached. They appear to suspect that here is a trap to drive them into service by forcing as their replacements

physicians who cannot be called satisfactory under the definition described. Such a suspicion appears unfounded. Your committee believes that the War Manpower Commission intends to live up to its statement that no man called essential will be commissioned until he is declared available. He will not be declared available until, in fact, there has appeared to take his place, a replacement who can leave no room for complaint.

In the September 11 number of the *Journal of the American Medical Association* was described a plan which will go into effect in 1944 for the allocation of interns and residents in hospitals. Stated briefly, this plan proposes henceforward to have the internship last for nine months instead of a year, thus synchronizing it with the accelerated medical school program. Each state will be assigned a quota of interns and residents which will total about two thirds of the numbers recorded in 1940. Each hospital, also, will have an assigned quota, though in individual hospitals consideration will be given to obvious injustices which might occur with too arbitrary an application of the allocation plan. The basic principle of the plan is to devise a method of equalizing the distribution of interns and residents in our hospitals and to prevent their overconcentration in certain institutions.

That a certain number of resident and assistant resident physicians are necessary for the proper conducting of hospital services is recognized. Thus hospitals in the habit of employing resident physicians will be permitted to retain a certain number. In establishing the quotas for residents, one third of the interns beginning their services at each nine months may be retained for a second nine months' service as assistant resident physicians and half of that group may be retained for a third nine-month period to serve as residents. A man may leave one hospital at the end of his nine or eighteen months' service to go to another so that under this plan, free movement of young doctors will be encouraged within the limits of the quota for the state.

The exact details of the manner in which the plan is to operate in Massachusetts have not yet been clarified. It seems probable, however, that our large hospitals will be asked to yield approximately a third of the house staffs to which they are accustomed, and that some 75 young men will thereby become available to the small hospitals so badly needing them.

Up to the present time your committee has been more occupied with the procurement of physicians for the armed forces than in their assignment to civilian needs. The time has come, however, when the latter phase of the work has begun to receive an increasing amount of thought. Analyses have been made which serve to illustrate the present distribution of physicians in Massachusetts. The small cities and the less densely populated areas continue to be poor in physicians while the large cities still claim a relatively high concentration of medical talent. This finding is easily explainable, since areas of dense population, by necessity, are required to perform a type of medical work which requires much highly trained specialism and medical teamwork that is extremely complicated.

In spite of the number of physicians who have left practice, there so far has been very little complaint of medical shortage. Such complaints as have been received, on critical study, have depended almost invariably rather on a given physician's personal popularity with his patients than on his essentiality. There are still a

number of physicians who can be spared without detriment to civilian care.

REGINALD FITZ, *Chairman*

APPENDIX NO. 5

REPORT OF THE WAR PARTICIPATION COMMITTEE

The first part of this report is one of progress. On May 24, 1943, the Council passed the following resolution:

WHEREAS, the War Manpower Commission has announced that there is immediate need for more physicians to serve as medical officers in the armed forces of the United States; and

WHEREAS, the War Manpower Commission has announced that Massachusetts should supply more medical officers than have so far been commissioned from the state; and

WHEREAS, a plan has been suggested by the War Manpower Commission through which the enrollment of medical officers may be accelerated with the help of county or district medical societies in certain states; therefore be it

RESOLVED, that Reviewing Committees be established by each District Society, the members of which shall be nominated by the District Society Presidents and appointed by the President of the Massachusetts Medical Society. Such committees shall serve for the general purposes outlined in this report.

Promptly on the appointment of the district reviewing committees by the President, the names of Massachusetts physicians considered available for military service by the State Committee on Procurement and Assignment were sent by this committee to the proper district committees together with pertinent information concerning each. The decision on each man by the local committees was thereupon sent to the State Committee on Procurement and Assignment. The work of the reviewing committees was in most instances conscientiously carried out. Much credit is due these men, and this has been duly bestowed by your chairman on the direction of the committee at its meeting of September 22, 1943, by letters containing a general report and an appreciation of their prompt and conscientious action.

The figures to date are as follows:

Names submitted to the Reviewing Committees	321
Names have been reported (23 outstanding)...	298
Available	102
Already in service.....	31
Application for commission already submitted	32
Essential	29
Not available.....	104
Graduate substandard school..	21
Sociologic reasons.	17
Rejected by Army.....	14
Unable to locate by mail or phone	16
Over 45 years old.....	5

Not a citizen	7
Osteopath	6
Moved out of state	8
Intern	1
Refused to apply	2
Dead	1
Out on bail	1
No reason given	5

In accordance with instructions from the committee at its meeting on July 28, 1943, your chairman requested in writing from Dr. Reginald Fitz, state chairman of Procurement and Assignment, an appraisal of the results of the activities of the reviewing committees. Dr. Fitz was not able to be more specific than is indicated in the following paragraphs of his reply.

A number of men by the time they were asked to appear for review had already applied for commissions and several had already gone into uniform and left. Happenings of this sort were inevitable because the names of men referred to the reviewing committees were already declared available, and many had accepted their classification somewhat slowly, but nevertheless surely. A second factor that has made the work of the reviewing committees difficult to analyze is that since all the names submitted had been declared available, the Army or Navy were applying pressure on many of the men at the same time as they were reviewed by the committees. The combination of all this pressure, however, has seemed to yield results, for both Army and Navy procurement offices inform me that the stream of applicants continues, although neither service can state with any assurance that there has been any sharp rise in the number of applicants since the reviewing committees were established. I repeat, however, that these committees have been helpful. It seems to me that their chief contribution has been to let a reluctant doctor in any community know that a larger group than the Procurement and Assignment Service, plus the Army or Navy recruiting offices realize that he has been declared available. This fact in itself has tended to stir up a favorable opinion toward making doctors take the word available more seriously than heretofore. To this must be added the constant appeal in medical journals and newspapers of the need for more medical officers in the large scale offensive which seems steadily more imminent.

A complete copy of this letter was forwarded to the chairman of each local committee along with the above mentioned word of appreciation.

The plan of the staff of the Beth Israel Hospital to care for the practice of those of their number who have entered the United States Service was referred to this committee and came under discussion at its meeting of July 28, 1943. The committee expressed its sympathy with the ideology involved but did not recommend approval by the Society of the plan as outlined in the protocol.

* * *

The second part of this report concerns itself with the future functions of the Committee on War Participation. In a letter from Walter F. Donaldson, chairman of the National Committee on War Participation of the American Medical Association, various possible functions were considered, ranging from the sending of reminders to fellow members in the services to active co-

operation with Civilian Defense organizations in each community.

Your committee considered carefully each of these suggestions and noted that the Massachusetts Medical Society is attacking many of the important problems posed in already organized committees, such as the Committee on Industrial Health, the Committee to Aid the District Rationing Administrator, and the Committee concerned with Prepayment Medical-Care Costs Insurance.

At our last meeting on September 22, 1943, there was much discussion as to what the committee should properly interest itself in now that the bulk of the reviewing has been completed. Many possible functions were considered, the most important being that of relocation of physicians to meet local community needs. It seemed to us that this and other complicated matters needed more consideration before a definite approach to them could be made—also that the influence of the committee should be broadened and decentralized so as to be more effective in local matters.

We, therefore, recommend that the present reviewing committees in the several Districts be not discharged, but be retained with the same personnel and organization (chairmen and secretaries) as district committees on war participation, subcommittees, so to speak, of this committee. We also recommend that an appropriation of \$300 be made to this committee for past and future expenses, largely clerical, from the time of its appointment to January 1, 1944.

APPENDIX NO. 6

REPORT OF PROGRESS BY THE POSTWAR LOAN FUND COMMITTEE

The Postwar Loan Fund Committee was organized on June 16, 1943, with fifteen members appointed by the president, Dr. Roger I. Lee.

The second meeting of the committee of the whole was held on Wednesday, August 11, 1943, at 8 Fenway, at which time the reports of the five subcommittees appointed by the chairman to study certain phases of this problem were read by the chairmen of each subcommittee and discussed by all members of the committee of the whole. This is a report of progress of the committee of the whole.

The first subcommittee (Dr. Pierce H. Leavitt, chairman) studied the following questions:

- (1) Amount of loan to be granted
- (2) Whether or not interest is to be charged
- (3) Whether or not endorsers will be necessary
- (4) Length of time the loan may run

The committee reported that it believes that the amount must, of course, be uncertain, but would depend on two factors: the amount of money raised by the Society and the need of the applicant. The committee expressed the opinion that just enough interest to remind the applicant that he had a loan and to cover the carrying charge should be collected—this interest not to exceed 2 per cent. The committee stated that in its opinion no endorsers

should be asked from members of the Society, and further stated that the length of time the loan may run should be within a two-year period. The committee of the whole, after discussing this subcommittee's report, accepted these conclusions.

The second subcommittee (Dr. Walter G. Phippen, chairman) then reported on the question studied by them:

- (1) Eligibility of persons to borrow money from the fund.
- (2) Whether or not physicians other than members of the Massachusetts Medical Society at the time of entering the armed services should be permitted to borrow from the fund.

The committee reported that it believed that only men who were members of the Massachusetts Medical Society when they entered the armed forces should be permitted to borrow from the fund. None of the members believed that the fund should be open to all physicians in Massachusetts. The committee of the whole discussed this report, and it was approved in principle.

The third subcommittee (Dr. Charles Wilinsky, chairman) considered the question whether the fund should be raised by:

- (1) Increasing dues.
- (2) Assessing members \$10 or more for one year.
- (3) Assessing members \$10 or more over a period of three to five years.

The committee reported as follows:

It is our considered opinion that these funds should be raised not by increasing the dues, but rather by an annual assessment of \$10 for the duration of the war, unless otherwise modified by future action of the Council.

The committee reported that the present by-laws of the Society make provision for such assessments and authorize the Treasurer to collect them. The report of this subcommittee was considered at great length by the committee of the whole, and the report was accepted in principle.

The fourth subcommittee (Dr. Herbert L. Lombard, chairman) reported on how best to inform the members of the Society in the armed forces of the availability of this fund. The committee reported as follows:

We unanimously agree on three points:

Information should be printed in the *New England Journal of Medicine*. There should also appear in a box on the cover of the *Journal* an announcement calling the article on the inside page to the attention of members.

Form letters should be sent to men in the armed services notifying them of this action by the Society.

Form letters should be sent to other members of the Society with the annual bills for dues, stating the availability of these loans.

This report was also accepted in principle by the committee of the whole after considerable discussion.

The fifth subcommittee (Dr. George Leonard Schadt, chairman) made a report on the question concerning the relation of the individual county district societies to the Society in developing and making the Postwar Loan

Fund workable. The subcommittee believed that the fund should be administered from the headquarters of the Massachusetts Medical Society, rather than from the district societies; so that no member would be embarrassed in going to his district society and asking for a loan. It was also thought that a member desiring a loan would be more apt to ask for it if it were done through the headquarters of the Society. This question was also discussed at length and agreed to in principle by the committee of the whole.

GEORGE LEONARD SCHAT, *Chairman*

APPENDIX NO. 7

MASSACHUSETTS MEDICAL SERVICE REPORT

This presentation is an informal report of progress to bring you information concerning the present status of Massachusetts Medical Service. Your corporation has been satisfactorily established, and active enrollment of subscribers is proceeding. Doubtless you have noted the excellent publicity procured for the Blue Shield by our Blue Cross associates, as they celebrated their own sixth birthday recently.

ENROLLMENT FIGURES

At the time of the last report in June, there was an enrollment of only about 2000 subscribers in the Blue Shield. This represented the culmination of six months' effort in which most of the work was preliminary ground breaking efforts in the industries. As a consequence of this preliminary groundwork, recent months have witnessed an increasing enrollment which promises a total subscription of about 10,000 members at the completion of our first year in January, 1944. Under the present arrangement with Blue Cross, each salesman is held responsible for a quota of 200 Blue Shield subscribers as a monthly average. The Blue Cross quota for each salesman is 500 subscriptions. The possible enrollments on this basis are 13,000 at the end of the first year. Our experience to date indicates that we may fall somewhat short of this objective—10,000 or somewhat over it, depending on prospective enrollments in one large company.

This first year experience compares favorably with the results obtained in other states with the exception of Michigan. However, the results obtained in Michigan must be regarded as anomalous and not related to the realities of experience in the bulk of the states where there are no massive industrial units ready to supply subscribers in the mass of 100,000 or over. It appears safe to assume now that the industrial pattern in Michigan is unique, and is largely responsible for the rapid expansion of Michigan Medical Service, and that no other state medical organizations are likely to encounter a pattern which will assure any such result. A state such as Massachusetts with a myriad of small or moderate-sized industrial units is going to encounter hard digging and slower growth. With reference to other states having medical society prepayment programs, Colorado enrolled somewhat less than 10,000 in the first year, but feels that further expansion is impeded by the fact that it cannot, under the law, sell the overincome group, as the Massachusetts Medical Service is empowered to do; Pennsylvania in about three years has enrolled approximately 10,000 subscribers; New Jersey with a complete hospital medical-surgical contract has enrolled somewhat less than 10,000 subscribers. This last result may indicate, from

our contrasting experience, that complete hospital coverage is not necessarily more attractive to the subscribing public than a surgical-obstetric contract such as Massachusetts offers. Significantly, no major group is now offering to the public a complete comprehensive medical care contract in and out of the hospital, as its basic policy.

ENROLLMENT PRACTICES

A brief statement regarding enrollment practices should be made because of its important bearing on the rate of growth of our corporation. Sale of contract, as in Blue Cross, is of necessity offered to groups of persons previously organized for nonmedical reasons. The practice is to require a certain percentage of any group to enroll before their acceptance as a subscribing group. The average requirement in the several state plans is 50 per cent of any group. Michigan requires 75 per cent. At a recent meeting of the medical service plans, an effort was made to extract the rationale for such high requirements from the various groups. There seemed to be no satisfactory account from any group for their percentage requirements. It actually appears possible that Michigan's 75 per cent rate (an impossibly restrictive requirement in most states) was imposed to delay enrollments until administrative problems were resolved. A second important observation was that all executives, when directly questioned, felt that some relaxation from rigid requirements could be made with reference to seasoning of a group by prior subscription to Blue Cross or a commercial carrier. However there were no specific recommendations, and suggestions relative to seasoning of groups was distinctly nebulous.

Consideration of these two facts led to our liberalization of Blue Shield enrollment requirements in Massachusetts with reference to seasoning of a group by a prior Blue Cross subscription. There was a large body of potential subscribers to Blue Shield (500,000) who were seasoned to varying extents (one to five years) by prior Blue Cross contracts. The experience of Blue Cross with regard to stabilization of the exposure in a given group is that after three years the hospital utilization, as measured by the loss ratio, can be fairly accurately measured. Loss ratio means the number of cents out of each dollar paid in as premiums by the insuring group, which has to be paid out for hospital care in a given year. The loss ratio was quite variable from group to group. It varied from a favorable figure of 60 cents or less in a group showing an acceptable rate of hospitalization, to 80 cents or more in a group with an excessive utilization record. Satisfactory seasoning or stabilization of a group was not achieved until after three years of insurance. Two important factors which influenced the loss ratio figure of a given group were the average health of the group, and the cultural level of the group. The lower the health standard or the higher the cultural level of a group, the higher the rate of utilization of a contract, and the higher the loss ratio (cents out of a dollar paid for hospital costs). The reverse also held true, the higher the health standard or the lower the cultural level, the lower the loss ratio, and the more satisfactory the financial experience with the group. With all these factors (seasoning, loss ratio, health and cultural levels) rationally synthesized it seemed reasonable to adjust the percentage requirements for enrollment according to the prospective experience with a given group. Our completely satisfactory financial experience in date seems to indicate the

basic soundness of assumptions derived from the above considerations. Following are the assumptions:

- (1) Any group seasoned by Blue Cross for a three year period or over, and having a satisfactory experience is indicated by a loss ratio of not over 75 per cent, may be accepted on any percentage basis.
- (2) Any group seasoned for two years with a loss ratio of not over 75 per cent, may with due consideration of health and cultural levels be enrolled on a 20 to 30 per cent basis.
- (3) Any group seasoned for eighteen months with a loss ratio of not over 80 per cent may, with due consideration of health and cultural levels, be enrolled on a 40 per cent basis. If a group is deficient in any respect, the requirement should be 50 per cent.
- (4) Failure to procure an adequate percentage in any industrial group could be safely circumvented if 75 per cent of the active Blue Cross subscribers sought enrollment.
- (5) Any large industrial group (over 500 workers) that is enrolled as a new group will be enrolled on the same base as for Blue Cross (50 per cent) unless there are sound actuarial reasons for relaxing the requirements.
- (6) With seasoned small groups (less than 10 persons) whether or not a satisfactory percentage participation is procured, will be left to the experienced judgment of Blue Cross executives who are familiar with the group as a risk.

FINANCIAL STATUS

Two sets of figures outlining our relative financial status are presented. The first figures represent an estimate at the end of the first six months' period, when subscriptions had not increased significantly, the second set of figures represent what should be our estimated status after the first year is completed in January, 1944, with a probable subscription list of 10,000. These figures indicate that by January we will be operating satisfactorily in the black; we shall have met the 25 per cent reserve requirement of the Commissioner of Insurance, we shall have ample reserves to take up the second year's load of obstetrics and tonsillectomy in children due on all contracts in force for one year, we shall (with an actual loss ratio of 25 per cent and an estimated loss ratio of 35 per cent) establish a condition wherein during the second year we can retire the carried-over organizational expense of \$4000, and create a reserve which will lead toward increasing benefits. On this basis none of the \$25,000 so generously voted by the Council will have been used. Furthermore, with this satisfactory background all payments to the physicians for services rendered under the contract will have been made in full as per the agreed fee schedule. This gives Massachusetts the unique experience of organizing, establishing and operating for its first year a prepaid medical-care program and doing it completely on the black side of the ledger, with unquestionably ample reserves in the process of building. These experiences are significant for those state groups which cannot safely anticipate the huge enrollments of Michigan Medical Service. These results have guaranteed to us the continued full support of the medical profession, without evidence of significant dissension, and the friendliest and most

effective working relations with the Blue Cross group. It bears out the assumption that a 10,000 subscription list carried on the basis of adequate premium rates, and

Estimated income	\$30,000
Operating expense	\$11,000
Payments to doctors	10,000
Premium tax (1 per cent)	300
Total estimated expense	\$21,300
Reserve requirement (25 per cent)	7,500
Total estimated financial requirements	\$28,800
BALANCED STATEMENT	
Income	\$30,000
Expense	28,800
Balance	\$1,200
Organizational deficit on books	\$4,476 51
Surplus (if reserve not applicable till 1944)	\$8,700

payments to doctors and operating expenses was \$11,309.77. The net loss was \$4476.51, or but little more than the initial expense for organization, which has been carried forward on the books to be paid off when our reserves accumulate. This means that in this very early period with restricted sales and large nonrecurring expenses the

books balanced themselves except for the early organizational expense that is being carried along.

Table 2 attempts to estimate our probable status as of January, 1944, when it appears certain our enrollment will exceed 10,000 subscribers. The total income should be \$30,000. The total financial outlay for operating expenses, payments to doctors, tax premium and the reserve requirement of 25 per cent should be about \$28,800. This would leave a balance of \$1200 (but still carrying the organizational cost of over \$4000 on the books). This means that very soon in the following year this initial cost can be retired, and a reserve created. When our cost for tonsillectomies and obstetrics in the second year is measured, and when the reserve for late reported cases can be determined and established, then we can accurately find out the rate of accumulation of a reserve and plan safely for our second contract of complete medical care in the hospital.

Below is a figure of \$8700, which may represent our available reserve (exclusive of organizational costs) if, as implied by the Insurance Department, we may not be required to set up the 25 per cent reserve until the second year of operation. Under such circumstances we could now retire our outstanding organizational expense and have an estimated surplus at the first of the year of nearly \$5000.

With reference to the loss ratio (the number of cents out of each dollar paid in as premiums by the insuring group, which has to be paid out for hospital care in a given year), it is running at present at the low figure of 25 per cent, with an estimated real loss ratio on receipt of slow reports of 35 per cent. This will rise in the second year when the cost of obstetrics and tonsillectomy care in children has to be met.

Our mid-year cost of administration is 50 per cent, and with the accumulation of premiums and dilution of nonrecurrent initial expenses should drop to about 15 or 20 per cent for the year. With a combined loss ratio and running expense of only 48 to 53 per cent out of a possible 100 per cent, we are in an excellent position to absorb the second year cost of obstetrics and tonsillectomies, and create a reserve to meet our obligation of providing complete hospital medical-care protection at the earliest feasible date.

For this hopeful outlook we are indebted to the profession for its kind support, and its confidence that our initial approach to the eventually complete program is sound; and to the co-operative support and sympathy of the Blue Cross organization which, by contractual arrangement, is handling the sales and administrative end of our project. The patience and forbearance of both groups have spared us many difficult problems which have arisen in other sections of the country. For this we may be properly grateful.

NEW HAMPSHIRE MEDICAL SOCIETY

PROCEEDINGS OF THE ONE HUNDRED AND FIFTY-SECOND
ANNUAL MEETING

May 11, 1943

THE scientific session of the New Hampshire Medical Society was opened at the Hotel Carpenter, Manchester, at nine thirty o'clock in the morning, with President Timothy F Rock presiding.

The first paper of the morning was one by Drs John P Bowler and Scott Pedley, of Hanover, on the subject, "Carcinoma of the Prostate and its Endocrine Relationships". The next paper was by Dr Oliver Cope of Boston, being entitled "The Treatment of Burns". The last paper of the morning was by Dr Roger I Lee, of Boston, on "Geriatrics The medical care of the elderly".

The afternoon session convened at two o'clock with President Rock presiding.

Dr Leonard B Morrill, of Centre Harbor, was awarded a gold medal for membership of fifty years in the Society, he spoke as follows:

I want to thank you for this medal and for the most wonderful association in the world—the New Hampshire Medical Society. Thank you very much.

Dr James W Jameson, of Concord, was presented as president elect, and spoke as follows:

I wish to express my gratitude and appreciation for this honor, and I can assure you that I will do what I can for the interests of the New Hampshire Medical Society, and also for the medical profession in the State of New Hampshire.

Dr Samuel T Ladd then presented the report of the Trustees.

FINANCIAL REPORT OF THE TRUSTEES OF THE NEW HAMPSHIRE MEDICAL SOCIETY FOR THE YEAR ENDING DECEMBER 31, 1942

Receipts

Interest on various deposits, other than Benevolence Fund	\$202.09
---	----------

Expenditures

Expenses of Society as voted	1,100.00
Pray and Burnham prizes	150.00
Total expenditures	\$1,250.00

Decrease in funds, other than Benevolence Fund	1,047.91
--	----------

GENERAL FUND

Deposits New Hampshire Savings Bank	\$3771.97
Portsmouth Trust and Guarantee Company	2083.41
Nashua Trust Company	225.44
United States Defense Bonds Series G	3,000.00
	<u>\$9080.82</u>

BARTLETT FUND

Deposits Portsmouth Savings Bank (\$352.11 of this is a permanent fund, the income to be expended only for the benefit of medical science, as may be directed by vote of this society)	\$2,784.23
United States Defense Bonds, Series G	2,000.00
	<u>\$4,784.23</u>

PRAY FUND

Deposits Stratford Savings Bank (\$1000 of this is a permanent fund, the income to be expended only for prize essays)	\$229.91
United States Defense Bonds, Series G	1,000.00
	<u>\$1,229.91</u>

BURNHAM FUND

Deposits New Hampshire Savings Bank (\$1140 of this is a permanent fund, the income to be expended only for prize essays)	\$1,099.82
United States Defense Bonds, Series G	1,000.00
	<u>\$2,099.82</u>

BENEVOLENCE FUND

Deposits New Hampshire Savings Bank (\$394.50 of this is accrued income available for the purposes of the fund)	\$2,032.19
United States Defense Bonds, Series G	3,000.00
	<u>\$5,032.19</u>

A prize of \$100 was awarded for a paper entitled

Pathology, Clinical Manifestations and Treatment of Lesions of the Intervertebral Disks by 'R Thritis, pseudonym for Dr Albert Oppenheimer, of Laconia, and also a prize of \$50 for a paper entitled 'A Summarizing Review of Coexisting Intrauterine and Extrauterine Pregnancies, with a Report of One Original Case' by 'Bruce King, pseudonym for Dr Samuel J King of Farmington.

It is expected that a prize will be offered in 1943-1944, and notice will be sent to members of the Society in due course.

Correction of Trustees' Report of 1942 The fifth set of figures at the right hand edge in this report should read \$782.88 instead of '\$782.78'.

The accounts of the Treasurer have been examined and found correctly cast and properly vouched.

SAMUEL T LADD
CLARENCE O COBURN
FREDERIC P LORD

The first paper of the afternoon session was entitled "Civilian Medical Defense and its Adaptation to Peacetime Civil Life," by Dr A William Reggio, of Boston.

The meeting was concluded by a paper, "Female Sex Hormone Therapy," by Dr George Van S Smith of Boston.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

Weekly Clinicopathological Exercises

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor**

BENJAMIN CASTLEMAN, M.D., *Acting Editor*

EDITH E. PARRIS, *Assistant Editor*

CASE 29471

PRESENTATION OF CASE

A seventeen-year-old housewife entered the hospital because of pain and swelling of the dorsum of the right hand.

About four months before entry, two weeks after hitting her hand on a door casing, the patient noticed swelling and aching in the dorsum of the right hand in the region of the distal portion of the middle metacarpal bone. The swelling increased until it was the size of a small walnut. The pain varied but often the throbbing and ache involved the entire hand, elbow and shoulder. About two months before admission she was seen by her family physician who incised the mass but was unable to obtain any pus. The incision apparently healed but the lesion increased in size, at first rapidly, but later slowly.

An x-ray film of the right hand about three weeks prior to entry showed a destructive lesion measuring 3.5 by 2 cm. in the distal portion of the third metacarpal (Fig. 1). This appeared to destroy and expand the shaft of the bone and to extend to the head of the metacarpal. In the anteroposterior view, the outlines appeared clear; but in the lateral view the outlines were not definite. Fine trabeculae were seen through the lesion, and there was a small amount of periosteal reaction along the anterior and lateral aspects of the shaft. The patient had lost 17 pounds during the preceding two months. There was no fever, swelling in the elbow or pain in the other bones, joints or muscles. Her general health had otherwise been excellent.

Physical examination showed a well-developed and well-nourished girl in no distress. Examination of the heart, lungs and abdomen was negative. Over the dorsum of the right hand was a hard, nontender mass, about 5 cm. in diameter, firmly attached to the underlying structures, but not to the overlying skin. The mass was situated near the head of the middle metacarpal bone.

The extensor tendons were apparently not involved.

The blood pressure was 112 systolic, 70 diastolic. The temperature was 99.6°F., the pulse 86, and the respirations 22.

Examination of the blood showed a red-cell count of 4,060,000, with 80 per cent hemoglobin. The white-cell count was 9300, with 73 per cent neutrophils. A blood Hinton test was negative. The blood calcium was 10.9 mg. per 100 cc., the phosphorus 3.6 mg., the phosphatase 4.6 Bodansky units. A repeat x-ray examination, three weeks after the first one, showed a definite increase in the size of the lesion. The majority of the bony trabeculations had disappeared. No evidence of metastases was seen in the chest.

On the fourth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. CHANNING C. SIMMONS: We have here a young woman with a painful tumor in the back of the hand following trauma. I assume that the x-ray films of the other bones and of the chest were negative. According to these x-ray films the tumor is in the distal end of the third middle metacarpal bone. It is expansile with a relatively sharply marked outline and with some periosteitis, but at the point where it joins the shaft, the bone has a moth-eaten appearance.

We have as usual the same three general groups of conditions as possibilities for diagnosis: first, an inflammatory condition, such as syphilis, tuberculosis, osteomyelitis or sarcoid; second, a generalized bone disease, such as osteitis fibrosa, fibrous dysplasia or one of many others—a congenital or possibly traumatic condition; and third, a tumor either primary, benign or malignant, or metastatic.

I shall assume from the history and the blood and physical examinations that the patient had no generalized bone disease such as osteitis fibrosa cystica. Presumably this was not congenital because she had no previous history of deformity of any sort. If it were due to trauma one would expect a history of swelling and pain that diminished in time and did not recur. In regard to tumor, there is no evidence so far as I can see of a primary malignant focus in this woman. It is true that metastases are likely to take place at a point on the body that has been traumatized. Presumably a hematoma following the trauma makes a good bed in which the metastatic cells may grow. Primary malignant tumors of the phalanges are almost unknown, and tumors of the metacarpal bones are rare.

*On leave of absence

The common benign tumors in this situation are chondroma and giant cell tumor. A benign tumor unless complicated by fracture is rarely painful, a malignant tumor is painful. One would expect that a benign tumor of the chondroma type

My diagnosis is either giant cell tumor or chondroma, with fracture, which would cause pain, or, possibly, a malignant tumor of the metacarpal bone, either osteogenic or Ewing's sarcoma. I do not see how a definite diagnosis could have

FIGURE 1 *Roentgenogram of Hand*

would be more clear cut in the x ray film and would not present a moth eaten appearance of the shaft. The same remark is true for giant cell tumor. A malignant tumor, osteogenic sarcoma, in this site is rare, as is also Ewing's sarcoma. I have seen both these tumors in metacarpal bones, but the x ray films in this case are not characteristic of either of them. The films of a giant-cell tumor may closely resemble those of a giant-cell tumor. In one such case, presented at a conference last winter, the lesion was located at the lower end of the fibula. Osteogenic sarcoma cannot be excluded. With an essentially normal temperature and white cell count, there was obviously no inflammation. The fact that the physician did not obtain pus when he operated is a further indication that it was not inflammatory.

been made without a biopsy. The physical examination is incomplete, and no mention is made of pigmented areas in the skin.

DR BENJAMIN CASTLEMAN: None were found.

DR MILFORD SCHULZ: One wonders about the change in character of the lesion, and the fact that the shaft seems to project into the tumor mass. I think that that was described by Dr E. A. Codman in giant cell tumors. Was it not?

DR SIMMONS: Yes, but they usually have a clean cut saucer shaped depression where the tumor joins the medulla. Pain unrelieved by rest is suggestive of either an inflammatory condition, fracture or a malignant tumor.

DR SCHULZ: The point was raised about malignant degeneration of a chondroma because of the change between the two x ray examinations.

DR ERNEST M. DALAND: Dr Codman has described this appearance and it has been present

in a number of cases that I have operated on. There usually is a saucer-shaped depression in the shaft proximal to the lesion, which is quite characteristic of giant-cell tumor.

DR. CASTLEMAN: Is that present in this case?

DR. SCHULZ: Yes, but it is exaggerated.

DR. SIMMONS: The point is that the shaft is usually not moth-eaten.

DR. SCHULZ: Could that not be due to the fact that we are looking at it tangentially. I do not see it in the lateral view.

DR. CASTLEMAN: What would you do about this, Dr. Simmons?

DR. SIMMONS: I should explore the tumor.

DR. CASTLEMAN: Would you do a biopsy, or take it all out?

DR. SIMMONS: That depends on what was found. If it were a benign tumor, I should be inclined to remove all the bone and amputate the finger. I do not believe that excision of a tumor as large as this will give a good functional result in later life.

CLINICAL DIAGNOSIS

Chondroma of metacarpal bone?

DR. SIMMONS'S DIAGNOSIS

Benign giant-cell tumor or chondroma.

ANATOMICAL DIAGNOSIS

Benign giant-cell tumor.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The surgeon removed the upper four fifths of the metacarpal bone. The finger was not amputated. When opened the lesion proved to be a benign giant-cell tumor filled with hemorrhagic yellowish material and fluid blood.

DR. WALTER BAUER: Benign?

DR. CASTLEMAN: Yes. The stroma was a little more active than that of the average giant-cell tumor. It might be classified Grade II according to Jaffe's grading.* In this group there is some tendency to recur and therefore resection of the tumor rather than curettage is the treatment of choice.

CASE 29472

PRESENTATION OF CASE

An eighteen-year-old schoolgirl entered the hospital because of pain in the right knee of two weeks' duration.

*Jaffe, H. L., Lichtenstein, L., and Portis, R. B. Giant cell tumor of bone: its pathologic appearance, gradings, supposed variants and treatment. *Arch. Path.* 30:993-1031, 1940

Two weeks before entry, four days after having been horseback riding, the patient noticed slight swelling and pain in the medial aspect of the right knee and exaggerated pain on full flexion. The pain kept her partially awake for several nights. A few days before entry x-ray films taken at an outside hospital were said to have shown a shadow in the right knee. The symptoms regressed and for the week prior to admission she was asymptomatic. There was no fever, chills, sore throat, pain in other joints, muscles or bones or other history of trauma.

No history of childhood diseases was obtained, but the patient was said to have had "growing pains" in her legs.

Physical examination showed a well-developed and well-nourished girl. There was a questionable slight thickening around the medial aspect of the right knee, without any limitation of motion or tenderness. No other abnormal findings were present.

The blood pressure was 120 systolic, 80 diastolic. The temperature was 98.2°F., the pulse 60, and the respirations 16.

Examination of the blood showed a red-cell count of 4,020,000, with a hemoglobin of 13.8 gm., and a white-cell count of 7100, with 64 per cent neutrophils. The urine was negative. The blood sedimentation rate was normal. A blood Hinton test was negative.

X-ray examination of the knee showed a 5-by-2.5-by-2.5-cm. area of rarefaction in the posteromedial portion of the lower shaft of the right femur just above the internal condyle (Fig. 1). Its margins were sharply defined and rather dense. There was a small amount of dense periosteal proliferation over it. No definite soft-tissue mass was seen. The remainder of the bone displayed slight decalcification. The skull, hands, feet and the right humerus were normal. There was slight decalcification of the bones of the right foot. The blood calcium was 12 mg. per 100 cc., the phosphorus 4.7 mg., and the phosphatase 2.7 Bodansky units. One observer noted two areas of brown pigmentation over the left thigh and one on the right shoulder.

On the third hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. ERNEST M. DALAND: The physical examination and the history seem to be entirely negative. The laboratory examination is essentially negative, except for slight elevation of the blood calcium. The problem comes down to one of interpretation of the x-ray findings. We have here an oval-shaped defect above the epiphyseal line that extends

down quite close to the epiphyseal line. This is not a central lesion. It is medial and posterior. It does not extend all the way through. In one view there is no expansion of the bone, and in another there is expansion or perhaps periosteal

myelitis or a Brodie's abscess is that it did not involve the medulla. We can also rule out a giant cell tumor. Giant cell tumors in the femur are much likelier to be in the condyle extending down to or close to the articular surface. A giant-

FIGURE 1. *Lateral and Anteroposterior Roentgenograms of Knee*

proliferation; but we are not dealing here with an expansile type of tumor. The x-ray interpretation points out also that the margins are sharply defined and rather dense, which gives one the impression of something going on for some time and well walled off from the rest of the bone. No soft-tissue mass was felt, which is important because it helps us rule out a malignant lesion, particularly a primary malignant lesion, such as an osteogenic sarcoma. The skull, hands, feet and so forth were normal. They were checking to see if the patient had other cysts of the same sort. The note is made about slight decalcification of this bone and also the bones of the right foot. I am not impressed with the decalcification in the bones that I see, although I have not seen the x-ray films of the foot. Two weeks' disability is hardly time for decalcification from loss of use.

The differential diagnosis comes down to the decision whether we are dealing with a benign tumor, an inflammatory condition or a malignant tumor. I think we can rule out acute osteomyelitis because of the lack of fever, elevated white cell count and definite localized tenderness. A lesion of this size due to osteomyelitis would probably have given symptoms much sooner than two weeks ago. Another point against osteo-

cell tumor in this region is usually central, expansile and spherical—that is, the transverse and perpendicular diameters are about equal. I think that we can also rule out a primary malignant tumor. The lesion does not have the appearance of an osteogenic sarcoma. The sharp line of walling off and absence of soft-tissue mass are the two cardinal points in favor of a benign condition. The blood chemistry helps us rule out hyperparathyroid disease, and also we can rule it out on the basis that this was a solitary lesion with a sharp line of demarcation, whereas in hyperparathyroidism we should expect it to fade out slightly.

The three possibilities are a solitary cyst, osteitis fibrosa cystica disseminata, the syndrome that Dr. Fuller Albright³ described, or a chondroma. In the syndrome spoken of as Albright's disease we should ordinarily expect to have multiple lesions, although that is not absolutely essential. The phosphatase is usually elevated and I suspect that the phosphatase is elevated according to the number of lesions and the activity of the lesions. Here we have a normal phosphatase, with only one lesion. We have the statement that one observer noted two areas of brown pigmentation over the left thigh and one on the right shoulder.

DR. BENJAMIN CASTLEMAN: That observer was Dr. Albright.

DR. DALAND: Dr. Albright must have been surprised to find them on the opposite side of the body, because usually these pigmented areas are on the same side as the lesion. I am a little skeptical about these lesions anyway. I believe that they can be found in most patients if one looks for them. We have no description of their size. A few years ago at the Memorial Hospital in New York someone was interested in melanomas and undertook to see if it would be possible to remove pigmented areas in all patients who came into the clinic. The first one hundred patients averaged 20 brown spots apiece, so that the three areas in this case do not impress me much. In Albright's syndrome, patients are apt to have disordered catamenia. There is no note here that there was any. I believe we can rule out that syndrome because these pigmented marks were not definite. The phosphatase was normal. The pigmented lesions were not on the same side, and there was only one bone lesion.

Putting aside that syndrome, we then come to the old diagnosis of solitary bone cyst. As Dr. Richard Schatzki has pointed out here, these solitary cysts when opened may not contain a fluid material. It may be semisolid material and perhaps the term solitary cyst is not a good one.

The last possibility is that this patient had a chondroma. A benign cartilaginous tumor usually occurs somewhere near the epiphyseal line. I think this is near enough to fall within that category. They develop in places where there has been cartilage previously, and that is true at the epiphyseal line. Another characteristic of a chondroma is that it may get to be fairly large before it gives any symptoms. It may be that it is the periosteal proliferation, where the tumor has bulged slightly, that produces the symptoms. With a chondroma we ought to have a sharp line of demarcation, such as we have here, and that is what I believe was found at operation.

DR. FULLER ALBRIGHT: A few weeks ago we had a case somewhat similar to this which I diagnosed (correctly, for once) as neurofibromatosis, and I pointed out at that time that any cyst-like appearance at the lower end of the femur might be neurofibromatosis as this is a favorite site for such lesions. So when I saw this case shortly after that conference, that diagnosis was strongly considered. I did not believe that it was neurofibromatosis, however, because the lesion expanded the bone a bit. I thought that it was a bone cyst. I agree that the three brown spots may have been coincidental. I do know, however, that

you get "my" disease (call it what you will) with lots of brown spots and lots of cysts, with a few brown spots and a few cysts, with no brown spots and one cyst and with one brown spot and no cysts!

DR. CHANNING C. SIMMONS: I cannot reconcile pain with a diagnosis of cyst. As a rule a cyst is painless. Benign tumor is rarely painful and malignant tumor is rarely painless, whereas an inflammatory condition is usually painful. In spite of the normal temperature and white-cell count I do not believe that one can entirely rule out low-grade osteomyelitis that has lain dormant for years.

DR. ALBRIGHT: The pain came on after horse-back riding and presumably was due to a small fracture.

DR. SIMMONS: There is no x-ray evidence of fracture.

DR. ALBRIGHT: There is periosteal proliferation.

DR. SIMMONS: If she had a fracture, I take back that statement. I cannot see any evidence of fracture, however, in these films.

DR. WALTER BAUER: I think if we end up with anything short of a biopsy, we are not going to make the correct diagnosis. I should not be willing to rule out Brodie's abscess as readily as Dr. Daland did, because we know that Brodie's abscess can remain silent for years. We have seen instances where multiple foci of osteomyelitis occurred at the time of the original septicemia, yet only one or two of them became symptomatic shortly thereafter; the other foci gave rise to symptoms one to ten years later. In the last analysis here is a lesion that is expanding and one is certainly not doing the right thing by the patient unless a biopsy is performed and the exact diagnosis established.

CLINICAL DIAGNOSIS

Bone cyst of femur.

DR. DALAND'S DIAGNOSIS

Chondroma of femur.

ANATOMICAL DIAGNOSIS

Fibrous dysplasia of femur.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: Dr. Smith-Petersen called me to the operating room just as he was about to unroof the lesion. He removed the cortex over the lesion exposing a cavity completely filled with yellowish-gray, somewhat gritty, fibrous material. A portion of this material was adherent to the

inner aspect of the cortical lid. The cavity was completely evacuated by means of osteotomes and gouges, and the lining was found to be roughened. No fluid or cystic degeneration was present. It was completely solid.

Microscopic examination showed this to be made up of connective tissue with a few small bone trabeculae that were neurotic and poorly calcified. The appearance was quite characteristic of fibrous dysplasia of bone or what Dr. Albright has called "osteitis fibrosa disseminata." We have just recently seen another of these lesions in a rib removed from a twenty-three-year-old girl. This was discovered on routine x-ray examination of the chest before joining the WAVES. Neither of this patient nor the one under discussion had other bone lesions. With the increase in routine x-ray examination we are probably going to see a lot more of this disease and find that it is much commoner than we realized.

DR. ALBRIGHT: Are we talking about the same thing? What do we mean by a bone cyst? The pathological finding was just what I expected.

DR. CASTLEMAN: This is not a bone cyst. It is what has been called by Lichtenstein and Jaffe^{2,3} "fibrous dysplasia of bone," which is apparently a maldevelopment of the mesenchyme as the bone is formed. A solitary bone cyst is quite different. It has a definite capsule and lining and is filled with fluid. Jaffe who has had extensive experience with bone pathology is quite convinced that a solitary bone cyst is an entirely different condition from fibrous dysplasia, although the latter may have areas of cystic degeneration in it.⁴ About half the solitary bone cysts are found in the upper end of the humerus.

DR. ALBRIGHT: I think the terminology is bad all the way through. Let us go back to hyper-

parathyroidism where three things are likely to be present—fibrous tissue, actual cysts filled with fluid, and giant-cell tumors. By x-ray they all look like cysts.

In talking of cysts clinically we do not necessarily mean fluid; it may be fibrous tissue. Perhaps we should. I appreciate that it is loose terminology not to do so, but when all the x-ray interpretations use the same terminology, one gets into bad habits.

I think the bone disease in question had better be called "fibrous dysplasia," as suggested by Jaffe, rather than "osteitis fibrosa disseminata," the term I originally used.

DR. BAUER: I am glad you feel that way about it, Dr. Albright. It will make for less confusion with osteitis fibrosa generalisata—that is, hyperparathyroidism.

DR. ALBRIGHT: The original name that you gave it would be better than "Albright's disease." I think it is unfortunate that we use a man's name to describe these things. We ought to use pathological terms that give visualization of what we see under the microscope.

DR. ALBRIGHT: Yes, but it is rather cumbersome. The term was "osteitis fibrosa disseminata with pathologic pigmentation and precocious puberty in females." I suppose a case with the brown spots and precocity but without bone lesions could be called "fibrous dysplasia sine fibrous dysplasia."

SUBSCRIPTION TERMS: \$6.00 per year in advance, postage paid, for the United States (medical students, \$3.50 per year); Canada, \$7.04 per year. Boston funds; \$8.52 per year for all foreign countries belonging to the Postal Union.

MATERIAL for early publication should be received not later than noon on Friday.

THE JOURNAL does not hold itself responsible for statements made by any contributor.

COMMUNICATIONS should be addressed to the *New England Journal of Medicine*, 8 Fenway, Boston 15, Massachusetts.

FE, FI, FO, FUM

THE idea has long been current that if members of the human race—essentially an omnivorous species—wanted good, red blood, they must eat good, red meat. It is a simple, chromatic idea, based on the assumption that like begets like: the closer the color of the meat is to blood, the better the blood it builds. How beef cattle get such good, red blood from the grass they eat is another story; their domestic economy is of a different nature and they are put on earth for man's service.

At any rate, the belief persists that since beef is meat, meat must of necessity be beef. Mutton is

a poor substitute and under suspicion, being not usually of a red color when cooked, and pork, of course, is pork. These are peasant foods and, presumably, not alone capable of preserving the virility of the descendants of the pioneers who first broke the soil of our great democracy.

With war, however, has come the rationing of many things, including food—not entirely for the sake of increasing, with beef, the bellicosity of our armed forces or of overstuffing our British allies, who for four long years have kept alive the flickering flame of freedom. It is mainly that, with limited production, the available supplies should be evenly apportioned and that each should have no less than his share because another wanted more.

To one group of persons special dispensation has been granted, as was their due. This group consists of those afflicted with certain chronic illnesses who would suffer peculiar hardships from accepting the dietary limitations to which the rest of the country has acquiesced. The stewardship of their rations has been placed, logically, in the hands of the medical profession, and already several thousand physician's certificates of patient's necessity have been granted in Massachusetts, the majority of which call for extra meat rations.

It might seem that, among the other great upheavals of the war, the fixed idea that meat must be red could also be uprooted. We are, indeed, reliably informed that lamb, pork, poultry, milk, eggs, cheese and even the lowly fish contain and furnish the same dozen essential amino acids as does good sirloin and that nutritionally these animal protein foods are practically identical—and half of them are not yet on the ration lists. Evidence seems even to be accumulating that man can exist and function on far less than his daily traditional 70 grams of protein. Add to these iconoclastic innovations the eruption of that complete food, the soybean, over the length and breadth of the land, like the dragon's teeth that Cadmus sowed, and roast beef may well go entirely on the luxury list.

CANCER CONTROL

A SYMPOSIUM on cancer control was held in New York City on October 11, the day preceding the opening of the Wartime Conference of the American Public Health Association in that city. Participants included representatives from the National Cancer Institute, the American Society for the Control of Cancer and the American College of Surgeons and from eleven states, two counties and one city having cancer programs, and among the audience were officers of the Women's Field Army.

The symposium was composed of four sessions: the first devoted to epidemiology, the second to administration, the third to service to cancer patients and the fourth to education. Approximately one hundred persons attended all four sessions, and about four hundred attended at least one session.

The symposium indicated that several trends are emerging in cancer control. The desire for prevention, early diagnosis and prompt treatment is manifest throughout the country. More rounded programs consisting of service to patients, research and education are to be preferred to a more limited program.

In New York City a cancer prevention clinic has been in operation for about three years. Approximately 75 per cent of the persons examined were found to have cancer and in most cases the disease was in a very early stage. The extension of the prevention clinic is a strong possibility in future cancer control.

Reporting of cancer, either through the physician or through the hospital, will probably be adopted more extensively in the future. The experience in compulsory cancer reporting by physicians in New York and in the reporting by hospitals in Connecticut indicates that both methods of obtaining a satisfactory knowledge of cancer morbidity are feasible.

A strong trend toward education in cancer in the public schools is being met by various types of programs in many different localities. From

this there may emerge a clear idea of whether cancer education in the schools is expedient, and if so, what its scope should be. The values of different methods of educational approach may well alter future practices. Two experimental school projects in cancer control in Massachusetts were presented at the symposium. In Malden a unit of four lecture periods was conducted in the eighth-grade classes last spring. In Lynn a cancer unit with four elements is being given in the biology classes in one high school and in the public-health classes in another, and the entire school is being instructed through the general assembly in a third. Prior to the inauguration of the Lynn program an estimate of the students' present knowledge of cancer was made by means of a true-false questionnaire. With this as a background, measures of improvement can be made at later periods.

All in all, in spite of the distractions occasioned by the war effort, it is evident that significant advances are continuing in the program devised for the control of cancer.

MEDICAL EPONYM

LAURENCE-MOON-BIEDL SYNDROME

This eponym is applied to a symptom complex described by Solomon Solis-Cohen and Edward Weiss in a paper, "Dystrophia Adiposogenitalis, with Atypical Retinitis Pigmentosa and Mental Deficiency—The Laurence-Biedl Syndrome: A report of four cases in one family," in the *American Journal of Medical Sciences* (169:489-505, 1925), which they thought identical with the conditions described by the authors of the papers here summarized.

In the *Ophthalmic Review* (2:32-41, 1866), John Zachariah Laurence (1830-1874) and Robert C. Moon (1846-1914) published a paper entitled "Four Cases of 'Retinitis Pigmentosa' Occurring in the Same Family and Accompanied by General Imperfections of Development." A portion of the article follows:

Marian T., aet. 7, 3 feet, 8 inches, in height, is a fat, flu-featured, heavy-looking child. . . .

Scattered over the fundus oculi . . . were several irregular figures of a deep black color. . . .

Harry S., aet. 20, is short for his age—measuring only 5 feet, 3¼ inches, in height. He walks with a slouching, heavy gait, as if he were tipsy.

The superficial stratum of the choroid is considerably atrophied. . . . A few isolated dark black pigment spots are scattered over the fundi. . . .

Frederick, aet. 18, measuring 4 feet, 6½ inches, in height, is a fatish heavy-looking boy. . . . Like his brother Harry, he walks with a slouching, helpless gait, dragging his legs from the hips.

Ophthalmoscopic examination showed exactly the same appearance as in Marian's eyes. . . .

Charles, aet. 15, measures 4 feet, 4½ inches. He is dull and inanimate, like the two other youths, and has a slouching gait, but not at all to the same extent as his brothers.

The ophthalmoscopic description of Harry applies to this boy. . . .

The height of each patient has been given for the purpose of directing attention to the dwarfish stature of the boys for their age. The organs of generation are also strikingly implicated in the general want of development.

The arrest of development was by no means confined to the eye, but affected several other organs of the body. In this latter point of view, and more especially when we regard the general imperfection of the mental faculties, these patients may in a certain sense be not inaptly compared to cretins in a mild degree.

In the *Deutsche medizinische Wochenschrift* (48: 1630, 1922), Arthur Biedl discusses this subject at a meeting of the Prague Society of German Physicians. A portion of the translation follows:

A brother and sister with adiposogenital dystrophy and a third patient were characterized by absence of any changes in the hypophysis or of any signs of brain tumor or pathologic intracranial pressure and by the presence of congenital malformations (retinitis pigmentosa, polydactylism and atresia ani), together with limited cerebral development, shown principally by a peculiar mental torpor. In one case a diminished basal metabolism was demonstrable. . . . This new symptom complex is to be attributed to a primary underdevelopment of the brain, especially that part of it containing the metabolism center.

R. W. B.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

BUEHLER — GEORGE VAN BUSKIRK BUEHLER, M.D., of Bedford, died November 19. He was in his sixty-eighth year.

Dr. Buehler received his degree from the University of Pennsylvania School of Medicine, Philadelphia, in 1895. He was founder of the Cambridge Relief Hospital in 1914. He was a member of the Massachusetts Medical Society and the American Medical Association.

His widow and a son survive.

HALLISEY — JOSEPH E. HALLISEY, M.D., of Boston, died November 18. He was in his sixty-second year.

Dr. Hallisey received his degree from Tufts College Medical School in 1908. He was physician-in-chief of the First Medical Service and chief of the Cardiac Clinic at the Boston City Hospital. He was a professor of medicine at Tufts College Medical School and a former president of the Boston City Hospital Alumni Association. He was a member of the Massachusetts Medical Society and the American Medical Association.

LODGE — ATHENS V. LODGE, M.D., of Brewster, died November 18. He was in his seventy-second year.

Dr. Lodge received his degree from the University Medical College of Kansas City in 1900. He was a member of the Massachusetts Medical Society and the American Medical Association.

His widow, a daughter and three brothers survive.

PERCY — KARLTON G. PERCY, M.D., of Brookline, died November 15. He was in his fifty-eighth year.

Dr. Percy received his degree from Harvard Medical School in 1911. He was on the staffs of the Children's Hospital, Boston, Chelsea Hospital, Chelsea, and the Whidden Memorial Hospital, Everett. He was a member of the Massachusetts Medical Society and the American Medical Association.

His widow, a son, a daughter, his mother, a sister and a brother survive.

CORRESPONDENCE

THE LATE DR. STETSON

To the Editor: I want to thank you and A.H.E. for the facts that the obituary on Dr. Halbert G. Stetson contained, in the October 28 issue of the *Journal*.

I do not think I ever before realized how cold cold facts can be and, therefore, I should like to add a little more about Dr. Stetson, of whom we were all so fond.

He was a man who, not only when he was president of the Massachusetts Medical Society but before and afterward, gave unselfishly of his time and strength to the Society. As a young man he quite rightly chose to practice in a small county seat and grew up with the community. His endless services to people as well as his medical ability soon gave him prominence. His most outstanding work was with the development of the local hospital. His unfailing kindness and common sense placed him high with all those who were fortunate enough to have been his friends.

The medical profession needs to have more doctors develop in the way Dr. Stetson did.

ABNORMAL NITROGEN METABOLISM IN PATIENTS WITH THERMAL BURNS*

F. H. L. TAYLOR, Ph.D.,† STANLEY M. LEVENSON, M.D.,‡ CHARLES S. DAVIDSON, M.D.,§ AND MARGARET A. ADAMS, A.B.¶

THE burned patient is not a simple subject for metabolic study. In addition to the large amount of tissue breakdown and subsequent nutritional demands by the healing processes and the continuous loss of nitrogenous material from the burned surface, the burned patient is seldom free from intercurrent complications. Disturbance of renal or hepatic function may be present.¹ Local and sometimes general infections occur.² Shock may be an early complication and may have protracted secondary effects.³ Fever may be present.² All these complications may cause severe disturbances in metabolism. In spite of these difficulties, a study of the nutritional requirements of the severely burned patient appears to be necessary since the healing of the burned surface may depend, in part, on the maintenance of good nutrition.

This paper presents certain observations on the disturbances of nitrogen metabolism in severely burned patients admitted to the Boston City Hospital as the result of the Coconut Grove disaster. In a subsequent report,⁴ methods for controlling some of these abnormalities in nitrogen metabolism will be presented, and detailed observations on one severely burned patient are given elsewhere.⁵

AZOTEMIA

Azotemia is a known complication of the se-

verely burned patient,⁶ and two distinct types were occasionally observed in the present study

FIGURE 1. Reversible and Irreversible Azotemia, associated with Early Oliguria, in a Severely Burned Patient

A reversible azotemia, associated with transitory oliguria, occurred frequently as an early complication. A typical example of this type of increase in the nonprotein nitrogen of the blood is shown in the upper part of Figure 1. This phenomenon is similar to that frequently found following surgical operations and in shock, when oliguria,

*From the Thorndike Memorial Laboratory, Second and Fourth Medical Services (Harvard), and the Burn Assignment of the Surgical Services Boston City Hospital and the Department of Medicine, Harvard Medical School.

†The work described in this paper was done in part under a contract recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and Harvard University.

‡The expenses of this investigation were defrayed in part by gifts from the Josiah Macy, Jr., Foundation of New York, and the Smith Fund and French Laboratories of Philadelphia to Harvard University.

§Research associate in medicine, Harvard Medical School, chemist, Thorndike Memorial Laboratory, Boston City Hospital.

¶Laboratory assistant, Thorndike Memorial Laboratory, Boston City Hospital.

or even anuria, may persist for some hours. In this type of azotemia, the restoration of a normal urine output results in a return of the increased nonprotein nitrogen level of the blood to normal. Since, however, the kidney can clear urea only at a fairly fixed maximum rate, the azotemia may persist for several days, as is shown in the patient illustrated in the figure.

Another type of azotemia was found in certain burned patients studied because of the presence of hemoglobinemia and hemoglobinuria. These problems will be discussed elsewhere.⁷ This type of azotemia occurred only in severely burned patients. In these patients from 20 to 55 per cent of the body was burned, and much of the burn was third degree. With one exception, they secreted an acid urine. In a group of 9 patients having these criteria, 6 showed azotemia. In 5 of them the azotemia was irreversible, and in 1 it was reversible.

The nonprotein nitrogen in irreversible azotemia did not rise to the high values usually encountered in renal shutdown and complete anuria. The level was quite constant and seldom rose above 80 to 100 mg. per 100 cc. of blood. A typical example of irreversible azotemia in one of the patients studied is shown in the lower half of Figure 1. It will be noticed that oliguria was present early but that a normal urine output was soon obtained. The urine did not have a fixed specific gravity. In spite of this, the nonprotein nitrogen of the blood did not fall. The patient died on the twelfth day following her injury. It is of some practical importance that sulfadiazine administered to patients with irreversible azotemia gave satisfactory blood levels of the drug and was apparently well cleared by the kidney. Under no circumstances was the drug administered until a normal diuresis was obtained.

It is known that the excretion of hemoglobin in an acid urine may result in deposition of hemoglobin or its derivatives in the kidney.^{7,8} If, however, this was the primary cause of the azotemia, the damage to the kidney was not complete, since, except for an early transitory oliguria, the urine output was normal in volume and total solids. It is therefore suggested that in patients such as have been described an irreversible azotemia can occur owing to a partially damaged kidney. It is also probable that the increased rate of protein catabolism in such severely burned patients was an important additional factor in the production of a high nonprotein nitrogen in the blood. The damage to the kidney alone was not of sufficient severity to account for the nitrogen retention.⁷

NITROGEN PARTITIONS OF BLOOD AND URINE

A partition of the nitrogenous constituents of the blood and urine of 3 patients with severe burns was done. The data of one patient are given in Tables 1 and 2. This patient sustained a

thermal burn involving 45 per cent of her body, with 30 per cent third-degree and 15 per cent second-degree burns. She had hemoglobinemia and hemoglobinuria as early complications.

Irreversible azotemia was present, and as shown in Table 1, a portion of the elevated nonprotein nitrogen was accounted for by an increased urea. However, there was present in the blood a relatively large amount of residual or undetermined nitrogen. This residual nitrogen is probably that referred to by Duval et al.⁹ and Lambret et al.¹⁰ as "polypeptide nitrogen." The characterization of this fraction by these authors, however, is far from conclusive.

As shown in Table 2, there was also an increase in the residual nitrogen of the urine. This high level could be equally well accounted for by the excretion of abnormal metabolites or by the presence in the urine of substances that interfered with the action of urease.

Characterization of the residual nitrogen was not attempted. On hydrolysis, it yielded both amino and amido nitrogen. In the present study, the occurrence of a high blood residual nitrogen was not uncommon in severely burned patients, but high urine residual nitrogen was quite rare.

The azotemia illustrated in Table 1 can be accounted for on the basis, previously stated, of the production of large amounts of protein degradation products in the presence of a partially damaged kidney. Liver disease cannot, however, be ruled out in the present series of cases, in spite of the fact that there was no clinical evidence of its presence in the patients studied.

HYPOPROTEINEMIA

The presence of hypoproteinemia in burned patients has previously been commented on.^{2,6} In the present survey, 81 patients with burns were

studied. In 40, hypoproteinemia developed. There appeared to be a definite correlation between the progressive type of hypoproteinemia and the severity of the burn. For example, in 12 patients having burns of between 10 and 50 per cent of the

cases, however, postmortem examination showed some degenerative changes. This subject will be reported on by others.¹¹

It appears necessary to seek causes other than early plasma loss to explain the hypoproteinemia

body surface, 8, or 65 per cent, showed progressive hypoproteinemia. In 51 cases with burns involving less than 10 per cent of the body surface, however, only 8, or 15 per cent, showed this abnormal-

of burns. It is a frequent observation that burned patients remaining in a hospital for long periods of time while awaiting skin grafting lose considerable amounts of weight. An opportunity has been given us to study such patients. We found that severely burned patients rapidly lost large amounts of nitrogen into the urine. As shown in Table 3, the nitrogen loss on occasion amounted to as much as 45 gm. a day. It is well known that the excretion of abnormally large amounts of nitrogen occurs in thyrotoxicosis, in severe infections and in other conditions associated with increased metabolism, and it has also been reported as occurring in burned patients.⁹ It has been thought to be due to a rapid destruction of structural protein and has been called by some authors "toxic protein destruction." Obviously, such losses of nitrogen into the urine may cause a marked protein deprivation.

FIGURE 2. *Plasma Protein Fractionation Showing Early and Late Reversal of the Albumin Globulin Ratio*

ity. Early hypoproteinemia was probably associated with protein loss from the burned areas, but other causes must be looked for to explain the progressive type of hypoproteinemia occurring in severely burned patients. This hypoproteinemia increased in severity until the anasarca level was reached and massive edema developed.

The fall in albumin and the reversal of the albumin-globulin ratio encountered early may be theoretically associated with the preferential loss of albumin from the circulating blood owing to the relatively low molecular weight of albumin as compared with that of globulin. It has been noted, as shown in Figure 2, that the albumin level may remain constant while the globulin fraction actually rises in the circulating blood. Such rises in the globulin have frequently been associated with infection and with hepatic dysfunction, as judged by clinical and laboratory evidence. In a few

In all burned patients admitted to this hospital, an attempt was made to meet the demand for protein by increasing the protein intake to from 100 to 125 gm. a day. Even at this level, there was a marked negative nitrogen balance in 9 patients with severe burns. Most of the patients with minor burns of less than 10 per cent of the body surface involved responded to the intake of 125 gm. of protein a day with a return of their plasma protein to normal, but in those patients with a continued marked loss of nitrogen into the urine this did not occur. Indeed, in some of the severely burned patients, it has been calculated that, on the basis of the loss of nitrogen into the urine alone, 300 gm. of protein a day would have been required to maintain nitrogen equilibrium. In addition to this loss, some patients continued to lose large amounts of nitrogenous material from the burned surface for long periods of time. This insensible loss could not be calculated. The restoration of protein under these combined circumstances was a difficult problem, since the amounts required were con-

siderably greater than those the patients could ingest.

A loss of as much as 30 per cent of the body weight has occurred, in some of the patients studied, as a result of failure to maintain adequate nutrition. Therefore, in severely burned patients, a careful appraisal of the nitrogen balance must

Practical considerations of how this problem may be attacked from a nutritional standpoint will be presented in a subsequent communication.⁴

SUMMARY AND CONCLUSIONS

In a series of burned patients, azotemia was a common complication of severe burns and was

be made early, and when marked deficits of nitrogen are expected, forced alimentation by a variety of routes should be begun. The problem becomes

usually of the reversible type. It occurred early and was relieved when the urine output became normal. In some severely burned patients, an irreversible type of azotemia occurred. This increase in nonprotein nitrogen was not progressive and may have been due to a partially damaged kidney in the presence of increased protein catabolism. So far this type of azotemia has been chiefly found in severely burned patients excreting an acid urine in whom hemoglobinemia and hemoglobinuria were present.

In certain severely burned patients having coincidentally hemoglobinemia and hemoglobinuria, there was an abnormality in the partition of both the blood and the urine nitrogen, associated with the presence of large amounts of residual or undetermined nitrogen. The percentage of total nitrogen of the urine present as urea was low.

Hypoproteinemia was a common finding in the severely burned patients. A transitory hypoproteinemia was associated with plasma loss and could be restored by simple dietary means, but the more progressive type was probably due to the loss of large amounts of nitrogen into the urine owing to increased protein catabolism, in addition to large losses of nitrogenous material at the burned surface.

Inversion of the albumin and globulin ratio frequently occurred. When it happened early, it was probably associated with a preferential loss of albumin, which has a low molecular weight. The cause of its late occurrence in burned patients has not been determined.

The serious problem of the maintenance of adequate nitrogen metabolism in severely burned patients is briefly outlined.

FIGURE 3. *Nitrogen Balance in a Severely Burned Patient.*

increasingly difficult as time goes on, so that whatever measures are to be used to ameliorate the nutritional deficits must be commenced early. It must also be remembered that estimation of the nitrogen requirements of a burned patient by the usual nitrogen-balance studies alone give only the minimum requirement. For example, as shown in Figure 3, in one patient, after positive nitrogen balance was restored by gastric intubation and intravenous amino acid, over 8000 gm. of protein was laid down in a period of six weeks without unusual increases in urine nitrogen and with evidence of complete utilization. Even after this apparently large nitrogen retention was established, the patient was still fifty pounds below the admission weight.⁵

PREVENTION OF VITAMIN DEFICIENCIES IN WARTIME*

FRANZ R STENZEL, M.D.†

WABAN, MASSACHUSETTS

THE prevention of vitamin deficiencies is an important problem and, if the duration of the war is prolonged, a serious one. Unquestionably nutritional deficiencies already exist in the occupied countries, and the United States will have to play a large part in the feeding of those peoples at a later date. We are shipping an ever increasing amount of food to the United Nations and to our troops abroad.

Our government has instituted a program with which we are all familiar. This includes rationing foodstuffs, increasing production on the farm and in Victory gardens, and preserving food in the home to conserve manpower and material. The Council on Foods and Nutrition of the American Medical Association and the Food and Nutrition Board of the National Research Council function jointly to advise on the rationing of food and the institution of educational programs relative to the food problem.

Vitamin deficiency is but one phase of nutrition. It happens to be the newest one, and the one in which a tremendous amount of work has been done in an incredibly short time. The therapeutic use of vitamins has become routine in all branches of medicine. The altered physiologic states associated with specific vitamin deficiencies are, in general, well recognized and well treated. There are also the milder, less well recognized, multiple deficiencies that are usually the province of the internist or the general practitioner.

The public mind is readily captivated by the concept of vitamins and their alphabetical nomenclature. Health giving properties and the vitamin content of processed foods are emphasized. News paper and radio advertising has aroused public consciousness. Over-the-counter sales of vitamin

tively colored and packaged vitamin preparations have reached tremendous proportions.

Obviously, the answer to the prevention of deficiencies in the face of increasing food shortage in the future is not more and bigger vitamin pills. This is not so facetious as it might sound, and the physician may have contributed at times to the impression that vitamins by definition are found in pills. To prescribe such preparations without having inquired into the patient's diet and without making obvious corrections is but a gesture in the right direction. There is not sufficient material to supplement the diet of the entire population by concentrates and synthetic material, even if it were economically possible to do so. With rationing and such shortages as already exist, many items that are the richest sources of vitamins are unobtainable in sufficient amounts to be included in the daily diet. It becomes necessary to look a little farther down the list, so to speak, and include larger amounts of less rich but more available foods.

This is well illustrated by ascorbic acid. People have largely depended on a daily intake of orange, pineapple or tomato juice—now obtainable only in limited quantity. The logical answer is the increased consumption of cabbage as salad or of potatoes properly cooked. All fruits, berries and vegetables contain significant amounts of ascorbic acid. In England a Walt Disney like character called 'Johnny Potato' is used in cartoons and posters to popularize the increased consumption of potatoes. Approved methods of cooking are published and prizes offered for novel ways of preparing potatoes without destroying their ascorbic acid content.

Many publications contain tables giving the vitamin values of particular food sources. These are usually unreliable and misleading. They are often based on the fresh uncooked animal or

*Presented at the annual meeting of the Massachusetts Medical Society on May 6 1943.

†Visiting physician, Newton Hospital.

vegetable source. The ascorbic acid content of green vegetables and fruits, for example, increases steadily to a maximum just before the fruit is ripe and then decreases steadily. The amount in a given fruit or vegetable is also influenced by proper fertilization and methods of growing. With many fruits an added factor is whether they are tree ripened or picked while green and allowed to ripen in storage. Further, the amount of vitamins contained in food after cooking or preservation varies as the process involves cooking, heating, washing, bleaching or the addition of chemicals. It can be readily appreciated that this multiplicity of factors makes for a wide difference in specimens of food as they are found on the table.

There has been set up a table of figures by the Council on Foods and Nutrition of the American Medical Association giving what constitutes daily vitamin requirements in the light of present-day knowledge. These are admittedly an approximation and at best a rough estimate. Changes must be made relative to age, pregnancy, lactation, infection and specific diseases. Revision of these figures tends to be upward as knowledge concerning the requirements is accumulated. It is well to have some basic table in mind as a point of departure. Special requirements with reference to altered physiologic states and specific diseases will not be discussed, as the present rationing system permits additional food in such cases at the request of the physician.

All known vitamins with the exception of vitamin D are synthesized by plants and used by them essentially for the same purpose as by man and animals. Man, however, is unable to synthesize these compounds, with the exception of vitamin D, and must depend on ingestion for his supply of vitamins or their precursors. Vitamins do not furnish energy and are not building units for the structure of the body, but are necessary for the transformation of energy and the regulation of metabolism. There are many gaps in the details of the physiological chemistry of these substances, but evidence has accumulated so far as the better-known vitamins are concerned regarding the general role that they play in the body. There is also a long list of lesser-known substances that apparently contain vitamins. The knowledge of these is fragmentary, their role in the human body is unknown, and no estimate concerning their requirements can be formed. These will not be discussed, but a review of the better-known vitamins should serve to indicate under present conditions the principal available sources, the changes in diet and certain points of preparation of food in order to prevent avitaminosis.

There is not much danger of avitaminosis so far as the A group of vitamins is concerned, provided that there is an adequate intake of vegetables. The daily requirement for the average person is 5000 international units. This is not increased during body activity, but is greater in lactation and pregnancy. Excluding restricted and scarce items, such as dairy products, eggs and liver, the principal sources are green-leafy and yellow vegetables. A single serving—that is, $3\frac{1}{2}$ to 4 ounces of beet tops, kale, mustard greens, spinach or turnip greens—will supply well over twice the daily requirement. A serving of carrots will supply about the same amount. The same serving of summer squash will provide a little over the daily requirement, and sweet potatoes a little under it.

As another approach to prevention of vitamin deficiency in the A group, the Council on Foods and Nutrition has recommended the fortification of oleomargarine to a level of 9000 international units per pound, so that 1 ounce will provide one fifth the daily allowance. The fortification and wider sale of oleomargarine is barred by law in some states and is opposed by dairymen, but there is no question that it provides a suitable vehicle for vitamin A. There is little difference between butter and oleomargarine except for a lower percentage of unsaturated fatty acids in the latter.

In considering the prevention of deficiencies in the vitamin B group, it should be pointed out that the deficiency of a single factor is an exception rather than the rule. These vitamins resemble enzymes and are concerned with the utilization of specific food substances. For example, the riboflavin enzyme system is concerned with the utilization of the essential amino acids, and a deficiency of such amino acids would eventually produce the clinical picture of riboflavin deficiency.

The known members of this group consist of thiamine, riboflavin and niacin. The other members have not been identified or have been studied so inadequately that their function and requirements are unknown.

Thiamine is said to be required in a daily dose of 1.8 mg. for the average person. This requirement is increased with activity, and also during pregnancy and lactation. The outstanding source of thiamine is lean pork. One 4-ounce serving provides almost the daily requirement. The next richest source is dried brewer's yeast, an ounce of which is equal to about the same amount. Thiamine is usually obtained in small quantities from a great many foods, including meat and vegetables. The most available sources are whole-wheat bread and whole-grain cereals. Dried peas and beans are also important. The problem of thia-

mine deficiency is obviously more acute now, with the rationing of meat and a probable decrease in the supply of pork as the war continues. Furthermore, the available amount of brewer's yeast, which is the principal source of natural thiamine concentrates used therapeutically, is inadequate.

This problem was a real one in England and was solved satisfactorily by the increased consumption of peas, beans and other sprouts. The bread in current use for the last several years in England has been made from an 85 per cent extraction flour. Sydenstricker,* who recently described his experience in examining several thousand persons in all parts of the British Isles, stated that the incidence of vitamin B group deficiencies is extremely low. He added that many people were homeless and so closely touched by the war that their incentive to consume these rather unpalatable foods as a constant diet is greater than before.

It is of interest in this connection that one of the largest baking companies in the United States bought the Earle flotation process—a method of getting rid of the woody portion of the hull, which lends a bitter taste to cereal products. This company developed the process, adapted mills to its use, and attempted to market an almost 100 per cent whole-grain bread that was priced the same as the usual white loaf. In spite of a vigorous advertising campaign, the bread did not sell, although it was recommended by nutrition authorities. The experiment was given up except in a few communities that are used as a barometer for public buying tastes.

From a scientific standpoint it would seem that to extract and bleach flour, reducing the vitamin content to about 10 per cent of the whole grain and then fortify it with vitamin concentrates, is a wasteful procedure. On the other hand, if the public will not eat whole-grain bread, this may be the only way that a deficiency can be prevented. Bread also provides a useful vehicle for the addition of riboflavin to the diet.

The next most important factor in the vitamin B group is riboflavin. The requirement is approximately 2.7 mg. per day, or almost twice that of thiamine. The requirement is increased with activity, is in proportion to body weight, and is higher in lactation and pregnancy. Milk is the most important source; one pint supplies half the daily allowance. Meat is another important source, the usual serving supplying about one twelfth the daily allowance. The richest source is liver—4 ounces yields over 3 mg. Riboflavin is readily destroyed by light; it is soluble in water and therefore there are losses in cooking. Omitting

liver and brewer's yeast, which cannot be advocated for general use because of their limited supply, one comes again to the dried sprouts and vegetables such as peas, beans, spinach, cauliflower and peanuts. An increased consumption of these items, together with a pint of milk daily and the use of enriched bread, is the principal method of combating riboflavin deficiency. It should be emphasized that evaporated, powdered or skim milk can be substituted for fresh milk. It is important too that milk that stands in clear glass bottles in sunlight soon loses its riboflavin content.

Niacin, formerly called nicotinic acid, is the third important member of the vitamin B group. The daily allowance is ten times that of thiamine, or 18 mg. The outstanding source is liver, a 4-ounce portion containing somewhat more than the daily requirement. A serving of red meat will furnish from 7 to 10 mg. in each 4 ounces. Dried brewer's yeast in the amount of 1 ounce yields well over half the daily requirement. This vitamin is relatively stable to heat and there is little loss through cooking, although it is soluble in water. Here again, bran and whole-grain cereals are the most important available sources, although peanuts, potatoes and carrots must be included.

The members of the vitamin B group are often discussed together. Their high value in liver, brewer's yeast and meat, all of which are limited in supply, added to the fact that their best secondary source is whole-grain cereals and legumes, indicates a number of points in common. As already stated, there is reason to believe that the general public does not react favorably to dark whole-grain breads and cereals. Bakers are now launched on a program of enriching bread with these three factors. This may be the answer to the problem, although as the war continues it may prove necessary to return to peas, beans, dark bread and potatoes in far greater quantities than anyone would enjoy. The physician in his daily contact can do a great deal to encourage the use of these items. In order to increase the consumption of such carbohydrates fat is necessary: first, because carbohydrate is eaten more easily if it is greased with butter, margarine or drippings; and second, because fat acts as a thiamine sparer in the body.

It is of interest that tests have been conducted on bread to show the loss of vitamin in baking. The bottom crust may show a loss up to 34 per cent of the total thiamine, whereas the top crust may show a loss up to 13 per cent. Toasting a slice of bread destroys somewhere between 11 and 25 per cent of the total thiamine content, depending on the time of toasting and the thickness of the slice.

*Sydenstricker, V. P. An address given at the Medical College of Virginia, March, 1943.

A consideration of vitamin C shows little reason why there should be any extensive deficiency. Although transportation and preserving facilities limit the supply of the favorite sources, such as oranges, tomatoes and pineapple juice, an adequate intake of a variety of home-grown and preserved berries, fruits and vegetables will ensure sufficient vitamin C. Raw cabbage and potatoes are good sources. The average adult requires about 75 mg. The vitamin may be lost in cooking, both because it is soluble in water and because it is destroyed by oxidation.

Previous reference was made to the method of preparing potatoes. A 5-ounce serving of boiled or baked potato provides 25 mg. or about one third the daily requirement. When potatoes are fried, the ascorbic acid is cut in half. Mashed potatoes show a severe reduction in the vitamin C content, and whipped potatoes lose the entire amount.

Vitamin C has been shown to be present in sweat, as is thiamine. It is known that riboflavin is needed in proportion to body activity. It has been suggested that in addition to feeding salt tablets to defense workers in heavy industry or under conditions of increased heat, thiamine, riboflavin and ascorbic acid be added either in the form of concentrates or as further allowance of food.

The average adult has little possibility of developing a vitamin D deficiency except in conditions of unusually scant exposure to sunlight. This vitamin is synthesized by the body and there is excellent storage. In the winter months an adequate intake should be assured through the diet or by the routine ingestion of concentrates. The outstanding source is fish-liver oil. Some varieties contain as much as 40,000 international units per gram of extracted material. Others contain little or no vitamin D. Eggs are an excellent source, and liver is of definite value. The acuteness of the problem varies with the available supply of these items.

It has been demonstrated that irradiation gives cereals, meat, milk, eggs and various oils antirachitic properties. At the present time milk is the most suitable medium for irradiation and is available in most urban communities.

A point that is insufficiently emphasized with reference to the fat-soluble vitamins A and D is the ingestion of mineral oil. This substance is inert and is not absorbed. It has been conclusively shown that absorption of the fat-soluble vitamins does not take place to any extent from a mineral oil solution. There are many patients who use large amounts of mineral oil over long periods of time. The use of mineral oil salad dressing in reduction diets means the constant ingestion of mineral oil with the food and is of questionable advisability. If used, mineral oil is best taken at bedtime after digestion of the evening meal is completed, when it interferes as little as possible with the absorption of vitamins A and D.

CONCLUSIONS

Deficiency in the A group of vitamins can be avoided by the daily intake of green-leafy and yellow vegetables, and by the use of fortified oleomargarine when dairy products are unavailable in adequate amount.

Deficiency in the vitamin B group is best controlled by the use of fortified bread, and the physician should encourage the use of whole-grain bread and cereals. The constant use of toasted bread should be discouraged. The average adult should drink a pint of milk a day, or its equivalent in the form of evaporated or dried milk used in food.

Ascorbic acid deficiency can be prevented by the increased use of a varied diet containing fruits, berries and vegetables.

Deficiency in the vitamin D group can best be prevented by adequate exposure to sunlight and the ingestion of eggs and liver when available. If these foods are unavailable, irradiation of food may become more widespread. The routine use of fish-oil concentrates may be advisable under special conditions.

The physician should assume greater responsibility in advising patients with regard to diet. The war may serve the purpose of improving food habits and introduce improved methods of cooking and preserving food.

ERYTHROBLASTOSIS FETALIS OF THE ICTERUS GRAVIS TYPE

Report of Two Cases With Recovery

DONALD A. NICKERSON, M.D.,* AND ROBERT T. MOULTON, M.D.†

SALEM, MASSACHUSETTS

RECENTLY 2 babies showing erythroblastosis fetalis of the icterus gravis type were delivered at the Salem Hospital, and both recovered following a course of treatment instituted in accordance with the recently devised ideas concerning the etiology of this disease. These results seem of sufficient interest to warrant presentation of the cases.

The concept that the production of erythroblastosis fetalis is the result of isoimmunization of the mother to the Rh factor of the fetal erythrocyte, as first shown by Levine, Katzin and Burnham¹ following the demonstration of the existence of the Rh agglutininogen by Landsteiner and Wiener,² is now generally accepted, and both these cases fit into this already familiar pattern (Table 1). In accordance with this theory, therefore, the

*Cases under discussion

treatment of the newborn infant manifesting any one of the three clinical types of this syndrome should be directed toward maintaining a satisfactory level of hemoglobin and red cells within the circulation by the administration of Rh- blood of the proper group, so that the patient may be carried over the first crucial days by transfused blood until the anti-Rh substance within the circulation has been eliminated, the destruction of red cells by this phenomenon ended, and the immature cells allowed to mature normally and to assume the function of oxygen transport.

The mortality of erythroblastosis of the icterus gravis type has been generally accepted as relatively high, two publications giving the percentage as 80³ and 75 per cent.⁴ The recovery in the cases here presented, although perhaps not statistically significant, seems to be important and in accord with the changed concept of the fundamental physiology and indications for treatment of this disease. In retrospect, the results indicate that the

previously accepted therapy in such cases, which usually consisted of administering blood taken from the father or some member of the family of the same blood group as the infant and compatible by the usual technic of cross-matching set up at room temperature, has oftener than not been deleterious. The probability is that these donors were of the Rh+ type and that administration of their blood to the infant added insult to injury by supplying the blood stream with more cells to be agglutinated by the anti-Rh substance in the circulation.

It seems worth while to point out, although it has been previously stressed in a recent paper and editorial in the *Journal*,^{5, 6} that determination of the presence or absence of Rh agglutinogens in the blood of the donor should be done before transfusion of the infant showing evidence of erythroblastosis, or of the mother if indicated, and that this procedure ordinarily takes two hours according to the original technic of Landsteiner and Wiener.² With the use of human anti Rh serum the test can be read in a shorter period of time, usually within an hour.

Although we agree entirely with the suggestion that Rh typing should be routine before all transfusions, it also seems important that it be commonly understood that the agglutinin operating in this phenomenon has a very narrow range of temperature specificity, operating at body temperature (37.5°C.) but not at ordinary room temperature. This lack of knowledge of the zone of temperature specificity provides an explanation of why seemingly properly grouped transfusions between the father or other persons and the infant, before the knowledge of the Rh factor was available, proved to be harmful. Therefore, it seems reasonable that anyone showing evidences of the result of isoimmunization to the Rh factor, whether it be the infant or the mother, and—equally important—any Rh- patient receiving multiple blood transfusions, should be safeguarded by setting up the crossmatching at a temperature of 37.5° C. for at least thirty minutes, or longer if possible. In small hospitals where Rh determinations with known anti Rh serums are not routine because of several factors—including an insufficient number of typings to keep changing personnel familiar with the interpretation of the test,

*Assistant professor of pathology, Boston University School of Medicine pathologist, Salem Hospital

†Assistant in pediatrics, Harvard Medical School, pediatrician in-ch of Salem Hospital

which is a difficult procedure, the expense and the fairly rapid deterioration of the typing serum—crossmatching at 37.5°C. is easily carried out, and its interpretation by inexperienced persons is simple. It not only detects Rh incompatibility, and must be done to supplement Rh typing, but

suggesting Rh isoimmunization. Both parents were healthy, with no history of tuberculosis, diabetes or blood dyscrasias. The health of the mother during this pregnancy was uneventful.

The patient, an 8-pound, 15-ounce girl, was delivered normally after a 12-hour labor with Nembutal and scopolamine medication, supplemented during the second

FIGURE 1. Case I.

may also demonstrate agglutination due to blood subgroup incompatibilities, and furthermore can be done quickly in emergencies.

Another departure from the routine care in these 2 cases was to forbid nursing by the mother. This was done on the assumption that the anti-Rh substance might be transmitted through the breast milk, a possibility suggested by a recent case report.⁷ Since both these children were critically ill, it was thought unwise to jeopardize them further by allowing them to nurse.

A problem that is unanswerable at the present time but is highly pertinent is whether in this type of erythroblastosis permanent damage to the brain may result from the severe degree of kernicterus. This was probably present in each of these cases, since the icteric index at its peak was estimated at 600 and 700, respectively. All that can be said is that after four months there is no clinical evidence of damage to the central nervous system in either case.

CASE 1. F. I. H. This patient was the result of a second pregnancy, the first having resulted in a miscarriage

stage with nitrous oxide, oxygen and ether. Considerable meconium was passed during the delivery, and at birth the patient was covered with bright-yellow vernix caseosa. Because of this, and because the placenta was large and edematous, a specimen of the cord blood was sent to the laboratory to be examined for the Rh factor and was subsequently reported as positive. No anti-Rh substance could be demonstrated in the maternal blood 5 days after delivery.

Twelve hours after delivery, because of respiratory distress, a pediatric consultation was obtained. Physical examination at that time showed deep, golden-yellow jaundice of the skin and scleras, in addition to marked pallor and respiratory distress. The latter was thought to be due in part to the existing anemia as well as to a distended abdomen, caused mostly by a greatly enlarged liver that reached nearly to the iliac crest and by an enlarged spleen that was felt 3 fingerbreadths below the left costal margin. The kidneys were not palpable. The heart was not enlarged and its action was good, with no murmurs. The blood-cell count showed 2,880,000 erythrocytes, 58,000 nucleated cells, of which 51 per cent were red cells, and a hemoglobin of 12.6 gm. (Fig. 1).

Because of pallor and respiratory distress the patient was placed in an oxygen tent. A transfusion of 60 cc. of citrated Rh- blood was given at 12 hours of age, and was repeated at 36 hours because extensive edema of the skin, eyes, scalp, chest, legs and arms had developed

Following the second transfusion, the patient was removed from the oxygen tent, since the generalized edema had begun to subside, and the respirations and color had improved. The icteric index remained at 700. Urinalysis revealed a positive test for bile, a slight trace of albumin and some white and red cells in the sediment.

There was no vomiting of the formula. The nutrition was good. The reflexes were not hyperactive, and development seemed to be progressing normally.

At thirteen months of age, this child had six erupted deciduous teeth, all of which had a deep greenish appearance, presumably due to discoloration by bile pigment.

FIGURE 2. Case 2.

The nonprotein nitrogen was 91 mg. and 44 mg. per 100 cc. on successive examinations during convalescence. There was no albumin, bile or cells in the urine at discharge. The serum protein fell to 5.15 gm. per 100 cc. on the 5th day, and because the hemoglobin had dropped to its lowest value (11.6 gm.) and the red-cell count was 2,600,000, a third transfusion of 60 cc. of Rh- blood was given. The blood for all three transfusions was from the same donor. Just before discharge a fourth transfusion was given, using the same donor. The stools revealed negative guaiac tests and negative cultures for pathogenic organisms, and bile tests, at first positive, were negative at the time of discharge. A blood culture taken on the 4th day of life was reported positive for *Staphylococcus aureus*, with slight hemolysis. A repeat culture was not obtained because the external jugular veins were thrombosed, and on account of the later course, the organism was thought to have been a contaminant. A Hinton test on the cord blood was negative. The patient was not allowed to nurse and took well, with little vomiting, a modification of milk, water and Karo.

At discharge the skin still had a moderately jaundiced hue, but on subsequent check-up examination this had completely disappeared and the patient seemed well.

this serves as confirmatory evidence of the marked jaundice at birth.

CASE 2. M. I. M. This patient was the third baby in the family, the two other siblings being a healthy boy and girl aged six and three years, respectively. There was no history of familial disease, including blood dyscrasias. The mother had no complications during this pregnancy and after a short labor was delivered normally of an 8½-pound boy.

At delivery several purplish spots were scattered on the baby's skin. The temperature was 96°F. rectally. He was jaundiced. Vitamin K was given intramuscularly and a pediatric consultation was obtained.

Physical examination at that time revealed several scattered purplish, ecchymotic areas in the skin of the face, extremities and trunk, moderate icterus of the skin and scleras and moderate pallor of the lips and mucous membranes. The liver was palpable two fingerbreadths below the right costal margin, and the spleen was felt one fingerbreadth below the left costal margin. Examination of the blood showed a bleeding time of less than 2 minutes, an erythrocyte count of 3,900,000 and a total nucleated-cell count of 13,500, of which 31 per cent were red cells, and a hemoglobin of 16.5 gm. (Fig. 2). The icteric index

was 160. The direct blood bilirubin was 5.3 mg. per 100 cc., and the indirect 0.69 mg. There was no bleeding from the mouth or cord. Urinalysis showed no red cells, and a guaiac test on the meconium stools was negative. A blood culture was taken and was reported positive for *Staph. albus*, but a repeat blood culture made a day later was reported as negative. The maternal blood was Rh-, and the undiluted serum taken 3 days after delivery showed agglutination of one of three known Rh+, compatible bloods. Blood determinations were made daily, and on the 2nd day the nucleated-cell count rose to 26,000, with 41 per cent red cells. No more ecchymotic spots appeared on the skin, and those present gradually faded and disappeared (Fig. 2). The icteric index on the 5th day was 200. The nonprotein nitrogen was 50 mg. per 100 cc. The hemoglobin had fallen to 12 gm. and the red-cell count to 2,670,000. The urine contained large amounts of bile and the stools were deep green, presumably owing to biliverdin, with persistence of this coloration until the 10th day. Since on the 5th day respiratory embarrassment had set in, the patient was placed in an oxygen tent. Because the pallor had become more marked and the liver and spleen had increased in size, he was transfused with Rh- blood.

For the next 2 weeks the illness was severe, despite a second transfusion with Rh- blood on the 6th day. The donor was the mother of the patient in Case 1, her baby at that time being 2 months old. The icteric index increased to 600 and the hemoglobin fell to 10.5 gm. A third and a fourth transfusion with Rh- blood were given on the 8th and 10th days, and although the hemoglobin did not rise significantly and the icteric index remained at 600, the color improved. No edema of the tissues developed, and the serum protein value of the blood remained normal. The patient was removed from the oxygen tent since the respirations were no longer labored. There continued to be large amounts of bile in the urine, and the sediment showed granular casts and occasional white and red cells. The stools also contained large amounts of bile but were negative for blood, and cultures were negative for pathogenic organisms. By the 18th day the icteric index had fallen to 300 and there was improvement except for the pallor. On the 21st day, the hemoglobin was 11.2 gm., the red-cell count was 3,200,000, and because the white-cell count was rising and another blood culture was reported positive for *Staph. albus*,—a subsequent blood culture was reported negative,—a fifth transfusion was given, the blood from the original donor being used. Following this the baby again became more jaundiced. Efforts to obtain blood for a repeat icteric index were unsuccessful. The hemoglobin and erythrocyte count, which were 13.9 gm. and 4,190,000 following this transfusion, slowly dropped, but with a sixth and last transfusion the blood remained at a satisfactory level, the jaundice slowly disappeared, and the patient seemed well. During his entire stay in the hospital he was not allowed to nurse and was placed on a modification of cow's milk, water and Karo, digesting this well without vomiting.

Subsequent check-ups have shown that so far the reflexes are not hyperactive; the patient's development seems to be within normal limits, and his nutritional status is good.

At the age of eleven months this child had eight deciduous teeth, all of which had the same deep greenish discoloration as those seen in Case 1.

DISCUSSION

It seems certain that the important life-saving factor in the treatment of these infants was the use of Rh- blood of the proper group in the early days of life. This, then, places a serious responsibility on any hospital to maintain either a current supply of Rh- blood of the various groups or a file of Rh- donors. In this connection, it might be worth while to consider some plan whereby hospitals strategically located and having blood banks, possibly those that are subsidized by the federal government under the Office of Civilian Defense, would be utilized as depots for Rh- blood. The expense of doing Rh typing on all donors might be defrayed by some state agency interested in maternal and infant welfare, and these depots would be subject to call from any hospital in the vicinity to provide the proper type of blood.

In the second case presented, it is noteworthy that the other two siblings, who showed no evidence of erythroblastosis at birth or subsequently, were both Rh+, and one may speculate that at the time of those births the development of the anti-Rh substance in the mother did not reach a sufficiently high level to damage seriously the cells within the fetal circulation. It may also be true that owing to the previous immunization to the Rh factor, the mechanism was accelerated during the third pregnancy.

From our one and a half years of experience with the Rh factor as related to isoimmunization in pregnancy, we have been led to develop a routine on all prenatal patients according to which the Rh factor and blood group are determined early in the course of the pregnancy, preferably when blood is taken for the Hinton test. If the mother is Rh-, or if there is history of erythroblastosis, stillbirths or miscarriage that suggests that isoimmunization of pregnancy may have occurred, blood is taken from the husband and siblings for determination of the Rh factor and blood group. If the mother is Rh- and the father Rh+, routine determinations of the former's serum are done biweekly from the seventh month on to determine whether any demonstrable anti-Rh substance can be found. This is performed by mixing the unconcentrated serum with a 2 per cent suspension of ten Rh+ bloods of the same blood group. If the patient's serum agglutinates a majority of these bloods when incubated at 37.5°C., the finding is taken as significant, and if possible, a titer is determined on a dilution basis. Demonstration of a significant and a rising titer is sufficient evidence to warrant prompt delivery of the infant—provided the baby is viable—to prevent excessive flooding of the

fetal blood stream with anti-Rh substance and possible intrauterine or neonatal fetal death

The determination of the blood group serves two purposes. First, it is a matter of convenience to have the group known in the laboratory in the event that transfusions are needed in the treatment of any of the complications arising from the pregnancy. Second, since occasional cases of isoimmunization to factors other than Rh, such as the blood subgroups, have occurred and have been estimated to be responsible for 2 per cent of the cases of erythroblastosis fetalis, the determination of the blood group is important.

Demonstration of the anti Rh substance in the breast milk⁷ and the clinical impression gained by us that infants showing no evidence of erythroblastosis but whose mothers showed an anti-Rh factor in their blood stream did not do so well as expected have led us to the decision not to allow them to be breast fed until further experience has been gained in the study of a large series of cases.

SUMMARY

Two cases of erythroblastosis fetalis of the icterus gravis type resulting from isoimmunization to the Rh factor, with apparent complete recovery, have been presented. Salient facts relative to the immediate care of the baby, with emphasis on the understanding of the mechanism of isoimmunization, have been discussed.

CLINICAL NOTE

OTOGENOUS INFECTION DUE TO THE PROTEUS BACILLUS

REPORT OF A CASE

OLIVER A. LOTHROP, M.D.*

BOSTON

THE emphasis on the rarity and severity of otogenic infections by the proteus bacillus (*Proteus vulgaris*), expressed in a recent paper by Gerzog,¹ makes it worth while to report an additional case. According to Gerzog, previous to the case that he reports with recovery, only 9 cases had been reported in the literature since 1912. Only 1 patient survived, and this was the only case in which there was not a positive blood culture for this organism. Three patients, he states, died of meningitis and 5 of overwhelming bacteremia. The case to be reported is unique because the patient survived after having had a positive blood culture.

CASE REPORT

C K., a private patient of Dr Warren W Marston, was a 25-year-old man who had had a right chronic suppurative otitis media, with a foul odor, for most of his life but had otherwise been well. The previous year

he had had a tonsillectomy, which did not change the ear condition.

On April 2, 1940, the patient began to have headache on the right side. This persisted until April 7, when he vomited all day and had a chill at night. He was sent to the Newton Hospital. On admission the temperature was 100.2°F rising that evening to 102.8°, and the white cell count was 13,600 with 92 per cent neutrophils. At the first operation, performed by Dr Donald H MacDonaid on April 9, the mastoid was opened and was found solidified with ivorylike sclerosis, a culture yielded unidentified gram negative bacilli and *P. vulgaris*. The lateral sinus at that time was not uncovered and the jugular vein was not ligated. For 3 days the patient was given large doses of sulfapyridine, and this treatment was followed by a temporary subsidence of the temperature.

On April 14, the temperature rose to 103.3°F and the pulse to 120, a blood culture was reported negative. On the following morning the patient had a chill and that afternoon the temperature rose to 103.1°F, the white-cell count being 10,700. At that time I saw the patient in consultation. Sinus phlebitis was believed to be the diagnosis, and further operation was advised. A lumbar puncture was performed on the same day, and the dynamics disclosed that the right jugular vein was blocked. On April 16 the jugular vein was ligated, the mastoid reopened and the sigmoid sinus uncovered. The mastoid antrum was reamed larger, and the dura uncovered. A liquid foul smelling pus kept accumulating in the antrum. Following incision of the membranous wall of the sigmoid sinus, there was an escape of foul pus. A culture from this showed *P. vulgaris*, and the same foul odor was present in the culture tube. Since it was believed that the abscess was walled off within the sigmoid sinus, no further exploration was attempted. The mastoid cavity was filled with iodoform gauze, and the mastoid wound was approximated to the drain. The patient again was put on large doses of sulfapyridine.

*Chief Otolaryngological Service, Newton Hospital.

For the next few days, the patient ran a spiking temperature, which rose as high as 104.8°F. On April 18, the white-cell count was 45,500, with 93 per cent neutrophils. Because of continued fever, with occasional chills, and three successive blood cultures that were positive for *P. vulgaris*, it was believed that the infection must be coming from the torcular end of the right lateral sinus. Hence, on April 22 the patient was again operated on, the lateral sinus being uncovered all the way around to the torcular by removing the overlying bone of the skull. The lateral sinus itself was then opened and found filled with grayish pus all the way around to the vicinity of the torcular. Owing to the danger of pushing the last walling-off into the venous circulation on the left side, further exploration was terminated and iodoform strips were laid in the opened lateral sinus. The incision was approximated with interrupted silk sutures. Following this operation there were no more chills, and within a few days the temperature and white-cell count were normal. Subsequent blood cultures were negative, and the patient made a slow and uninterrupted convalescence.

A year later a successful radical mastoid operation aided by skin grafting was performed, which eliminated discharge and odor.

Since Gerzog's paper was published, 2 more deaths have been reported. These additional fatal cases emphasize the grave pathogenicity of the proteus organism. Even the new chemotherapeutic drugs seem to have failed to stem its serious ravages.

In 1940, Neter and Chait,² of Buffalo, reported the case of a fourteen-year-old girl who was oper-

ated on for chronic mastoiditis due to an infection with *P. vulgaris*. This case was complicated—by meningitis as well as by septicemia. In spite of surgery and chemotherapy the patient died on the eighth day. In 1943, Adler and Klapper,³ of New Orleans, reported the case of a twenty-eight-year-old man with proteus infection of the mastoid. The symptoms were high fever, chills and vomiting. There was a positive blood culture for *P. vulgaris*, but no meningitis. Despite the use of sulfathiazole, sulfadiazine and finally sulfapyridine, the patient died on the twenty-second post-operative day. Autopsy revealed thrombosis of the lateral sinus, extradural abscess and a pulmonary abscess in each lung.

SUMMARY

A successfully treated case of otogenic infection due to *Proteus vulgaris* and complicated by septicemia is reported. The pertinent recent literature is reviewed.

MEDICAL PROGRESS

THE TREATMENT OF THERMAL BURNS*

II. Recent Developments

CHARLES C. LUND, M.D.†

BOSTON

THIS review is intended to summarize recent developments, and supplements the general outline prepared by the National Research Council.¹ The important articles of 1943 on the fundamental concepts of burns that should be read by every physician are those by Whipple,² Trueta,³ Glenn, Gilbert and Drinker,⁴ Barnes and Trueta⁵ and, in spite of the fact that it concerns wounds rather than burns, that by Orr.⁶ The best short

description of the most significant phases of local and general treatment of burns may be found in Volume V of *Military Surgical Manuals*.⁷ Harkins's⁸ book may be consulted for a complete résumé of the history of burns.

DETERMINATION OF DEGREE OF INVOLVEMENT OF THERMAL BURNS

The determination of the depth of a burn is of the greatest importance, because in the past many authors have claimed that by using a given treatment a burn was maintained as a burn with destruction of only part of the epithelial cells (second degree), whereas if any other treatment had been used the burn would have been one destroying all the epithelial cells (third degree). Usually

*The articles in the medical-progress series of 1941 have been published in book form (*Medical Progress Annual*, Volume III, 678 pp. Springfield, Illinois: Charles C. Thomas, 1942. \$5.00).

†From the Burn Assignment of the Surgical Services of the Boston City Hospital and the Department of Surgery, Harvard Medical School.

The investigations reported in this publication were made under a contract between the Committee on Medical Research, Office of Scientific Research and Development, and Harvard University.

†Assistant professor of surgery, Harvard Medical School; visiting surgeon, Boston City Hospital; member, Subcommittee on Burns, Division of Medical Sciences, National Research Council.

such claims were made without any detailed description of the differentiation of the various types of burns.

A fresh burn with erythema, a moist surface, multiple broken or unbroken blisters, moderate edema of the skin and no subcutaneous edema is probably a part-thickness burn. A fresh burn with a dry, leathery, dead white or brownish appearance is probably a full-thickness burn. But there are areas in many cases where no clear cut diagnosis can be made early.⁸⁻¹⁰ *The time when classification of the depth of burns should be made is after healing has occurred or successful grafting has been done.*¹⁰ The recognition of this fact is important because the elimination of unwarranted claims, based on impossible distinctions, from serious consideration is definitely a step toward scientific thinking.

TREATMENT OF MINOR BURNS

In small-area burns systemic effects such as shock can usually be disregarded. The important considerations in these cases are rapid healing, prevention of infection, minimizing of pain and reduction of disability during and after treatment.

Rate of Healing

Cannon and Cope¹¹ and Hirshfeld, Pilling and Maun¹² have shown that skin-graft donor sites, which are somewhat but not perfectly analogous to burns, heal much more slowly if escharotics such as tannic acid or triple dye are used than if boric acid ointment is employed. Taylor¹³ has demonstrated the same thing with second-degree burns. Clowes and his associates¹⁰ have shown that tannic acid-silver nitrate treatment delays the healing of burns. Their evidence in regard to triple dye is not so clear cut, but points in the same direction. They also found that there is a regional difference in the time of healing of burns treated by any given method, with the face healing more rapidly and the back more slowly after part-thickness burns than any other areas of the body.

Prevention of Infection

In spite of all the claims that have been made, there is no known method of keeping any burn sterile. A part-thickness burn will harbor pathogenic organisms in most cases, even when the treatment is carried out by groups specially equipped for the study of these cases.¹⁴ Cope¹⁵ has recently shown, however, that if a burn is dressed with a simple ointment without cleaning it, but with a bulky pressure dressing *that is left alone*, and the patient is given sulfadiazine systemically, the infection is relatively harmless. Infection has been found under the plaster casts of Levenson

and Lund¹⁶ and of Logie,¹⁷ but serious infection in minor cases has not been reported with this treatment. Sulfamilmide and related compounds applied locally have given good results in many cases,¹⁸ but their application in powder form may result in dangerously high levels in the blood.¹⁷ Their local use has been bacteriologically disappointing.¹¹⁻¹⁷ Intercurrent infection of burns at the time of dressings may be a much more serious matter than has until recently been recognized.¹⁹ In addition to careful aseptic technique at the time of dressing, Allen and Koch,²⁰ Siler and Reid²¹ Owens,²² Cope,¹⁵ Gurd, et al.,⁹ Clowes,¹⁰ Trueta,³ McClure²³ and Levenson¹⁶ all stress the value of infrequent dressings as another factor in reducing the danger of infection, even though there are minor differences in their methods. Clark and his associates¹⁹ have studied the use of penicillin and of propamidine as agents to control streptococcal and staphylococcal infections, with promising bacteriologic results. Their method, however, entailed two dressings a day, and their cases healed no more rapidly than have similar cases treated by more widely available methods. On the other hand, as penicillin becomes available in larger quantities and can be used in larger doses, it may become an extremely valuable therapeutic agent.

Prevention of Pain

The greatest cause of pain in burns is caused by friction under a dressing or by the changing of dressings. A second-degree burn should be and can be kept painless by a properly applied pressure dressing or cast from the time of first dressing until it is healed.

Reduction of Disability

Glenn, Gilbert and Drinker,⁴ have shown that the subcutaneous swelling of burns of the paws can be safely prevented in dogs by the application of plaster. Levenson and Lund¹⁶ applied this method in burned hands, and believe that the motion in burned fingers returns more rapidly in normal after this treatment than it does in cases treated by methods that do not prevent swelling. McClure,²³ in an excellent paper on the treatment of ambulatory burns, shows the value of a simple ointment dressing infrequently changed in reducing the amount of time lost from employment.

TREATMENT OF MAJOR BURNS

When large areas of skin are burned, the situation is complicated by the systemic effects of the burn. These are, according to Wilson, MacGregor and Stewart,²⁴ in order of occurrence, shock,

toxemia and infection. The indefinite term "toxemia" is avoided in this review, and the various manifestations frequently discussed under it are considered separately. Shock in burns is usually caused in large part by a great reduction in the circulating blood volume, which is generally accompanied by hemoconcentration. Other complications of severe burns are, in the usual order of occurrence, hemolysis of red cells and hemoglobinuria, azotemia, azoturia, hypoproteinemia and anemia. Infection is manifested by the usual systemic signs of infection and sometimes by anemia, hypoproteinemia and weight loss.

Shock

The preventive or therapeutic treatment of shock must precede or accompany surface treatment. To treat it intelligently, the hemoglobin level or the hematocrit must be determined at the earliest moment, since changes (concentration of red cells) frequently occur long before changes in the pulse or blood pressure and may therefore give warning of impending serious collapse.

Treatment with blood plasma is by far the most valuable procedure. Saline solution, saline and glucose solution or distilled water and glucose should be given cautiously in the first twenty-four hours^{25, 26}—not for the treatment of shock but to make up calculated losses of electrolyte occurring as a result of vomiting and exposure and from the collection of extracellular fluid in the burned area. Plasma was given by Cope and Rhineland²⁷ in doses of approximately 500 cc. diluted with an equal amount of saline solution to each 10 per cent of surface area burned. Others²⁸⁻³⁰ have used twice this quantity of undiluted plasma. In any case, however, repeated hematocrit determinations should be made to adjust the dosage. If hemoconcentration is present, about 500 cc. of undiluted plasma is suggested for each ten points the hemoglobin level is above 105.⁷ That the treatment of shock with plasma should be started *early*, as stressed by Elkinton,³⁰ has been confirmed by Taylor et al.²⁹

Cortin and other suprarenal substances have been extensively used in the treatment of burn shock.^{9, 31} Cope and Rhineland²⁷ did not find cortin useful in 2 cases. Rhoads and Lee³² now state that further experimentation has made it impossible for them to evaluate cortin because of the inconsistent reactions they have obtained. Morphine has had a traditional and important place in the prevention and treatment of burn shock, and many authors have recommended large doses. In the unusual cases from the Coconut Grove disaster, it was found that large doses of morphine were harmful.³³ Even in the absence of

associated pulmonary lesions, a more cautious use of this powerful drug should be made than has frequently been advised in the past. Tissue anoxia is a large factor in the harm from shock. Since morphine sedation may increase the degree of anoxia, it may be harmful.²⁰ Anesthesia was used by Clowes¹⁰ in the early part of his study, as it has frequently been in the past by other workers, to permit more careful cleaning of the surface. Again, there is serious question of its safety because of the danger of increasing the anoxia. During their more recent cases, Clowes and his associates have omitted the anesthesia. As seen below in the section concerned with surface treatment, the types of treatment in which anesthesia is necessary are no longer those of choice. Although there are no new observations reported on the subject to date, the caution of Blalock³⁴ regarding the danger of overheating in shock should be taken seriously. The patient with a large burned area and a bulky dressing may have been deprived of more than half his normal ability to lose heat by perspiration.

Other Complications

Hemoglobinemia and hemoglobinuria have been known for many years to occur in occasional cases of very extensive deep burns. Shen, Ham and Fleming³⁵ have recently studied this condition and have concluded, as has Drinker³⁶ from animal experiments, that the hemoglobin is derived from blood cells lysed by burning within the capillaries and other vessels of the burned skin and subcutaneous tissues. In occasional cases the excretion of hemoglobin is so rapid that damage arises from the passage of hemoglobin and from its precipitation in the kidney tubules in the usually acid urine. Repeated 4-gm. doses of alkalis (sodium bicarbonate or sodium lactate) are therefore indicated in such cases. Methods of calculating the doses are described by Levenson, Lund and Taylor.²⁹

The development of hypoproteinemia a few days after a severe burn has been recognized for years. Whole-blood transfusion was the only treatment for this condition until recently, when plasma transfusion became available. Neither of these is effective for this complication unless exceedingly large doses are given. Taylor and his associates^{37, 38} have shown that the use of plasma or whole blood for hypoproteinemia is impractical because of the enormous amounts that are needed to overcome the protein deficit. They found that in extreme cases 300 gm. or more of protein or the equivalent of this amount in amino acids must be given daily in addition to an ordinary high-protein

diet. To accomplish this result with plasma would require more than 4000 cc. per day.

In the first few days after a burn, a marked azotemia and azoturia^{37, 38} may occur. Cope and his co-workers³⁹ did not find that this was severe in degree and noted little relation to the severity of the burn. Only one of their cases, however, had an area of more than 10 per cent of full-thickness skin loss. Taylor,³⁸ working with a much larger number of more severely burned patients, found a direct relation to the severity of the burn. This nitrogen is found both in the plasma and in the urine largely as undetermined nitrogen. There is no specific treatment for this condition, but early establishment of adequate urine output is indicated.

Anemia has always been recognized as a complication of severe burns. No treatment save whole-blood transfusion has been effective. In some cases, twenty-five or more transfusions may be needed during a period of two to six months.^{27, 37}

Cope, Nathanson and their associates³⁹ also studied the 17-ketosteroid excretion of burned patients and found that this was depressed in inverse relation to the growth of abnormal amounts of hair on the faces and extremities of female patients. There was also cessation of catamenia for several months.

Infection

In his report of the results of work done by a large number of clinics investigating wounds and burns under the auspices of the National Research Council, Meleney⁴⁰ states, "The infection rate in burns is very disturbing, particularly in deep second and third degree cases." His statistics have not been studied in all useful aspects, but they show in general that large or deep burns have three times the incidence of serious infection that small or superficial burns have. It is difficult to estimate just what this means, because the term "serious infection" is not defined. Clowes¹⁰ showed that all patients with full-thickness burns covering 10 per cent and over of the total surface area were infected with a mixture of organisms and were seriously ill irrespective of which one of three original surface treatments was used. His treatments were tannic acid-silver nitrate, triple dye and vaseline gauze. He also showed that part-thickness burns irrespective of the surface area involved or of the treatment had no serious infection. Full-thickness burns covering up to 10 per cent of the total surface area had numerous infections, but they were relatively easy to control.

As shown by Lyons⁴¹ and Meleney,⁴⁰ cultures from burns usually show mixed infections.

Staphylococci are almost always present in the cultures, and frequently streptococci, colon bacilli, *Pseudomonas pyocyaneus* and various anaerobes are present. No antiseptics, new or old, can control these infections for a long time, but they may reduce the toxicity and invasiveness of some of the organisms. In some cases they may improve the degree of infection enough to allow earlier skin grafting.

Surface Treatment

As indicated in the general outline of the National Research Council,¹ a strong trend away from escharotic treatments prevailed in 1941 and 1942 in the United States and Great Britain. In 1943 this trend has continued and has become more marked.

Tannic acid. Evidence that tannic acid may be toxic to the liver has been increased this year by the paper of Erb, Morgan and Farmer,⁴² who studied autopsies on 61 cases. They found evidence of central necrosis of the liver in 25 of 41 patients dying after tanning, whereas no case of liver necrosis occurred in the untanned patients who died. On the other hand, they point out many real benefits that have arisen from tannic acid treatment. In a clinical paper published in the same month, Farmer⁴³ still advocated this treatment. One of the patients dying of burns in the Boston City Hospital in 1942 who was treated with tannic acid and silver nitrate had central necrosis of the liver at autopsy, but there was also so much pulmonary injury that the liver injury was not the only factor in the death. The British forces in the Middle East had such poor results with tannic acid treatment that they gave it up early in 1942.¹⁷ Their difficulty, however, was infection in third-degree burns. If the alternative to tannic acid treatment were the type of ointment dressings and care given to the average case so treated a few years ago, there would be no doubt that tannic acid, in spite of the real danger of poisoning, would be the better of the two treatments. But if ointment is used with pressure dressings or casts, and if proper attention is paid to all the phases of the patient's condition, the evidence is strong that ointments are better. Clowes, Lund and Levenson¹⁰ have presented comparative data on this and two other forms of treatment that suggest that in their series vaseline gauze or triple dye was somewhat safer than tannic acid and silver nitrate.

Triple dye. Triple dye escharotic treatment has numerous strong advocates.^{44, 45} In comparison with tannic acid, an eschar is formed more slowly and usually remains slightly more flexible. In spite of the fact that the dyes are antiseptics, in-

fection always extends under these eschars when those of full-thickness burns are separating. In fact, Aldrich⁴⁴ asserts that such infected areas should be unroofed and redyed daily. This treatment was used extensively at the Boston City Hospital from 1935 to 1942 and was used on a large number of the cases from the Cocoanut Grove disaster.¹⁰ There is no report of toxic damage to the liver as a result of the treatment, but some burns may not heal so rapidly as do those with other forms of treatment.¹⁰

Sulfonamide applications. Sulfanilamide, sulfathiazole, sulfadiazine and sulfaguanidine have all been used in burns in various manners. There are sprays, such as Pickrell's,^{46,47} preformed membranes, such as those of Andrus,⁴⁸ Skinner¹⁰ and Clark,⁵⁰ and ointments, such as those used by Dragstedt¹⁵ and by Gurd.⁹ Sulfonamides have also been dusted on the burn and covered with an ointment. There are reports, however, of very high blood levels with toxic manifestations when the powdered drug has been used in this manner in large-area cases.¹⁷ Gurd⁹ studied the absorption of so-called "micro" crystals of sulfathiazole from a creamy ointment in his cases, and found that high blood levels did not occur in them in spite of high tissue levels on the burn surface.

Propamidine. Propamidine is 4:4' diamidino diphenoxypyropane dihydrochloride, which is an aromatic diamidine possessing well-marked activity against various protozoal organisms as well as against the gram-positive cocci.⁵¹ It is of interest because its action is not inhibited by para-aminobenzoic acid as is that of the sulfonamides. As yet there are no published American studies on the use of this material, but there are several British reports.^{19, 52-54} To date it has been used mostly on minor burns, and the reports indicate some antibacterial activity. Healing takes place about as rapidly as with other nonescharotic treatments.

Penicillin. The only British report¹⁹ on penicillin showed a favorable antibacterial action. The single American paper⁴¹ was rather guarded in its claims because it was given to patients at the same time that sulfadiazine was being used.

Pressure dressings. Bulky dressings with more or less pressure are being used in major burns by Allen and Koch,²⁰ Siler and Reid,²¹ Owens,²² Cope,¹⁵ Gurd⁹ and Clowes.¹⁰ Five of the six papers report cleaning of the wound before dressing it, but Cope did aseptic dressings without preliminary cleaning. In three reports, boric acid ointment^{15, 20, 21} was used under the dressing, and in one each, sterile saline solution,²² sulfathiazole ointment⁹ and sterile vaseline.¹⁰ Sulfadiazine was usually, but not always, given by mouth.

Plaster casts. Trueta,³ Barnes,⁵⁵ Roulston,⁵⁶ Cohen,⁵⁷ Logic¹⁷ and Levenson and Lund¹⁶ have all used plaster casts as a primary treatment in major burns. This treatment is not new, having been previously recommended by Zeno⁵⁸ and Afonso.⁵⁹ The important experiments of Glenn, Gilbert and Drinker⁴ and of Barnes and Trueta,³ however, have placed this treatment on a firm scientific basis and have shown that the cast should fit closely and should be closed over the end of the extremity. Its most essential feature is that it prevents swelling and decreases the abnormally high flow of lymph that occurs in a limb that is not protected by a cast. Under these circumstances, the bacteria present on the surface become relatively harmless. Logic¹⁷ says: "The three burns I was able to culture at the end of a fortnight, when the plaster of Paris was removed, grew hemolytic streptococci, and this occurred despite the usual course of prophylactic sulfonamide by mouth. But neither the patient nor the burn seemed to mind."

Secondary treatment. Any secondary treatment that entails frequent changes of dressing may expose the patient to the danger of introduction of new strains of pathogenic organisms. Owens²² leaves his primary treatment in place for three weeks or more, and when he removes it from deep burns he wipes off the pus and debris and immediately covers the granulations with a Thiersch skin graft. In this way he avoids unnecessary contamination.

The only other relatively new secondary treatments concern the employment of new chemicals, such as propamidine and penicillin, as described above, and the use of the Bunyan⁶⁰ bag for saline irrigation. Clowes¹⁰ found the bag useful in the few cases in which it was tried, whereas Cannon⁶¹ did not. The trend of opinion is that infrequent dressings, simple applications and careful asepsis are the most important considerations in the surface care of burns during the time when areas of third-degree burn are being prepared for grafting.

SKIN GRAFTING

It is easy to say that early grafting should be done, but it is sometimes extremely difficult to get the patient into condition for such grafting. Rampant infection, anemia, hypoproteinemia and possibly vitamin deficiencies⁸ all prevent technically perfect grafts from taking. Clowes¹⁰ has shown that infection per se does not prevent the success of a graft if the nutritional status of the patient is in fair balance.

The technic of skin grafting is unchanged. More emphasis is placed on early grafting to avoid the thick scars that follow late grafts. Split-

thickness grafts, sewed into place under slight tension, have almost entirely displaced Reverdin grafts in the best clinics,^{7, 81} but there are a few desperately sick patients that can be grafted only by the Reverdin method.¹⁰ The Padgett dermatome is widely used to cut split grafts. Cannon⁶¹ successfully used an interesting type of abdominal flap very early in a case with total destruction of the skin of the dorsum of the hand and partial sloughing of the extensor tendons. In addition to Cannon's paper, the article on grafting in Volume V of *Military Surgical Manuals*⁸ is extremely useful.

ing to the lower lobe." In other words, this child had an atelectatic lower lobe without infection in the bronchi or in the pleural fluid surrounding the atelectatic lobe, and neither could be true if the atelectasis were secondary to intrinsic bronchial obstruction or infection, as productive bronchiectasis and empyema would surely have followed. Also, the collapsed lobe was in the midchest rather than in the posterior gutter, where intrinsically collapsed lower lobes are found. The final clue to the reason for compression atelectasis is given in the x-ray demonstration of a well-defined mass in the posterior portion of the right chest.

The differential diagnosis on admission of the patient to this hospital, at the age of six and a half, after an illness of at least six years, should furnish the answer to three simple questions: What kind of tumor was it? Where had it originated? and Why?

By exclusion, it was not a tuberculous abscess because of two negative tuberculin tests and no signs of tuberculosis elsewhere in the body. It was not a pyogenic abscess because all indications of systemic reaction to pyogenic infection were lacking. It was not a lesion of the adrenal gland because the blood pressure was normal and it had grown too large.

This lesion had grown in such a location and tissue plane that it pushed the liver and duodenum forward and to the left, the hepatic flexure downward and to the left and the right kidney downward and backward and that it penetrated the diaphragm and collapsed the lower right lung, displacing it forward and to the left. In other words, it lay in the right paravertebral gutter and in the retroperitoneal tissue plane.

The retroperitoneal tumors in this location that must be considered in this case include only the group derived from tissue elements of the embryonal urogenital ridge. They are carcinoma and hypernephroma of the kidney, embryoma, Wilms's tumor, ganglioneuroma and teratoma. Except for passive hydronephrosis from positional displacement, the data of the case afford no evidence of renal disease and establish the fact that the tumor had existed for five and a half years. For these two reasons carcinoma and hypernephroma of the kidney are untenable diagnoses.

Every feature of this lesion classifies it as an embryoma, using the term in its strict dictionary meaning of a tumor derived from embryonal structures. I should perhaps refresh your memory that the embryonal structures are those which exist during the embryonal stage, and that this stage refers to the product of conception from the end of the second to the beginning of the eighth week of its intrauterine existence. Such tumors tend to grow to enormous size, to show calcification with-

in their substance, as a result of hemorrhage infection or necrosis, and to usurp by displacement and pressure rather than invasion the space allotted to normal organs. Derived from embryonal tissue, they possess the abortive but nevertheless potential growth capacities of the three primordial germ layers, and express the attempt to produce organ facsimiles of their host with variable completeness of frustration and confusion. Any tissue may be represented except true genital cells. Ganglion cells are frequently numerous, and if nonmedullated, irregularly coiled masses of nerve fibers predominate, the tumor is given a sub-name of ganglioneuroma. If renal and striated muscle cells fill the pathologist's microscopic section and the host, usually a child, has died within two years from metastasis of a carcinoma developing in some point of the tumor epithelium, it is called a Wilms's tumor. This is not, therefore, a Wilms's tumor. If the specimen includes developmental products of independent or aberrant germ cells recognizable as rudimentary organ masses, it is called a teratoid tumor or teratoma. It would be futile for me to try to classify this tumor beyond the term *embryoma*.

If analogy from experiments on parthenogenesis in frog ova, asymmetry reversal in *Patiria* blastulae, polyembryony in nine-banded Armadillo ova, and deductions from human instances of situs inversus, twinning and monstrosity are correct, tumors of this sort result from temporary disruption of normal intrauterine environmental factors at a critical period of development, whereby a mass of embryonal cells is separated from its fellows, and later produces an embryoma through parasitic growth.

DR. EDWARD B. BENEDICT: How do you explain the lesion involving the chest as well as the abdomen?

DR. ADAMS: I¹ reviewed this subject six years ago and I have not had a chance to look into it since. Mall,² MacCallum,³ Newman⁴ and notably Bosaeus⁵ described tumors such as this, and in the lower animals those arising from the urogenital ridge often occupy both pleural and abdominal cavities. I think this tumor has expanded through the diaphragm.

DR. BENJAMIN CASTLEMAN: Do you want to go any farther and say whether you think the tumor is benign or malignant?

DR. ADAMS: I have gone quite far already. If it is an embryoma in the strict sense of the word or, to specify further, if it is a teratoma, it is a benign lesion; but having the three primordial germ layers originally present, it could become malignant. MacCallum had a patient with true teratoma who finally died of metastases, and it

was found post mortem that the metastasis was from a carcinoma that had developed within the teratoma and that blood-vessel emboli were the source of the metastatic growth.

DR. CASTLEMAN: Such a condition is occasion-

abdomen primarily, we should also have been in trouble.

We waited forty days and decided ahead of time to go into both places. An incision was made between the scapula and the spine, down

FIGURE 1. Roentgenogram of Chest and Abdomen.

The upper arrow points to the lipiodol injected into the mass within the chest; the lower arrow, to areas of calcification within the area of radiolucence.

ally found in the ovary and in teratomas, that is, the part that becomes malignant is usually the epithelial element.

DR. ADAMS: This tumor had not been malignant during the six known years of growth. I do not know how I could say whether eventually it showed malignancy in some one of its parts.

DR. RICHARD H. SWEET: I should like to say that it took us forty days to come to the conclusion that Dr. Adams has reached in a few minutes. I must confess that our approach was not so philosophic and certainly not so poetic; in fact it was very practical because I wanted to know where to make my incision. It turned out that if we had gone into the chest primarily, we should have been in trouble; if we had gone into the

through the ninth interspace, across the costal margin into the right rectus sheath and down the rectus sheath to a point below the level of the umbilicus. The abdominal portion of the incision was opened first, and the tumor was found lying retroperitoneally between the kidney and the liver. On incising overlying peritoneum, it was soon discovered that the tumor passed directly through the diaphragm. The incision was therefore enlarged by dividing the eighth, seventh and sixth ribs posteriorly. The attachments of the tumor to the diaphragm were then divided and the abdominal portion was freed. It was most adherent to the sides of the vertebrae, at which point great care had to be exerted to avoid the vena cava. There were several large branches of the intercostal ar-

teries going directly onto the tumor at this point. After freeing the abdominal portion and dividing the rim of diaphragm that surrounded the tumor, the dissection was carried up within the chest where the tumor was found to be cystic. That is what had been tapped all these years. The largest portion of the tumor lay within the chest, and it was adherent to the parietal pleura, to the under-surface of the right lower lobe of the lung and to the pericardium. All adhesions were separated by blunt dissection without much difficulty. The tumor was finally removed in one large dumbbell-shaped mass.

CLINICAL DIAGNOSES

Tumor of chest (? cyst).
Dermoid cyst of abdomen.

DR. ADAMS'S DIAGNOSIS

Embryoma of retroperitoneal space, with extension through the diaphragm into the chest.

ANATOMICAL DIAGNOSIS

Dermoid cyst of chest, abdomen, retroperitoneal space and postero-inferior mediastinum.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: This tumor was filled with large amounts of sebaceous material; the wall was in places hard, fibrous and cartilaginous, and in other places calcified and ossified. It had all the characteristics of what we ordinarily call a dermoid cyst or that type of embryonal tumor that is made up for the most part of skin, sebaceous glands, hair follicles, calcium, cartilage and bone, and that fits in with Dr. Adams's diagnosis of embryonal or teratoid tumor.

The patient went back to Nebraska and is now well, four months after discharge.

CASE 29482

PRESENTATION OF CASE

A forty-one-year-old unmarried woman, a factory worker, entered the hospital because of pain and marked swelling in the left foot.

At the age of seven years the patient developed multiple bony swellings usually preceded by "hot and searing" pain. From about the age of fourteen her general growth and physical development appeared considerably retarded. Slow growth was also noticeable in the various bony swellings to such an extent that the onset of a tumor in her finger, which at the time of entry markedly interfered with her activity, could not be remembered. The swellings, however, were always preceded by the sensation already described. Six years before entry she noticed weakness in the left ankle. This was followed in a few weeks by the hot-and-searing sensation. A small fusiform swelling appeared on the distal part of the tibia, which progressed slowly. One year prior to admission the swelling in the ankle became quite large and painful. She was admitted to a community hospital where x-ray films were taken and the tumor was removed. About six months later the swelling in the left ankle recurred and became more painful.

Her mother was said to have had "arthritis" in one knee. Five brothers and one sister were well developed and of normal height.

Physical examination showed a dwarfish woman, who was 52 inches tall. There was a left total curve of the spine. The right scapula was lower and more prominent than the left. The spinal motions were "good." There was considerable flaring of the right costochondral margin, and atrophy of both pectoral muscles. Multiple small nodules were present on the distal ends of the right radius, ulna and proximal phalanx of the thumb. Similar nodules were present in the middle phalanx of the left middle finger and in all the phalanges of the fifth finger. There was only minimal motion of the interphalangeal and the metacarpophalangeal joints but full range of motion in the other joints. The right anterior superior spine and the iliac crest were much more prominent than those on the left. A nodule was palpable in the right iliac crest. On the medial aspect of the left ankle, extending anteriorly and over the lateral side, with considerable gross deformity of the foot, was a mass about 10 cm. in diameter, which was hard and covered with tensely stretched, warm, slightly reddened skin. There was no motion in the left ankle. There were multiple small nodules on the left tibia and the lower aspect of the left femur, the phalanges of the second and third toes, and the adjacent metatarsal bones. The right lower extremity showed posterior bowing of the fibula, with multiple small palpable "bony masses" on the proximal aspect of the tibia and a small one on the distal portion of the femoral shaft. There were many small nodules on the phalanges of all the

toes of the right foot. The ankle motion was normal.

The blood pressure was 120 systolic, 50 diastolic. The temperature was 98.6°F., the pulse 86, and the respirations 20.

Examination of the blood showed a red-cell count of 3,860,000, with 70 per cent hemoglobin.

merous areas of calcification. The lower end of the left tibia was irregularly destroyed, and there was a grapefruit-sized soft-tissue tumor with areas of calcification and bone fragments within it that replaced the os calcis and talus (Fig. 1). There were numerous cyst-like expanding lesions in the bones of the hands (Fig. 2) A lateral film

FIGURE 1. Roentgenogram of Left Ankle.

The white-cell count was 5500. A blood Hinton test was negative. The urine sediment contained 10 epithelial cells per high-power field, and the urine gave a ++ Sulkowitch test for calcium. The sedimentation rates were 2, 12, 23 and 32 mm., respectively, at fifteen-minute intervals. The blood calcium was 10.5 mg., the phosphorus 3.8 mg., and the phosphatase 6.4 Bodansky units per 100 cc.

X-ray examination showed the bones of the lower legs to be shorter than normal. At the ends they were irregularly widened with multiple cyst-like expanding lesions. The bone structure at the ends of bones was irregular, and there were nu-

merous areas of calcification. The lower end of the left tibia was irregularly destroyed, and there was a grapefruit-sized soft-tissue tumor with areas of calcification and bone fragments within it that replaced the os calcis and talus (Fig. 1). There were numerous cyst-like expanding lesions in the bones of the hands (Fig. 2) A lateral film

of the skull showed a cyst-like area projected on the sella, but no other significant findings were present. There were no metastatic lesions in the chest; the costochondral junctions were irregular and widened with areas of calcification in poorly defined rib ends, which merged with the calcified costal cartilages.

On the third hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. WILLIAM BECKMAN: The essential features of this case—the bony nodules or lumps on the bones that developed progressively from child-

hood and were still developing at the age of forty-one, the short stature of the patient and the deformity of the skeleton, that is to say the bowed legs and the curved spine — constitute a syndrome that has been well recognized by the medical profession since at least the late eighteenth century. This is a syndrome called by many names, of which the commonest are multiple cartilaginous

FIGURE 2. Roentgenogram of Left Hand.

exostosis and multiple enchondromatosis. The way I was able to make the diagnosis was to take the x-ray films and look through an x-ray textbook until I encountered other ones like them. Then there was no question that it represented a characteristic syndrome. I think that Dr. Schulz might describe the x-ray findings at this time.

DR. MILFORD SCHULZ: Primarily, this patient shows a dysplasia of chondral bone growth. That portion of the bone involved in periosteal and endosteal growth is not particularly disturbed, but where this meets the epiphysis there is disruption of the normal character of the bone. These portions are wide, short and deformed. Here in the chest the costochondral junctions show severe deformities with irregular areas of calcification with-

in them. These lesions in the hands, of course, are quite characteristic of multiple enchondromas. You might be interested in seeing the films that were taken at the community hospital six years before entry. There was then only a small amount of calcification in the soft tissues around the ankle. Now the talus and calcaneus are destroyed, and the tumor has involved and destroyed the lower end of the tibia.

DR. BECKMAN: Another feature of this disease is that the bones are affected irregularly. That is particularly apparent in this case if you compare the metacarpal bones in the two hands. It can be seen that the corresponding bones are not always of the same length.

I have tried hard to work out a differential diagnosis because that is what one is supposed to do at these exercises; but it is difficult because there is nothing else that looks like this. I found one case that had been confused with hyperparathyroidism, but certainly this could not be considered here, particularly since there was no alteration in the blood chemistry.

Honeij¹ did metabolic studies and found that patients with the syndrome under consideration excrete more calcium on a low-calcium diet than an ordinary person does; but these experiments were repeated by Sanderson and Smyth² who found no deviation from normal. Hence, there is probably no disorder in the calcium metabolism. In 1917 a report by Ehrenfried³ from the Children's Hospital states that there were 600 cases in the literature at that time. Thus it is not so rare a condition as it might seem. The disease is usually hereditary, and in one family of seventy-six members, twenty-two of them were afflicted. This patient knew of no signs of the disease in any of her family so the hereditary aspect was not present, which is true in about one third of the reported cases.

One significant clinical datum was omitted when they did not tell the duration of the chief complaint but I assume from the story of the present illness that it was probably six months or so. At any rate it is quite evident that something different was going on in the left ankle.

It is unusual to have pain in benign tumors, and although this patient always had pain, it never bothered her enough to go to a hospital. Then, because of severe pain in the ankle she sought medical advice. The tumor in the ankle was also different because it grew much faster than the others, and six months after removal it had recurred. Also, the soft-tissue reaction around the ankle with redness and heat was different

from the changes observed during the development of the other swellings. Furthermore, she had evidence of constitutional disease, as shown by an elevated sedimentation rate and anemia. She also had a slightly elevated phosphatase, which suggests that osteoblastic activity was vigorous. I believe that one of the enchondromas in the left ankle had become malignant and that an amputation was performed.

DR. BENJAMIN CASTLEMAN: When you say "enchondromas," are you making any distinction between osteochondroma and enchondroma?

DR. BECKMAN: No, although I probably should have. Both are present in this disease. You can see all sorts of little ones in the phalanges—enchondromas and exostoses.

DR. CASTLEMAN: Dr. Schulz, will you comment on that? Are these tumors osteochondromas or enchondromas? I think there is a definite distinction.

DR. SCHULZ: I do not know whether one can classify them as exostoses or enchondromas. Those in the hands, of course, are quite characteristically enchondromas.

DR. GEORGE W. HOLMES: I believe that it would be possible for enchondroma to be responsible for the entire picture. A central tumor producing a local expansion of the bone might be projected in such a manner that it would appear to be partially outside the bone. Radiologically the only difference between an enchondroma and an osteochondroma is the location.

CLINICAL DIAGNOSES

Chondrosarcoma of tibia.

Multiple enchondromatosis.

DR. BECKMAN'S DIAGNOSES

Chondrosarcoma of tibia.

Multiple cartilaginous exostoses.

Multiple enchondromatosis.

ANATOMICAL DIAGNOSES

Chondrosarcoma of tibia.

Multiple enchondromatosis.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: There has been a lot of misunderstanding concerning these two diseases.

DR. WALTER BAUER: "Loose talk" is a better term.

DR. CASTLEMAN: First let me define some of the terms that we are all agreed on. We use the terms "exostosis" and "osteochondroma" interchangeably because these tumors appear to project out from the bone and because they are usually composed of both bone and cartilage. These tumors may be either single or multiple, and when

multiple the disease is usually hereditary and called "multiple cartilaginous exostoses" or what Jaffe⁴ in a recent paper prefers to call "hereditary multiple exostoses." Pathologically exostoses may be predominantly cartilaginous or osseous, and occur almost always in the vicinity of the epiphyseal cartilage. According to Jaffe they are covered with periosteum and their outlines are really irregularly outpouched cortex; they are not superimposed on the cortex.

An enchondroma is a cartilaginous tumor inside the bone, often occurring close to the epiphysis, but not necessarily. These tumors may also be single or multiple, and when multiple the condition is often called "multiple enchondromatosis" or, according to Ollier,⁵ "dyschondroplasia." This disease is not hereditary and is sometimes called Ollier's disease. Some of the confusion between this condition and multiple cartilaginous exostoses is due to the fact that Ollier⁶ also published a paper on the latter disease. Ollier, however, made a definite distinction between the two. There is no definite evidence that combinations of the two conditions have occurred in the same patient.

DR. BECKMAN: Ollier described a unilateral disease; Ewing,⁷ however, makes no differentiation between Ollier's disease and the condition present in this patient.

DR. CASTLEMAN: It is true that Ollier first described it as unilateral, and for that reason disease involving both sides was formerly not called Ollier's disease. Usually the lesions are only on one side, but there have been a number of cases reported in which they occurred on both sides. Even Ollier's own students⁸ described them on both sides.

This patient's foot was amputated about 8 cm. above the ankle. The tumor was composed of cartilaginous nodules, and microscopic examination showed it to be a chondrosarcoma. In addition many of the phalanges away from the tumor were almost completely replaced by enchondromas. No exostoses were found. I believe, therefore, that this is a case of multiple enchondromatosis with sarcomatous degeneration of one of the lesions in the lower end of the tibia.

THE HEALTH OF THE NATION

DURING the one hundred and fifteen years of its existence, the *Journal* has witnessed many changes in medical and public-health practices in the United States, all of which have been directed to the ever-present responsibility of the medical profession—the improvement of the health of the people.

Medical research has steadily advanced knowledge concerning the cause, prevention and treatment of disease. Drugs such as arsphenamine, insulin, liver extract, the sulfonamides and penicillin have been shown to possess phenomenal curative effects. Morbidity and mortality rates have declined to figures that, only twenty-five years ago, would have been considered fantastic. Certain communicable diseases, such as smallpox, typhoid fever and diphtheria, have been practically

eliminated as health hazards. Undergraduate and postgraduate medical education has improved to such an extent that it is unequalled in any part of the world. Hospital facilities in most regions of the country are adequate, regarding both number of beds, trained personnel and equipment.

Other factors that are indirectly concerned with the practicing physician have contributed to the improved health of the people. Measures promoted by public-health departments, such as sanitation, quarantine, tuberculosis case-finding and immunizing methods, have played a significant role, particularly in the control of communicable diseases. The creation of boards and colleges of specialists has led to the recognition of those who are properly qualified in their particular fields. Nationwide programs have done much to educate the population concerning medical matters, and in the majority of states opportunity for budgeting the costs of hospital or medical care, or both, is available.

In spite of all these things that are directly or indirectly concerned with the practice of medicine, a number of nonmedical conditions have influenced the health of the Nation. Among these should be included good wages, a high standard of living, unsurpassed educational facilities, excellent means of transportation, and well-endowed and well-administered charitable organizations.

The total result has been a nation as healthy as, if not healthier than, any other nation in the world, and one whose health is constantly improving, and yet the people of the United States and the medical profession are now faced with a proposed legislative act—the Wagner-Murray-Dingell Bill—that purports to promote an even healthier population by the federalization of many of the activities that have been responsible for the advances of the past and that, by and large, have been the direct result of the essence of democracy—individual enterprise and effort.

Within the past two months officially appointed representatives of the state medical societies of New England have jointly considered what steps should be taken regarding this epitome of bureaucracy. The group drafted a statement con-

cerning the proposed legislation, which is printed elsewhere in this issue of the *Journal*. The statement has been approved by the appropriate executive bodies of the state medical societies, and on December 2, copies were forwarded to each senator and representative in Washington by the medical society of his respective state.

The gist of the statement is a plea for the utilization by the states of existing voluntary agencies, if necessary with the assistance of federal grants-in-aid. In other words, it seems likely, if not inevitable, that federalization of medical and hospital care and of medical education and research would destroy the very foundation on which the health of the people of the United States is based. Certainly the threat is so ominous that every physician should explain to his patients and friends what agencies and philosophies have been responsible for the advances of the past, how these would be affected by the Wagner-Murray-Dingell Bill, and how such uncontrolled and radical experimentation can be avoided.

POSTWAR TUBERCULOSIS CONTROL

The foundation for ending tuberculosis in the United States, and for its control in all the world, is now being laid in wartime by the United States Public Health Service and the National Tuberculosis Association. The outlook for success is good. This is in face of the fact that, in long wars, tuberculosis has been a prime factor in raising the general death rate. The rise already has come in Europe. Its first signs appeared this spring in the United States, where the general tuberculosis death rate still was falling, but where an upturn came among the young. The small American setback had an ominous counterpart in Europe, where children were affected much more than adults, particularly by the nonpulmonary types of the disease. In England and Wales, deaths among children under ten years of age from all forms of the disease increased 45 per cent during 1941 over the 1939 figure, as compared with a 12 per cent increase for the general population. In Paris during the same period, the death rate among children from one to nine rose 28 per cent, as against only a 10 per cent increase for the

general population. This shows the insidious ways of tuberculosis and the magnitude of the job, because, when this war started, it was expected that those to be the hardest hit would be not British children but young women war workers, who were the foremost victims in World War I. An explanation suggested for the plight of American children is their mothers' diversion to war work.

In World War I, in Germany the tuberculosis death rate rose 61 per cent, in Italy 44 per cent, in England 42 per cent and in the United States 6 per cent. Authentic reports from Germany and Italy have not been available since the start of World War II. Meager reports from France show that deaths from tuberculosis have increased. But England held her increase in deaths from the disease to about 12 per cent during 1940 and 1941, and during 1942-1943 the number of deaths dropped to the 1938 level, which is the lowest on record. The tuberculosis death rate in the United States during a period lacking only a few months of the duration of her participation in World War I was still dropping. The 1941 death rate was an all-time low of 44.4 per 100,000, was probably about 43 for 1942, and this year will undoubtedly be still lower.

There are many angles behind this hopeful side, but the main weapon by which Americans propose to drive tuberculosis from the land is increasing use of x-ray films of the chest. The Selective Service boards and induction stations employ it on draftees, and state after state, and county after county, are following up the men deferred or rejected on account of tuberculosis. The United States Public Health Service and state tuberculosis organizations are extending the use of such films to war industries, and the same follow-up to promote medical care is used as in draftees. Furthermore, the Public Health Service is extending its offer of service to families of workers found to be tuberculous, and the War Emergency Committee of the National Tuberculosis Association has recommended to local tuberculosis associations many measures, including special attention to women employees and to emergency housing conditions.

Tuberculosis is coming to light in a great sector of the population where it was never before searched out on a large scale. The magnitude amounts to something new in this great health battle. The momentum here and in England promises success for the international postwar control activities now planned by the United States Public Health Service and the National Tuberculosis Association. Certainly the annual Christmas Seal Sale, the proceeds of which provide substantial support to this program, deserves the enthusiastic support of every physician!

MEDICAL EPONYM

LIBMAN-SACKS SYNDROME

Emanuel Libman (b. 1872) and Benjamin Sacks (b. 1896) are the authors of a paper, entitled "A Hitherto Undescribed Form of Valvular and Mural Endocarditis," appearing in the *Transactions of the Association of American Physicians* (38: 46-61, 1923). This same article also appeared in the *Archives of Internal Medicine* (33: 701-737, 1924). A portion of the discussion follows:

We have had the opportunity of studying the clinical and pathologic findings in four cases of a hitherto undescribed form of endocarditis, which we have for the present described as an atypical form of verrucous endocarditis. . . .

The disease . . . ran a subacute course, with fever and progressive anemia. Briefly enumerated, the clinical findings were pericarditis, white-centered petechiae, arthritis, erythematous and purpuric rashes, ulcerative lesions of the mucous membranes, pleuropulmonary symptoms, embolic phenomena, enlargement of the liver and spleen, acute glomerulonephritis, a tendency to leukopenia and repeatedly negative blood cultures. Two of the patients had an eruption on the face which resembled acute lupus erythematosus disseminatus. . . .

R. W. B.

MASSACHUSETTS MEDICAL SOCIETY

WAGNER-MURRAY-DINGELL BILL

The following open letter was forwarded, as of December 2, to all Massachusetts members of the Senate and House of Representatives in Washington. It is expressive of the collective viewpoint of the medical societies of Maine, New Hampshire, Vermont, Massachusetts, Rhode Island and Connecticut regarding Senate Bill 1161 and House Bill 2861 — the so-called "Wagner-Murray-Dingell Bill."

MICHAEL A. TIGHE, *Secretary pro tempore*
New England Conference
Wagner-Murray-Dingell Bill

MASSACHUSETTS MEDICAL SOCIETY
8 Fenway, Boston

December 2, 1943

Dear Sir:

The Massachusetts Medical Society, in conjunction with the medical societies of Maine, New Hampshire, Vermont, Rhode Island and Connecticut, has studied Senate Bill 1161 and House Bill 2861 now before the Congress of the United States and respectfully submits its views on this proposed legislation.

We approve of the broad medical objective of the act that we interpret to be an attempt to improve the health of the people. As a basis of our approval we cite the progressive leadership which the physicians of New England have always shown in the development of public-health enterprises. For more than fifty years we have consistently supported the plea for the establishment of a National Department of Health with a secretary in the President's Cabinet, under whom would be co-ordinated many important public-health programs, exclusive of the Army and Navy. These are now scattered through various departments and bureaus of the federal government and already play a large role in the provision of medical care for the people of this country.

We approve of the use of the insurance principle on a voluntary basis as a means to aid the individual to budget against the cost of medical care. We maintain that when insurance programs are not directly under the supervision of the medical profession by whom medical care is to be rendered, they should provide for cash benefits to be paid to the individual, for we firmly believe that the citizens of New England are capable of using cash benefits to pay the costs of medical care.

We believe that S. B. 1161 and H. B. 2861 do not provide for the sound development of a national health program. It is implied by the act that the distribution of compulsory savings managed by federal authorities will guarantee better health for all the people. We sincerely doubt that such an objective can be realized in this way. In the New England states, judged by any standards with which we are familiar, there is no need to revolutionize the habits of the people in their methods of obtaining medical care.

Private enterprises in the field of voluntary prepaid medical and hospital insurance are increasing rapidly. *These facilities should be utilized by the states, if necessary through federal grants-in-aid, so that each state can purchase medical care for those who cannot purchase it for themselves.* This we believe to be a development that would be acceptable to the New England people, for thereby medical care could be provided even for the indigent who are public charges, a provision most desirable in those communities that have been unable or unwilling to meet this obvious responsibility.

We shall be glad to work out plans with representatives of the federal and state governments to improve the health of all the people, but we should expect that any plans that might be devised would take full advantage of existing agencies and be developed within the social patterns that are well understood by our people.

Very truly yours,

[Signed] Roger I. Lee

STUDIES IN DIABETES MELLITUS AND TRANSIENT GLYCOSURIA IN SELECTEES AND VOLUNTEERS

HARRY BLOTNER, M.D., AND MAJOR ROBERT W. HYDE, M.C., A.U.S.

WITH THE ASSISTANCE OF SERGEANT LOWELL V. KINGSLEY, A.U.S.

BOSTON

A FEATURE of the medical examination of selectees and volunteers at the Boston Armed Forces Induction Station has been the frequency with which glycosuria was discovered. Since most studies in diabetes mellitus have been made on more or less select groups of people, few of them give a clear idea of the frequency and significance of mellituria in a cross section of the population. The incidence of the disease has been based on life-insurance examinations, mortality statistics and various surveys. Limitations of such results are obvious, and calculations from mortality figures are crude. Consequently, considerable variations in the frequency of this condition have been reported.

A most interesting large-scale survey of the occurrence of known diabetes mellitus in the general population was made under the direction of the United States Public Health Service¹ in 1935-1936. The results were based on a house-to-house canvass of some 800,000 families, which included 2,800,000 persons. It was estimated from this survey that there were 660,000 cases of diabetes mellitus in the United States. This figure, however, represented only known cases of diabetes, and no doubt there were many unrecognized ones in the population studied, as can be inferred from the number of unrecognized cases discovered in the present study. A report of the medical findings in the New York City Selective Service Administration showed the incidence of diabetes to be 416 cases (0.36 per cent) among 155,569 registrants in the City of New York.²

The majority of observations of the various phases of this disease have been made on cases of diabetes with symptoms in groups of people that are not representative of the male population. Consequently, not so much is known about the cases of diabetes that have been found on routine exam-

inations. The opportunity presented itself to study at the Boston Induction Station various aspects of transient glycosuria and diabetes and their relation to socioeconomic factors in a large unselected group of men. In this group, an estimated 78 per cent of the cases of diabetes were discovered without the persons' ever having known that they had the disease. It seemed that an investigation of such cases of diabetes as well as those of known duration would be of considerable significance.

This paper presents a study of diabetes mellitus and transient glycosuria in 45,650 consecutive selectees and volunteers, aged eighteen to forty-five years, who appeared for final examination at the Boston Induction Station, prior to induction in the armed forces. The men appearing for final examination at this station form an excellent cross section of men of military age without dependents, not engaged in essential industry, and not possessing obvious disqualifying defects evident on inspection by local-board examiners.

PLAN OF INVESTIGATION

All men had thorough physical and mental examinations, routine chest roentgenograms and urine examinations.

The test for sugar in the urine was made with Benedict's qualitative solution. The qualitative amounts of sugar in the urine were indicated according to the color changes: + for green, ++ for yellow, +++ for orange and ++++ for brick red. When sugar was found, the urine was tested again before and after lunch on the same day. If the repeated urine examinations showed sugar and if there was not a verified history of diabetes, the men were sent to an Army hospital for sugar-tolerance tests. A standard dose of 100 gm. of dextrose was employed and was ingested after the subject had fasted overnight. The con-

centration of sugar in the blood and urine was determined in specimens taken during fasting and at intervals of one half, one, two and three hours after the ingestion of the dextrose. The determination of the blood sugar was made on 2-cc. samples of venous blood according to the method of Folin and Wu.³

Observations were made on certain clinical and social aspects of diabetes mellitus and transient glycosuria. The clinical aspects studied were incidence and diagnosis, age at onset and at present, height and weight, frequency of hypertension and of pulmonary tuberculosis, general physical status and family history of diabetes. The social investigations consisted of community studies on the relation of the prevalence of diabetes mellitus to socioeconomic level, community welfare rate, population density, occupation and nationality. All cases of diabetes were classified according to the type of community from which they came. The social study of these communities was made according to the plan of Hyde and Kingsley.⁴ Their classification of community socioeconomic level was based on good, medium and poor community desirability. These findings were compared with those of a large control group of nondiabetic persons who were examined here.

INCIDENCE AND DIAGNOSIS

The incidence of glycosuria, which in degree varied from + to +++++, was found to be 367 cases (0.8 per cent) of the 45,650 men examined. For the purpose of simplicity the cases of glycosuria were divided into three groups, as follows: 208 cases of diabetes mellitus, 126 cases of transient glycosuria, and 33 cases of renal glycosuria, which have been reported elsewhere.⁵

Diabetes mellitus was diagnosed when the subject had a blood-sugar concentration that reached a level of 180 mg. per 100 cc. and some or all of the urine specimens contained varying amounts of sugar after the ingestion of 100 gm. of glucose. Some of the fasting urine specimens were sugar free and some of the fasting blood sugars were normal. Of the 208 cases of diabetes mellitus, 107 were mild, 58 were moderate, and 43 were severe. Illustrations of these are given in Figure 1.

The cases of mild diabetes usually showed normal fasting blood-sugar levels. Some of the fasting urine specimens contained sugar, whereas others were sugar free. After the ingestion of the test dose of glucose, the blood sugar rose in one half or one hour to 200 or 220 mg. per 100 cc., and then dropped in two hours to 150 mg. and in three hours to 100 or 125 mg. The urine specimens contained varying amounts of sugar.

The moderate cases of diabetes showed a fasting blood-sugar level of 140 mg. per 100 cc., with or without sugar in the fasting urine specimens. After the ingestion of the glucose the blood sugar rose in one half or one hour to 275 mg., and then

FIGURE 1. Characteristic Results in Mild, Moderate and Severe Diabetes Mellitus at Hourly Periods after the Ingestion of 100 Gm. of Glucose.

dropped to about 200 mg. in three hours. The urine specimens contained varying amounts of sugar.

The cases of severe diabetes showed a fasting blood-sugar level of 275 mg., with considerable amounts of sugar in the urine. After the ingestion of the glucose the blood-sugar level rose to about 475 mg. in one hour and dropped only slightly in three hours. All the urine specimens contained large amounts of sugar.

Transient glycosuria was diagnosed in the men who had varying amounts of sugar in the first specimen of urine tested, and showed negative reactions on subsequent tests during the day. If sugar-tolerance tests had been done in all these cases, it is quite probable that a number of cases of diabetes mellitus and renal glycosuria would have been discovered.

CLINICAL FEATURES

Age. Diabetes mellitus may be recognized at any period from infancy to old age. Although the men examined here were over eighteen years of age, a number of them knew that they had had the disease since childhood.

The incidence of glycosuria at the various present ages and the age at onset are given in Table 1. It shows that the average age of the diabetic patients was 34.4 years, that of the men with transient glycosuria 30.9 years and that of the control group 27.5 years. Ordinarily one thinks of the

severe cases of diabetes as being in younger persons and the mild cases in older ones. In this study, however, the average age in the mild cases was 31.2 years, in the moderate cases 36.6 years and in the severe cases 34.4 years. Forty-two (22

per cent) of 189 diabetic men had a known duration of the disease for one to twenty-three years, and the average age at onset of diabetes was 33 years, or 1.4 years lower than the average present age of all the diabetic men.

Diabetes is generally regarded as occurring with special frequency in the older groups, especially between the ages of fifty and sixty. Probably the incidence in the older age groups is not so great as previously thought because many people have undoubtedly had diabetes for some years without knowledge of it. As a result, a cumulative effect of age is obtained in later years of life. This effect was particularly brought out in a study of the present age and the age of onset of diabetes in 42 men who had had the disease for one to twenty-three years, as illustrated in Table 2. If

one notes the age at onset of the disease in this group, there is a preponderance of diabetes in the younger men and fewer cases in the oldest age groups. Yet if one studies their present ages, a marked contrast is observed.

Weight. One of the chief constitutional features in the onset of diabetes has been considered to be overweight. Consequently a study of the

weight was made in 196 cases of diabetes mellitus and 103 cases of transient glycosuria. These results are given in Table 3. In the diabetic men, the weights were studied according to the mild, moderate and severe cases, and since the results were approximately the same in the various types of cases, the weights are reported for diabetes in general. The average diabetic man weighed 158 pounds and was 34.4 years old, whereas the average man with transient glycosuria weighed 151 pounds and was 30.9 years old. The averages of 1000 consecutive selectees were 140 pounds and 27.5 years. Weights ranging from 12 pounds above to 12 pounds below the Army standard⁶ for height and age were called normal. When a

correction of 5 pounds is made for the greater age of seven years in the diabetic group, the excess weight over the control group is 13 pounds. After an adjustment of nine pounds is made for the greater height and age of the men with transient glycosuria, their excess weight is only 2 pounds. It is the few markedly obese diabetic men who increased so much the average weight of all the diabetic men.

Approximately 62 per cent of all the diabetic men, 75 per cent of those with transient glycosuria, and 68 per cent of the nondiabetic men were of either normal or subnormal weight. On the other hand, 38 per cent of the diabetic men, 25 per cent of those with transient glycosuria and 32 per cent of the nondiabetic men were 15 to 134 pounds above the standard. The weights of the men who had had diabetes for one to twenty three years were not significantly different from those of the control group.

Height. The heights of the men with diabetes mellitus and transient glycosuria ranged from 60 to 74 inches, as shown in Table 4. The average height of the diabetic men was 66.0 inches and of those with transient glycosuria 67.8 inches (In Joslin's male adult diabetic patients,⁷ the aver-

age height was 67.2 inches.) These compare with the control height of 66.4 inches based on the measurement of 1000 consecutive selectees. The diabetic men appeared of average normal height,

TABLE 4. *Heights in Diabetic Men, Men with Transient Glycosuria and Nondiabetic Men.*

HEIGHT	205 DIABETIC MEN	42 DIABETIC MEN WITH DISEASE OF 1 TO 23 YEARS' DURATION	122 MEN WITH TRANSIENT GLYCOSURIA	1000 NON- DIABETIC MEN

72-74	1	4	5	5
Average heights	66.0 in.	66.7 in.	67.8 in.	66.4 in.

whereas those with transient glycosuria were 1.4 inches above the normal, a fact that appears significant. Most of the men with glycosuria were between 64 and 68 inches tall.

Blood pressure. The blood pressures were studied in all cases. Hypertension that was comparatively mild (over 150 systolic, 90 diastolic) occurred in 7 per cent of the diabetic men and in 5 per cent of those with transient glycosuria. The diastolic pressures ranged from 80 to 124, and the systolic from 160 to 194. The incidences of hypertension in the severe diabetic cases and those of transient glycosuria were somewhat less than those in the mild and moderate diabetic cases, as shown in Table 5. In the 42 men with diabetes

TABLE 5. *Incidence of Hypertension in Various Groups of Diabetic Men, Men with Transient Glycosuria and Nondiabetic Men.*

Incidence of hypertension	7.5%	7.0%	5.0%	5.0%	2.2%

of one to twenty-three years' duration only 1 had an increased blood pressure (170 systolic, 110 diastolic).

Pulmonary tuberculosis. Pulmonary tuberculosis has been considered in the past as a significant complication of diabetes.⁸ The opportunity seemed excellent to compare the routine x-ray findings of the chest in diabetic men and in those with transient glycosuria with those in nondiabetic persons. In 208 cases of diabetes not an active case of pulmonary tuberculosis was found, in contrast to the average incidence of pulmonary tuberculosis of 0.9 per cent found in a one-year

study of selectees.⁹ There was, however, one nodular or arrested case and 6 cases of healed primary tuberculosis, which is consistent with the average of 3 per cent primary tuberculosis found by x-ray in nondiabetic persons. In 126 cases with transient glycosuria there were 2 cases with minimal pulmonary tuberculosis and 1 with moderately advanced tuberculosis. Root¹⁰ believes that the susceptibility of diabetics to pulmonary tuberculosis depends largely on the control of the diabetes. However, in our group, which consisted chiefly of men with uncontrolled diabetes, there appeared to be the same amount of pulmonary tuberculosis in the persons with glycosuria as in all other volunteers and selectees examined.

Physical condition. In general the physical condition of all the diabetic men and of those with transient glycosuria did not differ from the control group except for the increase in the incidence of hypertension, and the slight increase in the average weight of the diabetic men. No other endocrine disturbances were noted. On the whole it is fair to say that the diabetes had no effect on the physical state of the 42 persons aged eighteen to forty-five who had had this disease for one to twenty-three years. As a matter of fact, they were essentially free of vascular disease and, as previously mentioned, only 1 had an elevated blood pressure.

Treatment. The diabetic men discovered on routine examination had had no particular previous treatment. Of the 42 men who knew that they had had diabetes mellitus for one to twenty-three years, 11 cases were moderate, 6 were mild, and 25 were severe. Therapy in 9 of the 17 mild and moderate cases consisted of diet only, whereas 4 received small doses of insulin, 3 followed no treatment and no record of treatment was made in 1 case. Of the 25 severe cases, 19 took some form of insulin. Twelve injected daily 26 to 100 units of protamine insulin, and 5 of these received in addition 12 to 40 units of regular insulin a day. Seven patients took regular insulin only in daily amounts of 30 to 83 units a day divided into one to three doses. Three followed a diet only and 1 followed no specific treatment. No record of treatment was made in 2 cases.

Family history of diabetes. The inheritance of diabetes has been pointed out by many writers. The family history of diabetes was studied in 126 cases of diabetes mellitus and in 77 cases of transient glycosuria. The familial incidence of diabetes in mild, moderate and severe diabetic cases was much the same. Of 126 diabetic persons interviewed, 41 (32 per cent) gave a family history of this disease, which had occurred in one to seven members of the family. There was a family

history of diabetes in 36 per cent of the diabetic men who had had the disease for one to twenty-three years, and in 30 per cent of those cases that were discovered on routine examination. Of the 77 men with transient glycosuria, 7 (9 per cent) gave a family history of diabetes, which had appeared in only one or two members of each family. In a control study, 2293 consecutive nondiabetic selectees were interviewed and only 119 persons (5.2 per cent) gave a family history of diabetes; this occurred in all cases in only one member of the family. An analysis of the diabetic relatives is given in Table 6.

The diabetic relatives of the 41 diabetic men with a family history of diabetes amounted to 68. Of these, 29 had a history of the disease in only one member of the family. In 12 diabetic cases the disease had existed in two to seven members of each family, with a total of 39 diabetic relatives,

as follows: 6 with two relatives each, 2 with three relatives each, 2 with four relatives each, 1 with six relatives, and 1 with 7 relatives. Of the 7 men with transient glycosuria, 5 gave a history of diabetes in one member of the family and 2 in two members of the family.

COMMUNITY STUDIES

Community desirability. The classification of the community desirability was based on the seven factors of medical care, educational and recreational facilities, crowded housing, social class, public works and welfare rate. The good communities, largely well-to-do residential areas, were superior in all these aspects; the poor communities, with low ratings in these factors, were poor, crowded tenement areas; and the medium classification included all the intermediate socioeconomic gradations of the middle class. The incidence of diabetes in relation to community desirability is shown in Table 7.

This study shows no significant variation in the prevalence of diabetes mellitus in selectees from communities of different socioeconomic levels. This lack of relation to socioeconomic background

is quite unexpected in view of the stress that has been placed on the influence of inactivity and increased diet among the upper classes, but is what

TABLE 7. *Prevalence of Diabetes Mellitus According to Socioeconomic Level of the Community*

TYPE OF COMMUNITY	NO. OF MEN EXAMINED	PERCENT MEN WITH DIABETES MELLITUS
Good	5 221	0.71
Medium	17 059	0.73
Poor	7 869	0.75

might well be expected in a disease of such hereditary nature.

Communities were also classified by welfare level, on the basis of the amount of welfare paid per capita, as given by Lambie.¹¹ The relation of diabetes mellitus to the welfare rate of the community from which the selectees come is shown in Table 8. This relation shows that there is little variation in its incidence at different community welfare levels. In contrast, the total rejection rate for all causes increased in the poorer communities and in those with higher welfare rates, as might be expected from poorer living conditions and medical care, which are so often concomitants of increased welfare.

Previous work on diabetes¹² has suggested that this finding would be different—that is, a decrease in diabetes in the communities with the highest welfare rates, because of greater privation, and an increase in diabetes in the upper classes because of excess food intake and sedentary occu-

TABLE 8. *Prevalence of Diabetes Mellitus According to Community Welfare Rate*

\$40 and over	3724	0.8

pations. This, however, is not shown, since the communities with the highest welfare had 0.8 per cent of diabetes mellitus and the lowest bracket had 0.7 per cent.

Population density. Communities were grouped according to population per square mile, and their incidences of diabetes are shown in Table 9. The higher prevalence of diabetes in the communities with higher population density can hardly be explained by chance.

An increase of diabetes in urban areas has been recognized by Joslin,¹³ who explains it in several

ways: more sedentary living, a higher economic level with more abundant eating and a larger element of Jews in the population, with their high prevalence of diabetes. Previous findings indicating the failure of the community socioeconomic

TABLE 9. *Prevalence of Diabetes Mellitus According to Population Density.*

POPULATION PER SQUARE MILE	NO. OF MEN EXAMINED	MEN WITH DIABETES %
Under 1000	3928	0.4
1000-4999	7613	0.5
5000-9999	6778	0.8
10,000-19,999	7179	1.0
20,000 or over	5479	0.8

level to influence diabetic prevalence and the lack of relation to laborious occupations suggest that these factors cannot be considered in the interpretation of the increased prevalence of diabetes in increased population densities. The factor of nationality appears to be, in part at least, a satisfactory explanation for the high prevalence of diabetes in dense urban areas, for both Jews and Irish are concentrated in the urban high-density areas in sufficient number to elevate the prevalence to about 0.8 per cent for those areas from 0.4 per cent in the least populated regions. There may be other, as yet undetermined, factors relating to population density, but it will take much further investigation to demonstrate them.

Occupation. Occupation has been considered to be an important predisposing factor of diabetes mellitus, which has been thought to occur with much greater frequency in persons with sedentary occupations than in those with laborious occupations. Types of occupations were studied in 118 diabetic men and in 81 with transient glycosuria and compared with the occupations of 1400 consecutive selectees and volunteers.

Occupations were divided into three types, as follows: "white collar," light labor and heavy labor. The white-collar group included clerks, students and business and professional men. The light-labor group included factory and mill workers, taxi drivers, drivers of light delivery trucks, salesmen, pipe fitters, painters and electricians. The heavy-labor group included longshoremen, drivers of heavy trucks, shipyard welders, masons, plumbers, carpenters and farmers. The results are shown in Table 10.

It was most interesting to find that the percentages of diabetic men doing heavy labor, light labor and white-collar work were almost identical with those of the control group. The results with transient and renal glycosuria were also similar. These observations appear significant, and strong-

ly suggest that occupation in general is not a predisposing factor in the etiology of diabetes.

Those communities in which there was one predominant occupation were classified and the prevalence of diabetes considered as shown in Table 11. A great variation existed with shoe-manufacturing towns and urban commuters' areas having the greatest amount of diabetes. This again suggests that diabetes is as common in those engaged in manual labor as in those in sedentary occupations, for both the workers in the shoe

TABLE 10. *Occupation Classified According to Glycosuria of Various Types.*

	WHITE- COLLAR %	LIGHT LABOR %	HEAVY LABOR %

Transient glycosuria	20	75	5
Renal glycosuria	27	68	5

towns and the urban commuters' areas were for the most part doing manual labor, although many were clerks and office workers. The low prevalence in farming and fishing communities is hard

TABLE 11. *Incidence of Diabetes in Communities with a Dominant Occupation.*

Fishing	0.4

to understand. It is partially explained by the almost complete absence of both Jewish and Irish elements from the population of these areas, and Joslin's explanation that these groups are engaged in the hardest type of manual labor may pertain although it does not coincide with our finding.

Nationality. The incidences of the nationalities of 128 persons with diabetes mellitus and 88 with transient glycosuria were compared with that of a control group of 7350 consecutive persons at this induction station. The results are shown in Table 12. The nationality was determined according to the birthplace of the parents of the men examined. For example, the nationality was called American when both parents were born in this country. If a selectee was born in this country and his parents in Ireland, his nationality was called Irish. The Jewish persons were ordinarily Russian, Polish or Austrian.

The findings of the nationalities appeared of considerable interest. Of the men examined, 45

per cent were Americans, but they constituted only 33 per cent of the diabetic group and only 21 per cent of those with transient glycosuria. On the other hand, the non-American group in general showed a greater incidence of diabetes and a much greater incidence of transient glycosuria than did the control group.

It appears that the longer are the generations of nationalities in this country, the more the inci-

dent become into mixed communities. It has special value as presented here, not only because it confirms the study of nationality but also because it shows to just what extent nationality can affect a community, and hence helps to explain the

TABLE 12. *Incidence of Diabetes and Transient Glycosuria According to Nationality.*

dence of diabetes diminishes, at least to a certain point, because of the low incidence in those classed as Americans, who are of course originally of foreign extraction. The Jews and Irish were of particular interest. The Jews had more than twice as many in the diabetic group as in the control group. The Irish, who constituted 11 per cent of the control group, showed a marked increase to 18 per cent of the diabetic cases and 21 per cent of those with transient glycosuria. The marked increase in the per cent of transient glycosuria in the Irish may possibly be explained on the basis of chronic alcoholism, because Hyde,¹⁴ as well as Haggard and Jellinek,¹⁵ found a high incidence of chronic alcoholism in the Irish. The French, with only 0.1 per cent of the control group, made up 4.7 per cent and 7.4 per cent of the groups with diabetes and transient glycosurias, respectively. The French and Canadian groups may not be reliable because some of the French were probably from Canada. If the French and Canadians are considered as a whole, the incidence of these conditions is practically the same as the control group. The group of other nationalities showed a marked increase in the percentage of transient glycosuria.

Those communities wherein a major element of the population was of one nationality by extraction were considered by nationality, as shown in Table 13. This presents a different aspect of nationality than that presented by a consideration of nationality alone, for a minority of other nationalities exists in the community, and persons in a foreign community present more habits and customs of the nationality than do those who

correlation of the incidence of diabetes with population density or other social considerations.

SUMMARY

This paper presents certain clinical and socioeconomic studies on diabetes mellitus and transient glycosuria that occurred in 45,650 consecutive selectees and volunteers, aged eighteen to forty-five years, who appeared for final examination at the Boston Armed Forces Induction Station.

The incidence of glycosuria was found to be 367 cases, or 0.8 per cent of the men examined. The cases of glycosuria were divided into three groups with the number of cases as follows: 208 cases of diabetes mellitus; 126 cases of transient glycosuria and 33 cases of renal glycosuria. Of the 208 cases of diabetes, 107 were mild, 58 were moderate and 43 were severe.

The average present age of the diabetic men was 34.4 years and that of the men with transient glycosuria 30.9 years, as compared with the average age of 27.5 years of the nondiabetic group. The average age at onset of all the diabetic men was 1.4 years lower than their present age. The average present age of those with diabetes of one to twenty-three years' duration was 31.8 years, compared with the average age of 24.2 years at onset showing how a cumulative effect of age is produced as the diabetic men grow older.

The average weight of patients with diabetes and transient glycosuria was slightly higher than that of the control group. However, 62 per cent of the diabetic men and 75 per cent of those with transient glycosuria, as compared with 68 per cent of the nondiabetic men, were of either normal or subnormal weight according to Army standards. Except in a few cases, obesity did not appear to be an important factor in these cases. The average height of the diabetic men was the same as that of the control group.

The physical condition of the men with glycosuria did not differ from that of the nondiabetic

men, except that mild hypertension appeared in 7.0 per cent of the diabetic men and in 5.0 per cent of those with transient glycosuria, compared with 2.2 per cent in the control group. Pulmonary tuberculosis as determined from chest roentgenograms appeared with essentially the same frequency in the persons with glycosuria as in all the volunteers and selectees examined.

The inheritance of diabetes was of interest because family histories of diabetes were obtained in 32 per cent of the diabetic cases and in 9 per cent of those of transient glycosuria, as compared with 5.2 per cent of 2293 consecutive nondiabetic selectees. The number of diabetic relatives per family of each diabetic man was appreciably greater than that of the nondiabetic men.

Occupation did not appear to be a predisposing factor in the etiology of glycosuria, since the percentages of the men with glycosuria doing hard labor, light labor and white-collar work were almost the same as that in the control group.

Community studies of diabetes showed that the prevalence of diabetes was the same in communities of good, medium and poor socioeconomic levels. The relation of the prevalence of diabetes to community welfare rates showed little variation at the different community levels. In contrast, previous studies of diabetes have suggested that there is a decreased incidence in communities with the highest welfare rate, owing to privation. There was a higher prevalence of diabetes in communities with a high population density. Nationality seems to be, in part at least, an explanation for this phenomenon.

The nationalities, as based on the birthplace of the parents of the selectees, were studied. The incidence of diabetes and transient glycosuria was lower in the American group and higher in the non-American group, as compared with the incidence of the nationalities in the control group. The incidences of diabetes in the Jews and the Irish were outstanding.

CURRENT CONSIDERATIONS OF THE ARMY ANESTHESIOLOGIST*

MAJOR STEVENS J. MARTIN, M.C., A.U.S.†

FORT DIX, NEW JERSEY

MILITARY campaigns necessitate medical preparedness. The expanded Army today is serviced by an enlarged and one of the most competent medical departments ever organized. All pertinent specialties are represented, and key personnel are virtually hand-picked. Notwithstanding a roster of 35,394 medical officers on active duty,¹ the proportion of officer anesthetists to other medical specialists is still surprisingly low. The need for such personnel has arisen not only from the greater number of hospital installations but particularly from the growing appreciation of the services such officers can render. To many, this demand, as well as the recognition of anesthesiology by the Army, has presented a challenge met only by requests for active duty in the armed forces. Thus far, two hundred and seventy-eight members of the American Society of Anesthetists, thirty-nine of whom are diplomates of the Board of Anesthesiology, are serving in the Army as anesthetists.² The total number is still short of the quota desired, and thus it may be expected that many more of our civilian confreres will join our ranks. To facilitate their early orientation with respect to military anesthesia as well as to elucidate a few of their professional duties to civilian surgeons, internists and general practitioners, some of the current considerations of the Army anesthesiologist will be presented. These may be logically grouped as those of basic and those of specific nature.

BASIC CONSIDERATIONS

Scope of Anesthesia

The present-day military anesthetist is no longer the glorified medical technician of World War I, nor is he a superman of the present conflict. He is simply one link in the chain of command of a surgical installation. However, his sound training in the fundamental principles of physiology, pharmacology, anatomy and so forth and his thorough appreciation of their clinical application have made him indispensable to surgeons. His anesthetic duties are clear cut and not unlike those of his civilian colleagues. According to the present scope of anesthesia per se (Table 1), his primary obligations to his patient and surgeons concern adequate preoperative preparation; relief of pain;

muscular relaxation, prophylaxis and therapy for adverse cardiorespiratory derangements during surgery; and prompt and effective postoperative care to prevent or minimize complications of circulation or respiration. In addition, he may be

TABLE 1. *Present-Day Scope of Anesthesia.*

SURGERY	MEDICINE
Preoperative	Diagnostic

Postoperative	Suicida
Complications	
Therapy	

of some aid to the internist with the use of diagnostic or therapeutic blocks in treating peripheral vascular disease, the intractable pain of cancer, angina pectoris or status asthmaticus, or with the help of resuscitative measures in combating gas or drug poisonings. These duties constitute the minimal requirements of a competent anesthetist, military or civilian.

Orientation of Anesthetist

Notwithstanding their successful professional background, civilian anesthetists entering military service go through a period of orientation. Quite apart from adapting themselves to Army regulations, they become impressed early with the fact that favorite agents and per technics are not always popular or possible to employ. Such a practice is not conducive to good anesthesia, even in civilian life, where anesthetic management of patients should also be individualized and not routine. Orientation to the use of many accepted anesthetic agents and technics is simple and rapid with competent anesthetists but difficult and uncertain with others. The Army supplies a variety of agents and equipment—a policy that meets not only the demands of the physical status of all patients but also the necessities of surgeons. Furthermore, such a plan may better facilitate the activities of an anesthetist in a mobile surgical hospital whose armamentarium and supplies are affected by combat situations. Accordingly, many anesthetists have had to relearn their technics of open-drop ether and chloroform as well as the advantages and limitations of both. Others have had to review their procedures of spinal and intravenous

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 25, 1943.

†Chief of Section of Anesthesia and Operating Pavilion and Section of Resuscitation and Oxygen Therapy, Tilton General Hospital, Fort Dix, New Jersey

anesthesia and human anatomy to perform block anesthesia more successfully. In this phase of orientation, refresher courses³ have been helpful to many.

Organization of Section

Officer anesthetists, assigned to hospital units or surgical teams, after their orientation and basic military training are immediately confronted with the problem of organizing their section. The scope of this problem depends on the type, size and location of the unit as well as on its general functions. In named general and station hospitals, which also serve as training centers, the complement of the Section on Anesthesia and Operating Pavilion may be as large as twenty persons, consisting of two officers, four nurses and fourteen enlisted men. In small units, such as surgical teams, there may be only one officer anesthetist and an enlisted man trained by him. The anesthetist supervises the activity of his personnel, making them available for surgery on a twenty-four-hour basis. This includes not only anesthesia but also the preparation of the entire operating pavilion, the latter duty being totally foreign to the average civilian anesthetist. He requisitions bi-weekly expendable supplies, such as anesthetic agents, gauze, antiseptic solutions and ligatures, and is responsible for the care, repair and availability of all anesthetic equipment and surgical instruments. Finally, to promote the prime function of his section in scheduling and facilitating surgical procedures, he must incorporate in the local hospital regulations certain definite, clear-cut and fundamental policies referable to the interrelations of his section with the surgical service as well as with medical, dental and laboratory services. The regulations should include comment on the matter of scheduling operations and preparing and premedicating patients, transporting them to and from the operating pavilion and prescribing the first postoperative treatment. In this general plan of organization, attention must be given to Army regulations and to the many helpful suggestions of the commanding officer and chief of the surgical service.

SPECIFIC CONSIDERATIONS

General Functions of Section Chief

Once the period of organization has ended and the Section on Anesthesia and Operating Pavilion is performing satisfactorily, the anesthetist or section chief can assume additional duties. These have been emphasized elsewhere.⁴ His activities, briefly, can be of an administrative, professional or miscellaneous nature. Those of professional character may include not only the scheduling of all

surgical procedures and the administration and supervision of anesthesia, but also the sterilization and autoclaving of equipment and laundry of all wards of the hospital as well as of the operating pavilion, the administration of plasma and whole blood and, finally, the centralization and supervision of inhalation therapy. It can readily be seen that the responsibilities of the military anesthetist are admittedly great and far more diverse than those of his civilian colleagues.

Records

The tabulation and maintenance of records are prerequisites of successful administration. The section chief of anesthesia has his share of the paper work to take care of. Aside from records referable to property accountability and requisition of expendable items, there are those pertaining to surgical procedures, anesthesia, pathology specimens and so forth. A composite record in book form of all surgical and anesthetic procedures may be authorized by the chief of the surgical service for future reference or compilation. Standard Form 55-0-1 is necessary for all operative patients, and includes data of the preoperative status of the patient and his progress during anesthesia. These may be of inestimable value to a patient being considered for limited duty, discharge or retirement. Wangeman⁵ has suggested the use of a modified Hollerith punch card to compile surgical and anesthetic data in the Army for statistical studies.

Instruction of Personnel

One of the most important duties of the chief of Section on Anesthesia and Operating Pavilion concerns the instruction of his personnel. This applies to his officers, nurses and enlisted men. It is vitally necessary to ensure optimum efficiency of the section at all times, particularly in view of the fact that initially many of the personnel are inadequately trained for the functions they are to perform or, when trained, may be replaced by newcomers, owing to illness, combat injury or reassignment as a nucleus for new hospital units. Instruction is essentially of two types: training of surgical technicians and training of anesthetists. With the help and supervision of an experienced responsible and competent chief operating-room nurse, enlisted men of the medical detachment can be instructed satisfactorily within three months in the duties of scrub or circulating nurses and sterilizing-and-autoclave-room attendants. It has been particularly gratifying to see the proficiency attained and enthusiasm shown in these duties by enlisted men who have had no more than high school or general college training.

Training in anesthesia has been conducted by the chief anesthetist in almost every hospital unit owing to shortage of such personnel. The type and duration of the course have varied at different posts depending on the instructor, his teaching ability and the background of his students. Through the kind suggestions and wholehearted co-operation of Colonel S. Jay Turnbull, the first organized course in anesthesia in the history of the Army, consisting of a series of lectures, demonstrations and practical supervision in the operating room, was given at Tilton General Hospital in July, 1941.⁶ A year later the School of Anesthesia was officially authorized by the War Department, and several courses have since been given. Such training was designed to meet military needs. It was intensive and all-inclusive for the officers, but concerned only open-drop technique for the enlisted men. To conserve nurse personnel, and particularly to take advantage of the extensive laboratory background of many of the enlisted men, who could also be assigned to arduous duties in the operating pavilion when not administering anesthesia, enlisted men were preferred to nurses as students.

For medical officers, emphasis was given to inhalation, spinal, intravenous and block anesthesia with respect to the agents and equipment supplied by the Army. Fundamental principles and their clinical application were studied with agents such as ether, ethyl chloride, chloroform, nitrous oxide, procaine, Metycaine, and Pentothal Sodium, administered by techniques suitable for mobile or fixed hospitals. Other agents, such as Vinethene, cyclopropane and nupercaine, and procedures such as continuous spinal or caudal anesthesia were demonstrated to indicate their particular usefulness for definitive surgery at fixed general hospitals. In addition, special attention was given to instruction in endotracheal techniques, methods of resuscitation, inhalation techniques and fluid or shock therapy. No effort was spared in the intimate supervision of practical training and of adaptation to military necessities.

Anesthetic Management. at Various Medical Echelons

Considerations of anesthetic management constitute some of the most practical and significant problems the military anesthetist has to contend with. They are of prime importance to him, for therein lies his usefulness to his unit. To appreciate their magnitude fully, in contrast to the relatively complacent routine of the civilian anesthesiologist, some pertinent factors concerned will be mentioned.

Type of injury. Injuries may be those of the thorax, abdomen, extremities, central nervous

system or maxillofacial region, or any combination of these. They require different techniques and agents, and the choice of these by the anesthetist may play a significant part in the surgeon's program.

Severity of injury. Injuries should be classified and separated according to their major or minor character to expedite prompt and effective treatment of the more serious casualties.

Accompanying condition of patient. Major surgery may often be handicapped by delays in diagnosing and providing early treatment for patients showing asphyxia, variable degrees of peripheral vascular collapse, physical exhaustion, inanition, and exposure to extremes of temperature, sandstorms or snowstorms or tropical diseases.

Time interval between injury, diagnosis and treatment. This factor is admittedly of more importance to the surgeon than to the anesthetist, although its appreciation by the latter will favor a satisfactory anesthetic management.

Number of cases. Medical units, as in World War I, will either be in a state of readiness or be deluged with mass casualties. This latter situation will profoundly affect the anesthetic management in that individual considerations will be outweighed by those of the entire group.

Weapons or methods used in producing casualties. Patients exposed to gas attacks or suffering from blood loss may require resuscitation or shock therapy. Others showing tissue trauma will need surgery. A knowledge of the weapon causing the injury will aid the anesthetist in his plan of action.

Medical service available. Of all factors enumerated, the availability of medical service in the Army is of the greatest interest to the patient, the surgeon and the anesthetist. This problem has been fully appreciated, and after years of experience, intensive study and competent organization, the Medical Corps has developed the highest degree of efficiency in its history. Its functions of first aid on the battlefield, emergency treatment, evacuation and hospitalization of patients for definitive treatment are now being effectively carried out notwithstanding the complexities and difficulties of fluid and far-flung fronts. To the anesthetist, among others, it is imperative to understand the general plan of organization the anesthetic armamentarium available at the various medical echelons and the probable anesthetic management at these locations.

The medical service of the Army is divided into five echelons, the first three of which are mobile and attached to tactical troops, and the last two of which are stationary or relatively fixed⁷ (Table 2). The unit medical services, located some three

medical officers are assigned to all five echelons, the anesthesiologist is first found in installations of the Army medical service along with surgical

hundred to eight hundred yards behind forward-moving infantry, receive wounded by litter and provide emergency treatment, given in addition to the first aid administered on the battlefield. The divisional medical services, some twelve hundred to thirty-five hundred yards back, continue emergency treatment and sort out patients to be retained or to be evacuated to the rear. Several miles back may be found installations of the Army medical service, where surgeons, anesthetists and other medical specialists may be found. All types of emergency surgery may hence be performed. Some of these installations, such as surgical teams, may be sent forward in divisional areas for duty to facilitate early and prompt treatment. Thus the surgeons and the anesthetists are brought to the patient. This procedure obviates the necessity of transporting the seriously wounded, who can ill afford added physical strain. Units of the theater of operations may be one hundred to five hundred miles from combat areas, and those in the zone of interior are located in this country. In both these echelons, medical specialists are available to perform elective or definitive surgery or both. In the named general hospitals, both the personnel and the equipment are not unlike those found in leading hospitals of this country. All types of medical services are adequately equipped with an anesthetic armamentarium for the duties that they are expected to carry out. No suffering need be experienced, for relief of pain may be provided anywhere from the battlefield to home stations. Table 3 briefly summarizes the type of anesthetic agents and equipment that may be found at the various medical services. Whereas

MEDICAL SERVICES	ASSIGNED ANESTHETIST	ANESTHETIC ARMAMENTARIUM	
		AGENTS	EQUIPMENT
Unit	No	Ether Ethyl chloride Morphine sulfate Atropine sulfate Procaine Ephedrine Barbiturates	Yankauer mask
Divisional	No	Same, except for Army-supported surgical hospitals (see below)	
Army	Yes	Same as above plus: Nitrous oxide Oxygen in tanks Chloroform Pentothal sodium Meperidine	Same as above plus: Pharyngeal airways Laryngoscopes Endotracheal tubes Apparatus for closed-system anesthesia Modified suction apparatus Oxygen masks Needles and syringes for spinal and block anesthesia
Theater of operations	Yes	Same as above plus: Cyclopropane in some theaters	Same as above plus: Other equipment depending on theater
Zone of interior	Yes	Same as above plus: Avertin Certain nonstandard items, such as Vincethene, Nupercaine, Pontocaine and so forth	Same as above plus: Suction apparatus Iron lung Oxygen masks and tents Nonstandard items such as continuous spinal anesthesia equipment and so forth

specialists. No equipment is lacking to provide the patient with safe, modern anesthesia. Owing to dynamic elements of combat, it is not possible to carry out in forward areas the anesthetic program that may be desired any more than it is possible to do ideal surgery in the battlefield. Safe and adequate anesthetic management, however, can be provided for the surgery that can and must be done. In Table 4, it can be noted that relief of pain and muscular relaxation or both can be accomplished even in the unit medical services for emergency surgical procedures, such as débridement, control of active external bleeding, application of painful splints and bandages, and the severing of a mangled limb. For major and more specialized surgery, done from the Army medical service to the rear, a

choice of agents and technics may be had depending on the patient, the surgeon and the surgery contemplated. Anything from simple premedication and local infiltration to closed-system en-

TABLE 4. *Anesthetic Management in the Medical Services.*

Medical Service	Type of Surgery	Anesthetic Management
Unit	Emergency	Emergency treatment: asphyxia, shock, relief of pain and anesthesia for minor surgery. Local infiltration or open drop technics
Divisional	Emergency	Essentially same on larger scale, except for Army supported units (see below)
Army	Emergency (general and specialized)	Local infiltration or block anesthesia Inhalation anesthesia—open-drop, closed-system and endotracheal technics Intravenous anesthesia Spinal anesthesia
Theater of operations	Elective and emergency	Same as above, except for advantages of better condition of patient and more complete anesthetic armamentarium
Zone of interior	Elective and definitive	Same as above plus nonstandard agents and equipment similar to those in leading hospitals of country

doctracheal anesthesia may be performed. Anesthetic management may thus be individualized and not routine. The same principles concerning contraindications of agents and technics, practiced by the civilian anesthetist will be adhered to at Army installations. The Army casualty will thus receive as good anesthetic management as does the civilian patient, if not better.

DISCUSSION

The history of the military anesthetist in this country has closely paralleled the rapid development of anesthesiology. It can conveniently be divided into three distinct eras: prior to 1863, when anesthetists were practically unheard of in civilian and military hospitals; from 1863 to 1919, when the few anesthetic agents and technics known to anesthetists were employed in military installations⁸; and from 1919 to 1943, during which time anesthesiology became established and accepted as a medical specialty by the American Medical Association,⁹ and during which the Army designated the Section on Anesthesia and Operating Pavilion in station and general hospitals¹⁰ and authorized the status of an officer for an anesthetist in charge of such a section. The progress of the civilian anesthetist in the latter interval has been tremendous and far-reaching in its influence on military anesthesia. Aside from the introduction of new agents such as cyclopropane, Vinethene, Pentothal Sodium, avertin, Metycaine and Pontocaine and procedures such as the Waters¹¹ closed carbon-

dioxide absorption system of anesthesia, endotracheal and endobronchial technics, intravenous anesthesia (Lundy¹²), regional anesthesia (Labat¹³) and continuous spinal¹⁴ and caudal¹⁵ anesthesia, there developed a keen and thorough appreciation of the fundamental physiologic, pharmacologic and anatomic principles underlying all anesthetic management. The present-day military anesthetist has kept abreast of the progress of his civilian confreres and is infinitely better prepared to function in his surgical unit than were his predecessors.

Notwithstanding the fact that the Army anesthetist is indispensable in military hospitals, there is still a shortage of such personnel on active duty. Some³ have believed that there is an inadequate number of trained civilian anesthetists. Perhaps one of the reasons to account for the shortage of such trained men was the former lack of an organized training program for medical students, interns and residents. This, however, has been overcome by teaching outlines and laboratory and clinical investigations already published and available to all who are interested. It is more probable, however, that because anesthesiology per se is a relatively new medical specialty, some hospitals and medical schools have been reluctant to accept it as such. If true, this is a sad commentary on medical leadership, for anesthesia is a true American contribution to medicine. This situation seems to present a professional if not a patriotic challenge to those institutions still lacking modern organized departments of anesthesiology. With such departments in hospitals and medical institutions, competent anesthetists could be trained in large numbers for urgent military and civilian needs, and some of the current considerations of the Army anesthetist would be greatly minimized. His role in providing the safest and most modern anesthesia for military casualties would be even more significant than it now is.

SUMMARY

The military anesthetist has contributed significantly to the prompt and efficient service of the medical department of the Army. Whereas his current considerations have been many and quite diverse from those of his civilian confreres, he has materially aided the function of his surgical unit. Some of his problems and functions have been briefly summarized.

MEDICAL PROGRESS

THE GRAVE INFECTIONS OF THE HAND

MAJOR J. EDWARD FLYNN, M.C., A.U.S.*

BOSTON

LYMPHANGITIS, acute suppurative tenosynovitis and deep fascial-space abscess have been well named the grave infections of the hand. Any review of these conditions must be considered on an anatomic, clinical and therapeutic basis.

LYMPHANGITIS

Lymphangitis is an inflammatory process of the lymphatic vessels. Knowledge of these vessels dates from the time of Aristotle, but Herophilus and Erasistratus (circa 400 B.C.) deserve credit for discovering the chyloferous vessels. In 1622, Aselli discovered the lacteal vessels, and in 1651, Pecquet first described the receptaculum chyli and the thoracic duct. In 1651, Rudbeck discovered that the lymphatics of the intestines carried chyle to the liver. In 1664, Swammerdam discovered the valves of the lymphatics. In 1787, Mascagni published his atlas of the lymphatic vessels. About one hundred years later, in 1876, after twenty years of investigation, Sappey¹ published his exhaustive atlas. Sappey's anatomic descriptions form the basis of the modern concept of the lymphatic system. Little progress has been made in the knowledge of the anatomy of the lymphatics in the past sixty-seven years.

There are two types of lymphangitis, deep and superficial. Deep lymphangitis involves the deep lymphatic vessels, which are found in the deep tissues in association with the deep blood vessels. Superficial lymphangitis involves the superficial vessels, which arise in the skin. The collecting trunks of superficial lymphatics run in the subcuticular tissue. A knowledge of the anatomy of

the lymphatics is basic for the proper understanding of the clinical aspects and treatment of lymphangitis.

The deep lymphatics follow the brachial artery and its chief branches, usually with two lymphatic trunks for each artery. The deep lymphatics of the upper extremity may be divided into radial, ulnar, anterior interosseous, posterior interosseous and humeral. The radial trunks drain lymph from the part supplied by the deep volar arch and the superficial palmar branch of the radial artery. They ascend the forearm as far as the bend of the elbow. The ulnar trunks drain lymph from the part supplied by the superficial volar arch and the deep and dorsal branch is the ulnar artery. The anterior interosseous and posterior interosseous lymphatics follow the arteries of the same names. The humeral trunks are two to three in number. They run by the side of the brachial artery and terminate in the humeral chain of axillary lymph nodes.

The superficial lymphatics of the fingers consist of volar and dorsal networks that converge into trunks at the side of the fingers. The digital trunks reach the base of the fingers in the interdigital space and traverse the dorsal aspect of the hand to the wrist. The network of superficial lymphatics of the palm drain into trunklets that divide into external, internal, inferior, superior and central vessels. In the wrist there are two groups, volar and dorsal. The superficial lymphatics diminish in number as they go up the arm. Sappey¹ states that they number about thirty in the forearm and from fifteen to eighteen in the middle of the arm. In the forearm, the volar vessels divide into three groups—external, internal and median. In this part the volar lymphatics are more numerous than the dorsal lymphatics. In the arm, the trunks unite into a single bundle on

The articles in the medical-progress series of 1941 have been published in book form (*Medical Progress Annual*, Volume III, 678 pp. Springfield, Illinois: Charles C. Thomas, 1942. \$5.00).

the external surface. The majority of collecting vessels terminate in the axilla in the humeral chain of axillary nodes. Two or three of the most internal end in the epitrochlear lymph node. The efferent vessels of this node perforate the deep fascia in the middle of the arm and end in the deep vessels. When this gland is absent, the internal collecting vessels may perforate the fascia at the same point to reach the deep absorbing vessels. The most external trunk separates itself from the other collecting vessels in the region of the humeral insertion of the deltoid and ascends in the deltopectoral groove, where it may traverse one or several nodes. This trunk usually passes into a subclavian node, placed at the spot where the cephalic joins the axillary vein. Mascagni says that it may pass above the clavicle and empty into the supraclavicular node. Grossman states that this latter arrangement occurs in 38 per cent. of cases.

Lymphangitis was recognized in the earliest stages of surgery. Kanavel,³ however, reiterates the importance of differentiating lymphangitis from other grave infections of the hand, and stresses the need to distinguish deep from superficial lymphangitis. With deep lymphangitis there is usually a rapid increase of swelling of the whole hand and forearm, with some red lines running up the arm. Superficial lymphangitis usually lacks the rapid and great swelling of the entire hand and forearm. There is generally a history of abrasion of the hand. Red streaks are found extending up the arm. Kanavel emphasizes that with lymphangitis there is an absence of pain on hyperextending the finger and thumb, absence of tenderness over the tendon sheaths, voluntary movement of the fingers without pain, absence of bulging of the palm and absence of tenderness over the midpalmar and thenar spaces.

Until seven years ago, therapeutics in lymphangitis was based on the surgical principles of general rest, local rest, elevation of the part to facilitate lymphatic and venous drainage, local heat, proper diet, elimination and sedation. The specific treatment of lymphangitis dates from 1936, when Protosil, synthesized by Mietzsch and Klarer,⁴ proved by Domagk⁵ to be effective against the hemolytic streptococcus in mice, was shown by Colebrook and Kenny⁶ in their work on puerperal sepsis to be a potent chemotherapeutic agent in man.

Sulfanilamide, sulfapyridine, sulfathiazole and sulfadiazine have been used for lymphangitis. Many surgeons prefer sulfadiazine. When used in the proper dosage—4 gm. initially, 1 gr. every four hours for the first twenty-four hours and 1 gr. every six hours until the temperature remains normal for twenty-four hours—a blood level of

7 to 10 mg. per 100 cc is reached within six to eight hours, and is easily maintained. This blood concentration is adequate for bacteriostasis of the hemolytic streptococcus and *Staphylococcus aureus*, the organisms commonly found in lymphangitis. Clinically, sulfadiazine has the added advantage of being only slightly toxic.

Local measures designed to wall off and overcome the infection, together with procedures designed to support the system and increase its resisting power and to eliminate toxins, are necessary. In cases of lymphangitis until localization is present, warm moist dressings should be used and hospitalization should be insisted on, with local and generalized rest, together with cathartics, maximum fluid intake and sedatives.

Warm moist boric acid dressings are used locally. Such applications owe their value to the hyperemia caused by the moist heat rather than to the drug, although there is some evidence that the latter's chemical action is of value. The arm is placed on a sterile towel, and sterile dressings wet with a warm saturated solution of boric acid are applied. The dressings are covered with rubber sheeting and the rubber sheeting is enveloped in towels. Two perforated rubber tubes are inserted in the gauze pack, through which warm boric solution may be introduced every two hours. The heat is maintained by the use of hot-water bottles. In severe cases the dressings are applied to cover the entire arm and shoulder. The dressings should always be larger than the area involved in the infection.

Hospitalization and local and systemic rest should be insisted on, especially in severe infections. Immobilization is necessary because every movement of muscles of the fingers, hand, forearm and arm favors lymphatic circulation and dissemination of infection. The hand and arm should be elevated on pillows to provide for proper lymphatic drainage.

Incisions for lymphangitis should never be made except in the presence of abscess formation. Such incisions open new lymphatics for infection and fail to reach bacteria that have already entered the lymphatic stream.

Seriously ill patients should be given much fluid and small amounts of easily digested food. Large amounts of water or fluid by mouth are necessary. Fluids are of great value in diluting and eliminating toxins. Occasionally, intravenous saline and intravenous glucose solutions and blood transfusions are indicated.

The complications of lymphangitis are subcuticular abscess, lymph-node abscess, subpectoral abscess, suppurative tenosynovitis, subclavicular and shoulder abscess, septicemia and pyemia, and chronic or repeated infections.

MEDICAL PROGRESS

THE GRAVE INFECTIONS OF THE HAND

MAJOR J. EDWARD FLYNN, M.C., A.U.S.*

BOSTON

LYMPHANGITIS, acute suppurative tenosynovitis and deep fascial-space abscess have been well named the grave infections of the hand. Any review of these conditions must be considered on an anatomic, clinical and therapeutic basis.

LYMPHANGITIS

Lymphangitis is an inflammatory process of the lymphatic vessels. Knowledge of these vessels dates from the time of Aristotle, but Herophilus and Erasistratus (circa 400 B.C.) deserve credit for discovering the chyliferous vessels. In 1622, Aselli discovered the lacteal vessels, and in 1651, Pecquet first described the receptaculum chyli and the thoracic duct. In 1651, Rudbeck discovered that the lymphatics of the intestines carried chyle to the liver. In 1664, Swammerdam discovered the valves of the lymphatics. In 1787, Mascagni published his atlas of the lymphatic vessels. About one hundred years later, in 1876, after twenty years of investigation, Sappey¹ published his exhaustive atlas. Sappey's anatomic descriptions form the basis of the modern concept of the lymphatic system. Little progress has been made in the knowledge of the anatomy of the lymphatics in the past sixty-seven years.

There are two types of lymphangitis, deep and superficial. Deep lymphangitis involves the deep lymphatic vessels, which are found in the deep tissues in association with the deep blood vessels. Superficial lymphangitis involves the superficial vessels, which arise in the skin. The collecting trunks of superficial lymphatics run in the subcuticular tissue. A knowledge of the anatomy of

the lymphatics is basic for the proper understanding of the clinical aspects and treatment of lymphangitis.

The deep lymphatics follow the brachial artery and its chief branches, usually with two lymphatic trunks for each artery. The deep lymphatics of the upper extremity may be divided into radial, ulnar, anterior interosseous, posterior interosseous and humeral. The radial trunks drain lymph from the part supplied by the deep volar arch and the superficial palmar branch of the radial artery. They ascend the forearm as far as the bend of the elbow. The ulnar trunks drain lymph from the part supplied by the superficial volar arch and the deep and dorsal branch is the ulnar artery. The anterior interosseous and posterior interosseous lymphatics follow the arteries of the same names. The humeral trunks are two to three in number. They run by the side of the brachial artery and terminate in the humeral chain of axillary lymph nodes.

The superficial lymphatics of the fingers consist of volar and dorsal networks that converge into trunks at the side of the fingers. The digital trunks reach the base of the fingers in the interdigital space and traverse the dorsal aspect of the hand to the wrist. The network of superficial lymphatics of the palm drain into trunklets that divide into external, internal, inferior, superior and central vessels. In the wrist there are two groups, volar and dorsal. The superficial lymphatics diminish in number as they go up the arm. Sappey¹ states that they number about thirty in the forearm and from fifteen to eighteen in the middle of the arm. In the forearm, the volar vessels divide into three groups—external, internal and median. In this part the volar lymphatics are more numerous than the dorsal lymphatics. In the arm, the trunks unite into a single bundle on

The articles in the medical-progress series of 1941 have been published in book form (*Medical Progress Annual*, Volume III, 678 pp. Springfield, Illinois: Charles C Thomas, 1942. \$5 00).

bloodless field is obtained by constricting the arm with a blood-pressure cuff inflated to 250 mm. The arm is elevated for one minute as soon as the patient is relaxed, and the blood-pressure cuff is inflated while the arm is still elevated. The arm

angers the vessels and nerves and may lead to herniation of the tendons.

Recently, Auchincloss¹⁰ has suggested the use of a truncated flap incision including all tissue down to the tendon sheath. In this incision, the distal

FIGURE 1. Incisions for Draining Infected Tendon Sheaths, Radial and Ulnar Bursas, Spaces in Wrist and Forearm. (Reproduced by permission of Surgery, Gynecology and Obstetrics.¹⁴)

The dotted lines represent rarely used incisions.

is then lowered, and a bloodless field can be maintained until the operation is completed. Only by good visualization can injuries to blood vessels and nerves be avoided, recognition of the site and extent of involvement be made, and adequate incisions with minimum injury be performed.

Surgically, Helferich,¹⁷ over fifty years ago, showed the need for an adequate incision of the involved sheath. Incisions should drain every pocket of pus. Until about 1930, it was common to make interrupted incisions over the medial and lateral aspects of the proximal and middle phalanges. These incisions have been discarded because drainage was incomplete, secondary incisions were required in too many cases, and the incidence of tendon slough was too great. It was also common to make medial or lateral incisions from the base of the distal phalanx to the level of the proximal volar digital crease, anterior to the digital vessels and nerves. These incisions are condemned because they necessitate cutting across the volar digital crease, and this procedure en-

ends is cut along the flexion crease. The medial and lateral parts of the flap are cut obliquely downward, the digital vessels and nerves being avoided, and the incision is extended nearly to the next proximal crease. The incision has been made over the proximal and middle closed spaces. Rubber tissue and thread have been used for post-operative drainage. It affords excellent exposure of the sheath, but the subsequent sloughing of tendons is often great, and the exposure of the tendon may be too extensive. Also, a rolling backward and sloughing of some of the distal part of the flap sometimes occurs, which delays healing.

Some knowledge of the underlying anatomy is basic for correct surgical treatment. The proper digital arteries are slightly posterior to the digital nerves, and are found at the level of the anterior third of the medial and lateral aspects of the fingers.

Auchincloss has shown that the digital arteries give off branches that form an anastomotic

arch of blood vessels in the anterior subtendinous space. This arch gives off vessels to supply the bone, the synovial membrane of the joint and the tendon sheath, and the tendon itself. The tendon receives its branches through the mesotendon or so-called "ligamenta brevis."

In my experience,¹¹ the lateral incision has proved of the greatest value. It extends from the distal crease to the proximal volar crease (Fig. 1). The incision is posterior to the lateral extensions of the volar transverse creases and posterior to the digital vessels and nerves. The only objection to it is that it involves cutting the branch from the digital artery that makes up part of the anastomotic arch of blood vessels in the anterior subtendinous space, from which the mesotendon is supplied. This small cut branch, however, is not an end artery, and anastomotic circulation from the other side appears to be adequate to nourish the tendon sheath and tendon. In almost all cases of septic tenosynovitis of the flexor tendons of the index, middle and ring fingers it is necessary to drain the palmar portion of the tendon sheath. This is accomplished by a longitudinal incision from the base of the proximal digital crease, which is carried about 2 cm. proximally into the palm. The incision is begun on the same side of the digital crease as the digital incision.

In the surgical treatment of infections of the little finger tendon sheath and the palmar portion of the ulnar bursa I¹⁴ use the following steps. A longitudinal incision is made over the lateral aspect of the little finger, posterior to the digital vessels and nerves and to the lateral extensions of the volar digital creases (Fig. 1). The palmar prolongation of the tendon sheath is drained by making an incision 2 cm. long from the center of the volar aspect of the proximal digital crease into the palm. The palmar portion of the ulnar bursa is drained by an incision extending from a point just proximal to the distal transverse crease in the palm to about the apex of the triangle in the base of the palm. The incision is made over the lateral edge of the hypothenar eminence. The digital branches of the ulnar nerve about 2 cm. proximal to the metacarpophalangeal joint, the anastomotic branch of the ulnar nerve to the median nerve and the ulnar artery about 1.5 cm. distal to the distal edge of the volar carpal ligament must be identified and medially retracted.

In the surgical treatment of infections of the thumb, a position of abduction of the thumb should be assumed to obviate anatomic distortion, particularly of nerves. I¹⁴ use a longitudinal incision from the base of the distal phalanx to the base of the thumb on the ulnar side (Fig. 1). The palmar incision is a separate one that starts at

about the middle of the proximal volar crease, just below the center of the volar aspect of the thumb. The incision is carried over the medial aspect of the thenar eminence, about two thirds of the distance to its base. The sensory and motor branches of the median nerve must be identified and retracted. At about the middle of the first metacarpal bone, a branch of the median nerve divides to send sensory branches to the medial and lateral aspects of the thumb. The important motor nerves to the opponens pollicis, abductor pollicis brevis and lateral portion of the flexor pollicis brevis, which rotate the thumb, arise from the median nerve, usually about 1.5 cm. proximal to the digital branches. The portion of the radial bursa proximal to where the nerves to the thenar muscles are found is not drained unless the volar carpal ligament is cut. The distal three fourths of the volar carpal ligament was cut in 2 cases in the series, not to expose the radial bursa but to avoid injury to the median nerve and flexor tendons. Incisions through the entire volar carpal ligament, as suggested by some surgeons should not be made because of exposure of the tendons and their prolapse.

Auchincloss¹⁹ stressed the fact that accumulations of pus in the radial and ulnar bursas in the wrist may rupture into the space bounded posteriorly by the pronator quadratus muscle and anteriorly by the flexor digitorum profundus and flexor pollicis longus tendons. From the wrist pus spreads up the forearm into the space bounded anteriorly by the flexor digitorum sublimis and posteriorly by the flexor digitorum profundus and flexor pollicis longus.

Various anterior, medial and lateral incisions have been described, but any incision into these spaces must be made with due regard for the underlying vessels and nerves. If both the ulnar and radial bursas are involved, or if pus has ruptured into the pronator quadratus space in the wrist, an incision on the ulnar side of the wrist may be adequate. I¹⁴ prefer an incision 6 cm. long over the anterior surface of the ulnar about 2 cm. above the styloid of the ulnar (Fig. 1). The approach is behind the flexor carpi ulnaris muscle and ulnar vessels. When the deep fascia is incised, the bulging ulnar bursa may be seen in the wound.

If the radial bursa alone is involved, an incision over the radial side of the wrist is made. A 6-cm. incision is made over the volar lateral aspect of the radius, as close to the bone as possible and posterior to the radial artery. When the deep fascia is incised, the bulging radial bursa may be seen in the wound.

Most infections from the wrist tend to spread up the ulnar side of the forearm, where most of the flexors are found. With infections of the intermuscular space of the forearm, a 6 cm. incision is made between the flexor carpi ulnaris and the ulnar margin of the flexor digitorum sublimis. The ulnar margin of the flexor digitorum sublimis is retracted laterally, and the space between it and the flexor digitorum profundus is entered by blunt dissection toward the latter. Great care should be taken not to injure the ulnar nerves and vessels that are adherent to the undersurface of the flexor digitorum sublimis.

An incision over the ulnar surface of the forearm, together with the wrist incisions, is usually adequate. With extensive accumulations of pus, however, an incision is made over the radial side of the forearm. The incision is about 6 cm long at the middle third of the forearm and is made along the outer edge of the flexor carpi radialis. At this point, the lateral edge of the flexor digitorum sublimis muscle can be identified and retracted inward and the space entered by blunt dissection. The approach is internal to the radial artery.

Postoperatively, the infected hand is elevated on a pillow at all times to facilitate venous and lymphatic drainage. During the stage of acute infection, the hand and wrist are immobilized in an aluminum splint in the so called "position of function." If treatment is prolonged, this position favors early and satisfactory use and provides fixation in a useful position if disability ensues. The fingers are semiflexed, the wrist is dorsiflexed, the hand is extended in the cocked-up position, and the thumb is abducted and rotated so that its flexor surface is opposite that of the index finger. With the fingers and hand in the position of function, even though tendons may be lost or ankylosis ensues, a fair degree of function results. It is strongly advised to permit no motion until infection is controlled. With a sloughed tendon, however, in the absence of osteomyelitis or septic arthritis, the joints may be manipulated to prevent adhesions and to permit future tendon grafting. Warm, moist dressings are applied under aseptic conditions. If the incisions are adequate, rubber-tissue drains may be omitted in twenty-four to forty-eight hours. Hospitalization until the infection subsides is of paramount importance.

Sulfonamides are administered, sulfadiazine being the drug of choice. Since the advent of sulfonamide treatment in purulent tenosynovitis there has been no great decrease in the incidence of tendon slough. This is apparently due to the time factor. With septic tenosynovitis existing for forty-eight to seventy-two hours, it is obvious that the sulfonamides cannot be a great factor in

correcting physiologic changes that have occurred in blood vessels, pathologic changes in the involved tissues or mechanical changes in the tendon sheaths. Despite the fact that there has been no appreciable change in the incidence of sloughed tendons with sulfonamide therapy, there has been a decided decrease in the incidence of other severe complications in septic tenosynovitis.

DEEP FASCIAL-SPACE ABSCESS

The fascial and aponeurotic strata of the hand, especially in their formation of important surgical spaces, have been inadequately or improperly described in textbooks and the anatomical literature up to the time of Kanavel.

Kanavel,⁹ after multiple dissections and injections, described the deep fascial spaces—that is the midpalmar and thenar spaces. He stated that these two spaces are separated in the palm by a fascial septum that arises from the undersurface of the flexor tendon of the middle finger and fuses with the fibrous tissue overlying the middle metacarpal bone.

Brickel,²⁰ in 1939, stated that in all his dissections and injections he never found a special palmar septum extending from beneath the flexor tendons to the middle metacarpal bone, dividing the palmar space in halves. Thus, he stated, it is justifiable to discard the concept of a midpalmar space in favor of a broader interpretation of its boundaries, and to discard the term "thenar space" in favor of the term "abductor space, anterior and posterior." I believe that Brickel's observations and conclusions are wrong.

Anson and Ashley,²¹ in 1940, dissected many hands with special consideration of the fascial distribution. Their report, however, was inconclusive so far as the existence of the important surgical fascial spaces in the palm is concerned.

Because of the confusion concerning the existence of important surgical fascial spaces in the hand, I²² dissected 100 hands with special consideration of the fascial distribution. In all the cases there was a definite septum of fascia coming from the undersurface of the flexor tendon of the middle finger, which was attached to the entire length of the middle metacarpal bone. This septum divided the palm into two main fascial spaces, and in no case was it possible to insert a probe beneath the flexor tendons in the proximal half of the palm and move it from side to side without meeting obstruction. Furthermore, in no case was a direct communication between the midpalmar and thenar spaces found.

Anatomical dissection of the fascia of these hands revealed that there are definite midpalmar and thenar spaces. The midpalmar space extends

from the middle metacarpal bone ulnaward to the radial side of the metacarpal bone of the little finger. Anteriorly, this space is bounded by the flexor tendons of the middle, ring and little fingers, the third and fourth lumbrical muscles and the thin fascia that connects these tendons and muscles.

The posterior boundary or floor is formed by the fascia covering the second and third volar interosseous muscles and the third, fourth and fifth metacarpal bones. In the distal third of the floor, small compartments are formed, since septums coming from the undersurface of the palmar aponeurosis are attached to the fascia of the volar interosseous muscles. These small compartments communicate with the midpalmar space. The medial boundary is the fascia on the radial side of the hypothenar muscles. The lateral boundary is the midpalmar septum, which extends from the undersurface of the flexor digitorum profundus tendon of the middle finger to the middle metacarpal bone. Distally, the midpalmar space extends to about 2 cm. proximally to the webs. The distal boundary is composed mainly of fascial septums extending from the palmar aponeurosis to the floor of the space and to some transverse fasciculi. The proximal boundary is a thin fascial septum usually found at about the level of the proximal end of the transverse carpal ligament. Clinically, however, abscesses do not usually enter the carpal tunnel. This fact is probably due to tissue response to infections—that is, serous, cellular and fibrinous reactions.

The thenar space is bounded posteriorly by the adductor pollicis muscle. Medially, the boundary is the midpalmar septum, a thin fascia extending from beneath the flexor digitorum profundus tendon of the middle finger to the third metacarpal bone. Proximally, in all cases, this fascia, which is part of the adductor fascia, forms the boundary. This proximal boundary is found at about the level of the distal end of the transverse carpal ligament. The anterior boundary or roof is the thin layer of fascia formed as the midpalmar septum splits and courses laterally. In its lateral course this roof ensheaths the flexor tendons of the index finger to form part of the anterior boundary. The lateral boundary of the thenar space is formed by the thin fascia as it extends over the lateral edge of the adductor pollicis muscle and is attached to the dorsal aspect of this muscle. This distribution of fascia over the anterior, lateral and dorsal aspects of the adductor pollicis muscle clearly indicates why abscesses of the thenar space may extend to the posterior aspect of the muscle. The fact re-

mains, however, that abscesses of the space tend to remain anterior to the adductor pollicis muscle.

Bunnell²³ stated that the midpalmar septum is so thin it is of questionable surgical value. In all my dissections there was an involvement of midpalmar and thenar spaces in only 2 cases, and this occurred after extensive local necrosis in which even osteomyelitis was found.

The symptomatology and differential signs of deep fascial-space abscesses are well known. In thenar-space abscess, there is tenderness over the palmar aspect of the thenar space. In midpalmar-space abscess, there is tenderness over the palmar aspect of the midpalmar space. Swelling is significant. In midpalmar-space abscess there is obliteration of the concavity of the palm and a slight bulge over it. In thenar-space abscess there is usually a rapid increase in size of the thenar area: the tissues seem to balloon out from the radial longitudinal crease of the palm. In both infections there is usually great swelling over the dorsum of the hand. The position of the fingers is of some diagnostic value. The middle and ring fingers are flexed when the midpalmar space is involved. The index finger is usually flexed when the thenar space is involved. The temperature for each infection ranges from 100 to 104°F. Midpalmar space abscess is relatively rare.

Other attempts at description of the symptomatology of the deep fascial-space infections have been made in the past few years. These descriptions have added nothing but confusion. It should be repeated, however, that a definite diagnosis must be made from history and physical examination before surgery is attempted.

Various incisions have been made in thenar-space abscess. Some earlier surgeons made a through-and-through opening from the palm to the dorsum. This incision is to be deprecated. It is followed by contractures, deformities and deranged function, and often new channels for infection are opened. Incisions over the volar aspect of the thenar eminence may cut across the proximal transverse crease and cause later contractures. Kanavel³ was the first to show that adequate drainage can be obtained with an incision over the dorsum of the thumb-index web, and that a scar on the palm is thus avoided. Brickel²⁰ suggested an incision over the palmar edge of the first dorsal interosseous muscle. However, a large branch of the radial artery may be cut at the proximal end of the wound.

The incision for thenar-space abscess should drain pus, which may be found either volar to the abductor pollicis muscle or on both its volar and dorsal aspects. The incision of choice is made over the dorsum of the thumb-index web,

at the middle of a line drawn between the distal ends of the metacarpal bones of the thumb and index fingers, with the thumb in a position of abduction.

In midpalmar-space abscess various incisions have been used. Through-and-through incisions, employed by some surgeons even fifteen years ago, should be strongly condemned. If one remembers that the cellular tissue on the dorsum of the hand is loose, that edema of the dorsum is constantly found with infections involving the volar surface of the finger or palm, and that the lymphatics take the shortest route to the dorsum of the hand, a through-and-through incision will not be made. Spread of infection and contractures are certain to follow if an incision is made through the volar skin, midpalmar space, volar interosseous fascia, interosseous muscles, dorsal interosseous fascia, dorsal aponeurosis, subcutaneous tissue and dorsal skin.

Volar longitudinal incisions have been made, cutting across the proximal and distal transverse creases of the palm. These incisions are condemned because contractures follow.

Kanavel³ first suggested that a vertical incision be made between the middle and ring fingers or between the ring and little fingers, with the idea that such incisions in addition to giving direct access to the midpalmar space would afford more adequate drainage of an involved lumbrical space and be associated with less risk of injury to the digital nerves and blood vessels.

Bunnell²³ first emphasized the danger of contracture resulting from vertical scars. Such contractures are found when the incisions completely divide the web or when the incision is carried too far proximally in the palm. Various types of transverse incisions have been described.

The incision of choice for midpalmar space abscess is a transverse incision through the distal transverse crease or on a line parallel with the distal transverse crease, or over the center of convexity of the palm. This incision is carried transversely through the skin, superficial fascia,

and palmar aponeurosis. The digital vessels and nerves are identified and retracted with the flexor tendons. Usually a point between the flexor tendons of middle and ring fingers is entered. This latter incision is placed longitudinally through the thin subaponeurotic fascia between the flexor tendons, and enters the midpalmar space.

Sulfonamides, particularly sulfadiazine, are of value in decreasing the incidence and complications of deep fascial-space abscess.

Postoperatively, one must diligently adhere to elevation of the hand, splinting in a position of function, hospitalization with local and systemic rest, warm moist dressings under aseptic conditions, proper diet and adequate intake of fluid

CASE 29491

PRESENTATION OF CASE

A sixty-eight-year-old housewife entered the hospital because of chills and fever of forty years' duration.

About forty years before entry the patient began to have intermittent bouts of chills and fever. The chills were severe and shaking in character, lasted an hour and a half and were followed by fever and profuse sweating. They occurred two or three times a year and occasioned no alarm. No treatment was deemed necessary. She lived in New England at that time and had not been elsewhere. About eleven months before entry the chills increased in frequency, ranging between two times a week and once in ten days. The chills lasted up to an hour, were followed by fever of 104°F. and profuse sweats. The attacks were followed by prostration lasting for a day or two. During an attack the systolic blood pressure fluctuated between 210 and 110. Seven months before admission the patient went to Florida, where, during the course of one of the attacks, a physician found the blood "teeming with malarial parasites." She was given atabrine, sulfathiazole and barbitol without relief. She returned to New England. The symptoms persisted and seemed to increase in severity. Her family physician was unable to find any parasites in the blood.

Six months before entry the patient was noted to have jaundice. The urine was dark, but the stools were normal in color. It is not stated how long the jaundice lasted or how severe it was, but it gradually cleared up. For the four weeks preceding admission, the chills and fever occurred at weekly intervals. There had been a weight loss of 50 pounds in the past year. Some nausea and vomiting of watery material were present occasionally after chills, as well as a mild pain across the upper abdomen. There was occasional dysuria, and some low back pain. The patient was said to have lived "on an inadequate bland diet because of ulcers diagnosed ten years before

entry," but no additional information was available.

The patient had had a complete hysterectomy at thirty-seven for fibroids and a right radical mastectomy at fifty-four for carcinoma. Her father was said to have had a similar illness with severe shaking chills, aches and fever, which had been contracted in the South during the Civil War and was thought to be malaria. He died, however, from massive gastric hemorrhage.

Physical examination showed a well-developed and well-nourished woman lying quietly in bed. Numerous senile keratoses were seen below the breasts. The scars of the mastectomy and the hysterectomy were well healed. There was no superficial evidence of recurrence of the carcinoma. The pupils were round and equal and reacted to light and accommodation. The scleras were clear. There were tortuosity and narrowing of the fundal vessels, with arteriovenous nicking. The nasal septum was perforated, the hole being 0.5 cm. in diameter; the location of the perforation was not given. The lungs were clear. The heart was of normal size, the sounds were of good quality and regular. There were no palpable organs, masses or tenderness in the abdomen.

The blood pressure was 170 systolic, 70 diastolic. The temperature was 100.4°F., the pulse 88 and the respirations 20.

Examination of the blood showed a red-cell count of 4,360,000 with 12.8 gm. of hemoglobin. The white-cell count was 12,900 with 86 per cent neutrophils. A blood Hinton test was negative. The icteric index was 5. Repeated blood smears failed to show malarial parasites. The urine was light brown, with a specific gravity of 1.008 and a + test for albumin; the sediment showed occasional red cells, 8 white cells and 10 epithelial cells per high-power field. The culture was negative. The stools were light brown and guaiac negative. A stool culture was overgrown by a proteus bacillus.

X-ray examination of the chest showed the lung fields to be clear except for a small area of calcification in the region of the lower lung field. There was no evidence of metastatic cancer in the bones of the shoulder girdle. The diaphragm was smooth. The heart was not remarkable. An intravenous pyelogram was negative. Two Graham tests failed to show concentration of the dye in the gall bladder.

On the third hospital day an abdominal exploration was performed.

DIFFERENTIAL DIAGNOSIS

DR. CHESTER M. JONES: It has been a long time since I have read a case protocol that presents so

many points of uncertainty. I am sure that I cannot make an absolute diagnosis. There are many discordant statements, which make a diagnosis difficult. One is the fact that the patient's physician found her blood "teeming with malarial parasites." This was not substantiated, but the examination was done in the South where such procedures should be adequately carried out. Secondly, the patient had a previous history of cancer of the breast. Thirdly, the nasal septum was perforated. Whether these facts have any bearing on the present situation is a question. I am inclined to think they do not. It is hard to forget all of them, however. The physical examination, except for evidence of arteriosclerosis and a perforated septum, was absolutely negative. Nothing was felt or found on auscultation or inspection that gave a clue concerning the existence of organic disease. The only evidence is the story of chills and fever, plus the fact that on two x-ray examinations the gall bladder failed to fill with dye. It is hard to correlate this paucity of facts with a story of about forty years of chills and fever.

What are the things that could give chills and fever of that duration? Obviously chronic infection has to be considered. One may properly ask the question whether these episodes of chills and fever that had occurred for thirty-nine years were the same things that were occurring during the eleven months before entry. There is no reason for saying that they are not, but that is a long duration of episodes that are preceded by rigor. In 1900, malaria was prevalent in and around Boston. I do not know where this patient lived, but if she lived around the Charles River Basin at that time she could have had it.

DR. BENJAMIN CASTLEMAN: She lived on the North Shore.

DR. JONES: I am not at all sure that there was malaria at that distance from Boston, but the story of malaria for forty years does not ring true. The Florida physician who found the parasites was not able to control the chills and fever with atabrine, a drug that should have a definite action on the parasites. There is every indication that adequate doses of atabrine should control the chills and fever of malaria. Whether or not sulfadiazine would have been effective is a question. She had chills and fever here, and malarial parasites were looked for, both in the hospital and outside, but none were found. It seems to me that even if she had had malaria in the past, this disease was not the condition that was productive of the recurrent chills and fever that brought this woman eventually into the hospital. I am not

aware of any other parasitic manifestation that will cause recurrent chills and fever of this sort except amebiasis. It is conceivable that she might have had an amebic infestation followed by intrahepatic disease with abscess formation, which could have caused chills and fever for a long period of time. I do not know how far back a story of recurrent chills and fever on the basis of amebic abscess can go, but I know of one patient with an amebic abscess that caused symptoms twenty years after the original infestation. Here we have a story of chills and fever that began forty years ago and constantly recurred. It seems inconceivable to me that amebic abscess of the liver was the basis of the patient's difficulty. One fact that conceivably may help us here is that her father was in the Civil War and had something that caused diarrhea and chills, which also was thought to be malaria. Of course there was plenty of dysentery of the bacillary and amebic types in the Civil War. He might have been a carrier and contributed the source of the amebic infestation. I have no enthusiasm for that as a diagnosis in this case. The duration was too long, and after such a period it is surprising that there were no physical signs of liver involvement other than the fact that she was jaundiced on one occasion some months before she came into the hospital.

If it was not a parasitic infestation, was it a bacterial infection? What are the infections that persist for forty years and cause chills and fever? Osteomyelitis, undulant fever, tuberculosis and possibly endocarditis might cause chills and fever for a year prior to admission or perhaps a little longer, but hardly for forty years. We have no evidence clinically of tuberculosis, undulant fever or endocarditis. Chills and fever are sometimes due to an intermittent blockage of the ball-valve type of the ureter or renal pelvis causing hydro-nephrosis, or of the cystic or common duct. That does happen with ureteral stones, with a stone in the pelvis of the kidney and with gallstones either in the cystic duct near the ampulla of the gall bladder or in the common duct. Of course as a rule these are associated with attacks of pain, but I can recall certain patients with chronic cholecystitis and stones who, from time to time, had recurrent episodes of chills and fever without any pain whatever. We know that this patient had these symptoms for a long time. We also know that her father, with whom she presumably lived, was very sick with chills and fever and diarrhea during the Civil War. I do not want to draw too much on that lead. On the other hand, typhoid fever was frequent; he might have been a typhoid carrier, and she might have had

a mild attack of typhoid fever, with residual infection in the gall bladder. These are conceivable probabilities but not at all clear, and certainly I have a great deal of difficulty in accepting any as a logical explanation of what brought this patient to the hospital.

In trying to reconstruct this case it seems to me that of the possibilities I have mentioned, a stone in the gall bladder that occasionally went down into the cystic duct and caused obstruction to the flow of bile from the gall bladder and infection, possibly with cholangitis, might answer the requirements for a diagnosis going back forty years. It is entirely possible that she could have had a real cholecystitis at twenty-eight years of age. I am inclined to suggest that as the only reasonable explanation of this history. It is backed up by the two x-ray films in which the gall bladder failed to fill. If the test was done properly, and no evidence of duodenal ulcer, intrahepatic disease or diarrhea was present, then such findings mean a nonfunctioning gall bladder.

As a remote cause of recurrent chills and fever, one might mention recurrent thrombophlebitis. I do not believe that the patient had it. Similarly, I do not believe that the patient had liver abscess. The perforation of the nasal septum could have been due to syphilis; but the evidence is against it. It may have followed a submucous resection, which was a frequent occurrence some years ago. I do not believe this patient had metastatic cancer. It could not explain forty years of chills and fever, nor could it explain eleven months of chills and fever in the absence of physical signs anywhere. Therefore I shall abide by a diagnosis of cholecystitis with stones in the common duct.

CLINICAL DIAGNOSES

Charcot's intermittent hepatic fever.
Cholecystitis.

DR. JONES'S DIAGNOSES

Chronic cholecystitis.
Cholelithiasis.

ANATOMICAL DIAGNOSES

Chronic cholecystitis.
Cholelithiasis.
Choledocholithiasis.
Cholecyst-duodenal fistula.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: Dr. Roger I. Lee saw this patient before operation and his note reads, "History and findings strongly suggest Charcot's intermittent hepatic fever." Dr. Arthur W. Allen operated on this patient and I shall read part of his operative note.

The liver was slightly darker than normal. The omentum was adherent to the under surface of the liver. It was freed with some difficulty by sharp dissection. As the operative site was further developed it became apparent that there was a cholecyst-duodenal fistula. The gall bladder itself was of normal size but its wall was markedly thickened. The fistula measured approximately 2 cm. across. Before division of the wall of the fistula it was thought wise to expose and explore the common duct. The ampulla and cystic ducts were developed, and finally the common duct was exposed. The latter measured 2.5 to 3 cm. across, and its wall was 2 mm. thick. The duct was opened, and there was an immediate gush of thick bile and numerous, black, friable, mushy stones. The distal centimeter of duct was packed with this sediment. A generous opening was made in the duct, and the sediment was removed with a scoop. The duct was finally irrigated with saline through a catheter.

After it had been ascertained that the obstruction was of a benign nature, the cholecyst-duodenal fistula was dissected. A finger could then be inserted into the duodenum, and the ampulla was accurately identified. The common duct was probed with this exposure, and the ampulla admitted a 3-mm. dilator snugly. Dilation was carried out through the 9-mm. dilator. The left and right hepatic ducts were calibrated, the right duct admitting a 7-mm. dilator.

The gall bladder was next removed from above down. The cystic duct was only slightly dilated. A No. 16 T tube was then sutured into the common duct, and a watertight closure was accomplished. Finally the duodenal defect was closed transversely, using two rows of catgut, reinforced with a third row of interrupted cotton.

This patient, therefore, had chronic gall-bladder disease for forty years, and each time one or more stones entered the fistula a block occurred that caused chills and fever; when the stones went through into the duodenum, she was relieved.

DR. JONES: At one time there must have been a stone impacted in the cystic duct with empyema of the gall bladder, because the perforation into the duodenum must have occurred while the cystic duct was blocked.

DR. CASTLEMAN: She remained in the hospital three weeks following the operation, free from fever and chills, and then went home.

DR. JONES: Were the stones cultured?

DR. CASTLEMAN: Yes, and the cultures showed only colon bacilli.

CASE 29492

PRESENTATION OF CASE

First admission. A thirty-six-year-old American laborer was admitted complaining of pain in the chest.

About two years before entry, while lying in bed, the patient was suddenly seized with a severe pain in the left chest that radiated down the left

arm. The pain lasted about four hours and was very severe. At intervals thereafter he noted a vague sensation of pressure in the chest and moderate dyspnea on exertion. About two weeks before entry he had a severe attack of pain in the chest and left arm, which occurred during the night and lasted about an hour. The pain was less severe when he sat up, and was associated with a moderate amount of gaseous eructation. A sedative afforded relief and he was able to fall asleep. Shortly afterward he again awoke and voided a large amount of urine. On the following day he visited the Out Patient Department, where a general physical examination was said to be negative; the blood pressure was 135 systolic, 80 diastolic. A blood Hinton test was negative, and an x-ray film of the chest showed the lung fields to be clear. The heart was at the upper limit of normal in its transverse diameter and showed slight relative increase in the size of the left ventricle. The supracardiac shadow was normal, and the trachea was not displaced. An electrocardiogram was entirely negative. About a week before entry, in the afternoon while sitting at his work, the patient had another attack. This began as a sudden sensation of soreness in the left chest but was not severe enough to cause him to stop work. On his way home, however, he had a severe attack, during which he could do nothing but stand still for a minute or two. The pain at that time radiated down the left arm. He was compelled to take a taxi and on arriving home attempted to climb four flights of stairs, but was unable to do so. A physician administered some tablets that produced relief. The patient then tried to continue up the stairs but was compelled to stop frequently and finally succeeded in reaching his apartment after thirty-five minutes. He then lay down and went to sleep. The following morning he felt weak but was able to get up and go to work. During the succeeding week he had three minor attacks of chest pain and another very severe one, during which he entered the Emergency Ward. The last attack followed notification that his salary would be cut.

Examination showed a well-developed and well-nourished man lying flat in bed in no evident discomfort. There were no abnormal physical signs. The lungs were clear. The apex impulse of the heart was seen and felt in the fifth interspace in the midclavicular line. There were no murmurs.

The blood pressure was 120 systolic, 70 diastolic. The temperature, pulse and respirations were normal.

Examination of the urine was negative. The blood showed a red-cell count of 4,500,000, with a hemoglobin of 75 per cent. The white-cell count

was 8800, with 71 per cent neutrophils. The stools were essentially negative. An electrocardiogram showed a PR interval of 0.16 second with normal rhythm; T₁ was low and slightly inverted, T₂, T₃ and T₄ were upright, and Q₁ was present. A Graham test and a gastrointestinal series were negative.

Six days later another electrocardiogram showed a late inversion of T₁; T₂ and T₃ were upright, with a slightly high origin. The patient's condition remained good through his hospital stay, and on bed rest he exhibited no discomfort. On the twentieth hospital day another electrocardiogram showed a slightly low T₁, which, however, was practically within normal limits; T₂, T₃ and T₄ were upright, T₁ was diphasic, and Q₁ was markedly shortened. He was discharged on the twenty-fourth hospital day.

Second admission (one and a half months later). The patient was followed in the Out Patient Department, where he complained of recurrent attacks of vague pain, always following mild exertion. The pain occurred in the left chest and frequently radiated down the left arm. An electrocardiogram taken two weeks after discharge showed a low T₁, an upright T₄ and an M-shaped QRS₁. One and a half months after discharge he was seized with substernal pain that was much severer than usual. It lasted for about an hour and was replaced by a dull constant ache in the chest and left arm. He went to sleep afterward and was suddenly awakened by a severe upper retrosternal squeezing pain even severer than the previous pain. There was an aching sensation in the left arm and jaw, and a splitting headache, and the patient was unable to lie back without aggravating the pain in his chest. He was placed in a taxi and immediately brought to the Emergency Ward.

Physical examination was again essentially negative. The heart was not enlarged but the sounds were distant in character.

The blood pressure was 110 systolic, 90 diastolic. The temperature was normal. The pulse and respirations were not recorded.

The blood showed a white-cell count of 10,000. He continued to have substernal pain and vomited once after entry. Four hours later a few in constant rales were heard at the bases of the lungs, but there was no change in his condition. The temperature remained normal. Although no significant change had been noted in his general condition, the patient suddenly died eight hours after entry.

DIFFERENTIAL DIAGNOSIS

DR. CONGER WILLIAMS: This case concerns a man of thirty-six with a history of recurrent at-

tacks of severe pain in the chest radiating down the left arm. He ultimately died, following one of the attacks two years after the onset of symptoms. In spite of the age of the patient the diagnosis of coronary heart disease with angina pectoris and myocardial infarction seems the best possibility. The pain was located in the left chest during the first few episodes but was later described as recurring in the substernal region. The pain of coronary insufficiency or myocardial infarction is usually located in the sternal region but may occur to the right or the left of it.

The negative findings on physical examination and electrocardiogram the day following the first attack do not exclude either myocardial infarction or coronary insufficiency. On admission to the hospital two weeks later, after recurrent episodes of pain in the chest and arm, the electrocardiogram was definitely abnormal, with an inverted T wave in Lead 1 and a Q wave in Lead 4. Six days later the T wave in Lead 1 was more deeply inverted. These electrocardiographic changes, especially the presence of a Q wave in Lead 4, are practically diagnostic of myocardial infarction, provided that the Q wave was of significant size. It would be helpful to see the electrocardiograms in this case, but they are not available. Apparent changes in the QRS complexes toward a more normal pattern during the first admission do not necessarily point against the diagnosis, since such changes may occur with minor differences in placing of the chest electrode at the apex. Furthermore, the T wave in the apical lead may be upright in an anterior infarction, with significant changes occurring either to the right or to the left of the apex.

I believe that at the time of the first hospital admission the patient had had several episodes of coronary insufficiency and probably at least one myocardial infarction. In the interval between admissions pain was present only on effort, further evidence in support of a diagnosis of coronary heart disease. The patient died eight hours after the onset of the final episode with symptoms suggesting myocardial infarction. His sudden death can therefore be explained by the onset of ventricular fibrillation.

Another possibility that must be considered is rupture of one of the coronary arteries, with death resulting from acute pericardial tamponade. Death does not necessarily occur immediately, but may follow in several hours, depending on the size of the break. The blood-pressure change, with the low systolic pressure and a narrow pulse pressure, is consistent with such a diagnosis, but no mention was made of dyspnea or distended neck veins, although the latter finding might have been missed after admission. Myocardial rupture must

also be considered, but is most unusual only eight hours after the onset of an infarction.

There are several other possibilities, but I believe that coronary heart disease with recurrent myocardial infarction and angina pectoris is the only diagnosis that fits all the findings. Dissecting aneurysm of the aorta can produce pain of this type, but repeated episodes over a period of two years are hardly in keeping with the nature of the lesion, and the absence of hypertension is against it. Syphilitic aortitis with narrowing of the mouths of the coronary arteries may produce coronary insufficiency at an early age, but it is hardly in keeping with a history of prolonged episodes of pain suggesting infarction. Furthermore, the blood Hinton test was negative. The nature of the pain does not suggest saccular aneurysm of the aorta, and negative x-ray films dispose of this suggestion.

Other possibilities that might be considered briefly are mediastinal emphysema, pneumothorax and pulmonary embolism, but there is no evidence to support any of these diagnoses. Thus, I am left with only the diagnosis of coronary heart disease. Because of the patient's age one should raise the question of a systemic disease that produced involvement of the coronary arteries as one of its manifestations. Occasionally such a condition accounts for involvement of the coronary arteries in young people. Syphilis has already been considered and rejected. Xanthomatosis is a possibility, but no mention was made of splenic or hepatic enlargement, the blood cholesterol level was not studied, and no skin nodules were reported. Periarteritis nodosa and Buerger's disease are other conditions to be considered, but again there is no supporting evidence.

CLINICAL DIAGNOSES

- Coronary thrombosis.
- Coronary heart disease.

DR. WILLIAMS'S DIAGNOSES

- Coronary heart disease with myocardial infarction (? anterior).
- Ruptured coronary artery with pericardial tamponade?
- Angina pectoris.

ANATOMICAL DIAGNOSES

- Coronary thrombosis, recent, right.
- Coronary thrombosis, old, left descending and circumflex branches.
- Myocardial infarction, old.
- Myocardial fibrosis.
- Arteriosclerosis, marked, coronary and aortic.
- Hydrothorax, slight, bilateral.
- Pulmonary edema.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: This patient did have severe coronary heart disease. Both main vessels were markedly atherosclerotic and calcified. There was an old thrombotic occlusion 3 cm. in length beginning a few millimeters beyond the origin of the left main coronary artery and another similar occlusion of the left circumflex branch near its origin. Most of the blood supplying the heart, therefore, must have been coming via the right coronary artery. This vessel was markedly narrowed in a few places but still patent except for one point about 4 cm. from its origin

where there was a recent thrombus completely occluding the lumen. This was undoubtedly the cause of the last substernal attack that led to death. There was an old myocardial infarct involving the septum and anterior wall of the left ventricle, and scattered small foci of fibrosis in the rest of the heart, but no definite evidence of acute infarction. Eight hours is too short a period for one to be absolutely sure of changes in the myocardial fibers, and unless numerous sections were taken from various parts of the heart, a small area of acute infarction might be missed. The heart weighed only 325 gm. and was not hypertrophied. There was no hemopericardium

EPIDEMIC INFLUENZA

EACH fall and winter following mobilization for this war there has been an increasing expectancy and uneasiness concerning the possibility of a recurrence of a pandemic of influenza similar to what occurred in 1918. This anxiety stems from the natural fear that such a pandemic might again take a tremendous toll of human life both in and out of the armed forces and that, in addition, it might so cripple temporarily both the battle and production fronts that it would necessitate alterations in the present schedules aimed at the successful termination of the war at the earliest possible date. Furthermore, all those concerned

are only too well aware of the unhappy fact that although much has been learned about the etiology of influenza since 1918, little specific information has been acquired that offers hope of altering in any way the course of such an outbreak or even much hope of altering the outcome in individual cases.

During the past decade viruses have been recovered from circumscribed epidemics of influenza. The commonest of these is designated as influenza A, and another is called influenza B. A third and related virus has been isolated from swine during an epizootic of influenza in this species. The characteristics of these viruses are now fairly well known. It is not known, however, whether these viruses are in any way related to the causative agent of the pandemic of influenza of 1918.

The last epidemic of influenza of any significant proportions occurred during the fall and winter of 1940-1941. At that time, influenza A was found to be the infecting virus in many parts of the United States, as well as in other countries.^{1,2} Similar outbreaks occurring in various parts of Canada have been studied since that time. Two of the latter have been identified as due to influenza A and one as probably due to influenza B.^{3,4} In one of the recent outbreaks of influenza A infection, vaccination with this virus was found to be totally ineffective as a prophylactic measure. All the outbreaks that have been studied since the new viruses were discovered have been relatively mild and have been associated with an extremely low mortality. In view of the fact that epidemics of influenza are prone to recur at two-year to three-year intervals, it is not unreasonable to expect an outbreak in this country during the present season.

A number of considerations lead one to believe that any epidemic in the near future is likely to be much less severe than was the pandemic of 1918. This, of course, is only speculation but is based on significant observations. In the first place, the influenza of the last war, at least in the Army camps from which complete reports are

available, was associated with a high mortality, but the deaths were accounted for chiefly by complicating pneumonias, in which the hemolytic streptococcus was the organism most frequently encountered. Other organisms, including the Pfeiffer bacillus and *Staphylococcus aureus*, were also involved. A similar high mortality accompanied the epidemics of measles that occurred in the same Army camps, and the mortality from this disease was also attributable chiefly, if not entirely, to the complicating hemolytic-streptococcus pneumonias.

During the 1940-1941 influenza outbreak, the staphylococcus played an important role in the complicating pneumonias, both in Boston and elsewhere.^{1,2} The results of intensive treatment of the complicating pneumonias with sulfadiazine and sulfathiazole were quite encouraging, and it was suggested that, should another outbreak of influenza occur, it might well prove useful to employ these sulfonamides in severe cases. This was particularly advocated in patients with severe prostration who had the signs or symptoms of tracheo-bronchial and pulmonary involvement, especially those in whom bacteriologic examination of the sputum had revealed the presence of hemolytic streptococci and staphylococci in appreciable numbers. In such cases, intensive treatment begun early and continued from three to five days might be expected to prevent an appreciable number of the fatal pulmonary complications. More prolonged therapy would be necessary, however, if the bacterial infection had already become established.

Another encouraging omen, which possibly has a more direct bearing, comes from the recent reports concerning measles. During the past year, outbreaks of this disease have occurred in the Army, but deaths from this cause have been rare.³ The low mortality may be directly attributable to the widespread use of sulfonamide drugs in all cases having pulmonary complications, and it is not unreasonable to expect a similarly low fatality

rate from influenza occurring under like circumstances.

From recent observations, particularly those made in the 1940-1941 epidemic, one may also expect that the staphylococcus will play a considerably greater role than in any of the previous epidemics. The increased frequency with which this organism is being encountered in complications of other respiratory diseases, as well as in surgical conditions, strengthens this possibility. The use of penicillin in staphylococcal pneumonias that occur as a complication of influenza would, of course, be most desirable; but the limited supply of this agent will probably preclude its employment on a large scale, at least during the coming season.

BOOK REVIEWS

THE question whether book reviews should be signed or initialed or should remain anonymous has been discussed many times at meetings of the editorial board of the *Journal* during the past several years. Owing to a letter published in the November 4 issue of the *Journal*, the matter has again been considered by the board, as well as by the Committee on Publications of the Massachusetts Medical Society.

It is obvious that a book review, to fulfill its function, must present to the reader the true opinion of the reviewer concerning the value of the book. If the latter is required to append his name or initials, he is likely to be less frank in his criticism of a book whose merit he questions, particularly if the author happens to be well known. On the other hand, anonymity permits unjust, possibly prejudiced, criticism, whereas the signed name

or initials often enable the reader to judge whether the reviewer is qualified to pass judgment on the book in question. That both sides of the question have supporters is evidenced by the fact that some medical periodicals have adopted one policy, whereas the remainder have selected the other.

During the many years that the *Journal* has been the official organ of the Massachusetts Medical Society the members of the editorial board have always been of the opinion that an anonymous review is likely to be more truly informative and useful than one that is signed or initialed. Furthermore, at recent meetings of the board and of the Committee on Publications, both bodies voted unanimously to continue this policy, with the added provision that the anonymity shall be absolute—in other words, that the name of the reviewer shall not be revealed on inquiry. This, of course, places considerable responsibility on the editorial staff, inasmuch as properly qualified reviewers must be selected and unjust criticism must be deleted. Such accountability, however, is nothing new and will continue to be accepted by the staff, with the earnest hope that it can be properly met.

MEDICAL EPONYM

MENDELIAN LAW

The law that the type of one or other parent is predominant in hybrid progeny is one of the implications arising from the extensive experiments of the Austrian monk, Gregor Johann Mendel (1822-1884). A summary of Mendel's experiments was printed in the *Verhandlungen des Naturforschenden Vereines in Brünn* (4: 1865, 1866), under the title "Versuche über Pflanzen-Hybriden [Experiments in Plant Hybridization]." The extract translated below was taken from a reprint of the original article and appears in *Verhandlungen des Naturforschenden Vereines in Brünn* (49: 3-47, 1911); the following is found on page 24:

An important clue is offered by the fact that in *Pisum* [the pea] constant forms appear among the progeny of hybrids in every combination of associated characters. So far as our experience goes, we find it universally true that constant progeny can be formed only if both

the germ cells and the fertilized pollen are endowed with the capacity to produce identically similar individuals, as occurs in the normal fertilization of pure varieties. Therefore, we must also regard it as necessary that, in the production of constant forms by hybrid plants, completely similar factors must be working together. Inasmuch as the various constant forms are produced by *one* plant or even by *one* of its blossoms, the conclusion seems logical that there are formed in the ovaries of hybrids as many kinds of germ cells [germinal vesicles], and in their anthers as many kinds of pollen cells, as there are possible constant combination forms, and that these germ and pollen cells in accordance with their essential nature, correspond to individual forms.

In fact it can be shown theoretically that if we assume that the different kinds of germ and pollen cells are formed in the hybrids on the average in equal numbers, this hypothesis would be entirely adequate to explain the development of hybrids in single generations.

R. W. B.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

GAGE—JAMES A. GAGE, M.D., of Lowell, died November 29. He was in his eighty-sixth year.

Dr. Gage received his degree from Harvard Medical School in 1885. For many years, he was staff surgeon at the Lowell General Hospital until he retired from active practice in 1930. He was a member of the Massachusetts Medical Society and the American Medical Association.

His widow survives.

GIVAN—LIEUTENANT COMMANDER JAMES A. GIVAN (MC), U.S.N.R., formerly of Worcester, died November 14 at the United States Naval Hospital, Norfolk, Virginia. He was in his forty-fourth year.

Dr. Givan received his degree from Tufts College Medical School in 1922. He was appointed to the staff of the Worcester City Hospital in September, 1925, and rose to the post of assistant orthopedic surgeon. He had practiced orthopedic surgery in Worcester for over fifteen years when he entered the Navy in August, 1942. At the time of his death he was chief of the orthopedic staff at the hospital of the Naval Operations Base at Norfolk. He was a councilor of Tufts Medical Alumni Association and a past president of the Tufts Alumni of Worcester County. He was a member of the Massachusetts Medical Society, American Medical Association, Worcester District Medical Society and Boston Orthopedic Club and a fellow of the American College of Surgeons and American Academy of Orthopedic Surgeons.

His widow, his mother and four children survive.

POTHIER—JOSEPH C. POTHIER, M.D., of New Bedford, died December 1. He was in his seventy-ninth year.

Dr. Pothier received his degree from McGill University faculty of Medicine, Montreal, in 1887. He was a member of the Massachusetts Medical Society and the American Medical Association.

His widow, a son, a brother and a sister survive.

SILBERG—MORRIS A. SILBERG, M.D., of Roxbury, died November 20. He was in his fiftieth year.

Dr Silber received his degree from Tufts College Medical School in 1920. He was a member of the Massachusetts Medical Society and the American Medical Association.

A daughter and a son survive.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

STATIONS FOR DISTRIBUTION OF ANTIPNEUMOCOCCUS SERUM

For the past twelve years, the Department of Public Health has maintained a statewide service for the provision of antiserums for pneumococcal infections. At the height of the demand for serum, in 1939, over nine hundred requests for serum were received. In the last few years the introduction of sulfonamide therapy for pneumonia has changed the situation so that the number of calls for serum has decreased over 90 per cent. Furthermore, the need for serum, when indicated, is no longer as urgent as it formerly was.

In the interests of efficiency and economy, therefore, the department has revised its schedule of depots for serum distribution, of which there were eighty-two at one time. Hereafter, serum furnished by the department will be available only at the following stations:

Types 1-33 inclusive

Boston Bacteriological Laboratory, State House

Types 1, 2, 4, 5, 7, 8, 9, 14 and 18

Holyoke Providence Hospital

Worcester Worcester City Hospital

Types 1, 2, 5, 7 and 8

Haverhill Hale Hospital

New Bedford St. Luke's Hospital

Pittsfield House of Mercy Hospital

Type 1 only

Ayer Ayer Community Memorial Hospital

Beverly Beverly Hospital

Boston Antitoxin and Vaccine Laboratory

Brockton Brockton Hospital

Framingham Framingham-Union Hospital

Gardner Henry Heywood Memorial Hospital

Greenfield Franklin County Hospital

Great Barrington Fairview Hospital

Hyannis Cape Cod Hospital

Lowell St. Joseph's Hospital

Malden Malden Hospital

Nantucket Nantucket Cottage Hospital

Newton Newton Hospital

North Adams North Adams Hospital

Plymouth Jordan Hospital

Quincy Quincy City Hospital

Walpole Pondville State Hospital

Ware Mary Lane Hospital

No changes are being made at this time in the facilities for pneumococcus typing or in the procedure for issuing serum. This procedure may be summed up as follows:

1 The pneumococcus must be typed in a laboratory approved for this diagnostic procedure by the Department of Public Health or in a federal laboratory.

2 The patient must be suffering from clinically diagnosed pneumococcal pneumonia, septicemia, endocarditis, meningitis or peritonitis.

3 In pneumonia, antiserums for Types 1, 2, 4, 5, 7, 8, 9, 14 and 18 are furnished for treatment on identification of the pneumococcus isolated from the sputum. Antiserums for the other types are supplied only when the blood culture is positive. (It is regretted that limited funds necessitate the continued application of the restrictive provision.)

4 In the other infections previously mentioned, antiserums for all types are furnished when pneumococcus is found in the blood, cerebrospinal fluid or peritoneal fluid.

5 In all circumstances antiserum is furnished only with the understanding that any unused serum will be properly refrigerated until the patient is discharged and then will be returned promptly to the Antitoxin and Vaccine Laboratory, 375 South Street, Jamaica Plain, Massachusetts, and that when the patient is discharged, a case history on the form provided will be filled out and sent to the Antitoxin and Vaccine Laboratory.

MISCELLANY

DANGER FROM FLUOROSCOPY

Much used by both internist and surgeon in other fields of medicine, the fluoroscope has proved a valuable aid in the diagnosis of pulmonary lesions and in the periodic check of their progress. A competent examiner using good equipment is often able to secure information that may not be ascertainable by means of conventional films such as the movements of the diaphragm, the contrasting appearance of the expanded or contracted lung, and the effect of moving the thorax into different positions before the screen. Warnings that this method should supplement, not replace, good roentgenograms have been frequent. A recent editorial (Stenstrom K. W. *Danger from Fluorocopy* *Minnesota Med.* 26:558, 1943) contains a timely warning of another danger—one inherent in the physical properties of the electric current and of the roentgen ray. This safety first appeal merits serious thought.

A number of articles have been published concerning the dangers connected with fluoroscopy. Recent measurements have shown that these warnings must be taken seriously and that they concern the whole medical profession. The problem is more acute now when the serious film shortage may call for more extensive use of the fluoroscopic method and it seems advisable to call attention to a few pertinent facts.

No fluoroscopic unit should be used unless the doctor in charge has convinced himself that the conditions under which it is operated are reasonably safe. A continuous vigilance is necessary, and it is not enough to know that the conditions were satisfactory at one time in the past.

A shock-proofed arrangement should remove electrical dangers but a broken cable or a casual repair may

lead to electrical hazards, and many of the old machines have exposed high-voltage leads. Grounding a part of the apparatus may not always serve as protection, and if the ground is applied at the wrong place the danger may be increased. A careful expert inspection is needed and there can be no valid excuse for an accidental electrocution. Such accidents have occurred a number of times.

Roentgen rays from fluoroscopic units have caused innumerable sequelae to both patients and physicians, and serious damages often still result in spite of the knowledge that now is available.

In order to obtain adequate protection, it is first required that the tube be shielded so that no radiation of any consequence escapes in any direction except in the useful beam. This may be checked roughly with a hand fluoroscope or more accurately with a roentgen meter with a sensitivity of 0.01 r or a Geiger-Muller counter. After this first requirement has been fulfilled several other precautions must be taken.

For any intelligent use of fluoroscopy, it is important to know the amount of roentgen rays reaching the skin of the patient and of the examiner, and that has to be determined by means of measurements. The total dose received depends on the intensity and the time of exposure. The intensity depends on a number of factors and varies widely in practice. A reasonable intensity at the skin of the patient nearest to the tube amounts to about 20 r per minute.

A representative of the Division of Biophysics, University Hospitals, has recently checked some machines in Minnesota, and has found intensities during routine practice up to 114 r per minute. It is evident that such an intensity is dangerous and must be reduced by proper adjustments. The question is how many of the machines which have never been calibrated are used under similar conditions with an unnecessarily high intensity.

The intensity may be reduced by increasing the distance from the target to the patient. This distance should be at least 28 to 30 cm. It can also be reduced by lowering the current, which should not exceed 4 to 5 ma. If the fluorescence is not bright enough the voltage may be raised and it is advisable to use rather high voltage, preferably 80 kv. or 100 kv. if possible with the equipment. With a high voltage a filter helps to lower the intensity considerably and a 1-mm. aluminum filter should be permanently attached.

With the use of a target skin distance of 28 cm., 90 kv., 4 ma., and a 1-mm. aluminum filter, the intensity can undoubtedly be kept within the safe range, but it is still advisable to have it measured so that the number of roentgens applied per minute will be known.

The time used for an examination should be kept at a minimum. It should be measured and recorded. A foot switch should be used so that the current applied to the tube may be limited to the time of inspection. The use of a timer, which sums up the exposure and shuts off the machine when the dose decided on has been given, is advisable.

Some fluoroscopic examinations require an exposure of 5 minutes. With an intensity of 20 r at the patient's skin, this means a dose of 100 r. A dose of 75 r is often used for the treatment of skin diseases, and the title of an article in the *Journal of Radiology*, "Roentgen Therapy in Fluoroscopy," is therefore no exaggeration.

The rules laid down here for the safety of the patient may seem drastic. They are, however, not difficult to follow after they once have been accepted, and certain

ly patients have the right to expect the physician to take the necessary precautions in order to avoid serious injury from a simple examination. These rules also help to protect the examiner, though any injury to him is due to accumulation of exposure over a long time rather than to a single dose. He must be particularly careful to protect the hands, which are inevitably exposed at palpation during the fluoroscopic examination. The use of lead-rubber gloves may help, but not unless the gloves are heavy and designed to shield the whole hand can they be relied on to give complete protection. Light gloves may give a false sense of security. The examiner must in any case be aware of the danger and take all possible precautions.

The most dangerous procedure, and the one that has caused most of the injuries, is the setting of fractures under fluoroscopic visualization. This practice must be condemned and the radiologist in charge should enforce the rule that nobody on the staff be permitted to use the apparatus in this manner. The doctor may receive enough exposure from the setting of a single fracture to produce a severe skin reaction. It is, of course, good practice to inspect the position fluoroscopically and that can be done several times without exceeding the permissible total dose.

A number of physicians already have suffered the consequences of too much exposure during fluoroscopy. They have been severely handicapped, and some have paid with their lives. The tragedy has been extremely impressive, and it is hoped that others will heed the warnings before it is too late.—Reprinted from *Tuberculosis Abstracts* (November, 1943).

REPORT OF MEETING

TRI-DISTRICT MEETING

A joint meeting of the Middlesex East, North and South district medical societies was held on November 10, 1943, at the Boston Medical Library. The presiding officers were the presidents of the district societies,—Dr. Roger M. Burgoyne, Dr. Herbert M. Larrabee, and Dr. Harold G. Giddings,—and the last acted as chairman.

The meeting was called to order at 8:15 p.m. The chairman stated that on the receipt of a telegram from Washington less than a week before, arrangements were promptly made in order to extend the utmost co-operation to the Procurement and Assignment Service, to the medical departments of the Army, Navy and Public Health Service and to Selective Service, which groups had asked that such a meeting be called in the shortest possible time. Dr. Giddings thought that few district medical society meetings had been arranged so quickly, which indicated the willingness of the profession to assist in solving the medical problems of the armed forces. The assembly was then addressed by various persons representing the State and the Government.

Dr. Reginald Fitz, chairman of the Massachusetts Committee of Procurement and Assignment, stated that in 1942 there were approximately 8000 physicians of all ages, including interns and residents, who were practicing in this state and that of this number about 2000 are now in the service.

Dr. Frank Lahey, chairman of the Directing Board of the Procurement and Assignment Service, spoke about the recruitment program. He stated that every man marked "available" is now needed by the military forces

He thought that any physician was privileged to question any other physician concerning how he had been rated. He stated: If a man has been marked essential he can be conscience clear since he has had nothing to do with such a rating. If one so marked wishes to join the service, he must find a substitute, and he may request the Procurement and Assignment Committees to assist him. Dr. Laher then spoke about the men who had been marked available. He said: If such a person does not agree with his rating he should appeal his classification to the state chairman. He emphasized the fact that a physician who has been marked available and has not sought an appeal indicates by his action that he is disinterested and therefore is truly available for military service. Dr. Laher then read a copy of a personal letter that he had sent to physicians informing them of the great need and asking them to file their papers for a commission. He further stated that there were about 10,000 physicians in the Navy and about 40,000 in the Army but that the armed forces still needed every available physician who could pass his physical examination.

Lieutenant Colonel Durward Hall, representing the Office of the Surgeon General, spoke about the Army needs. He, like the officers who followed him, brought greetings from the various offices of the Surgeon General. He stated that the Army needed 48,000 medical officers by the end of 1943 and that during 1943 about 1,000 physicians had been released from the service. He spoke forcibly of this need and urged that all available physicians come before the currently organized committee of which he was a member, and present their problems so that appropriate advice could be given.

Commander Francis J. Bracefield from the Bureau of Medicine and Surgery then spoke about and stressed the Navy needs. He said that the Navy was short about 6,000 medical officers, that it would welcome specialists and that physicians even above the draft age would be accepted.

The needs of the United States Public Health Service were then discussed by Dr. John Trautman. A history of the Public Health Service was presented as well as facts pertaining to the increased war services of this branch.

A question period was then conducted by Dr. Paul Barton, assistant executive officer of the Washington Office of the Procurement and Assignment Service. Some of the questions and answers are as follows:

Q What are the present age limits for service in the medical corps of the armed forces?

A The upper limit in the Army is, in general, the forty-fifth birthday, but for specific position vacancies men up to sixty are eligible. The limit in the Navy is, in general, the fiftieth birthday.

Q What is the present status of physical requirements?

A The Navy at the present time still has the highest standards although they are lower than they were. The Army is next and those who are physically disqualified for Army service may be eligible for commission in the United States Public Health Service.

Q What ranks are being offered by the services at the present time?

A The Army is limiting those under thirty-eight to first lieutenancies and those about thirty-eight to captains and above if they meet the special requirements of the Surgeon General.

rankings depend on special qualifications. The Navy is limiting those thirty-four and under to lieutenancies, junior grade those from thirty-four to thirty-eight to lieutenancies, and those from thirty-eight to forty-four to lieutenant commanderships. For specific position vacancies requiring special qualifications higher commissions may be offered. The Public Health Service has commissioned ranks similar to those in the Army.

Q What are the present needs of the services?

A All three branches of the armed forces are in immediate dire need of several thousand additional medical officers. This immediate period of need is between now and January 1.

Q Why is the Public Health Service classed as one of the three branches of the armed forces so far as medical officers are concerned?

A For many reasons among them the fact that they supply the medical personnel for the United States Coast Guard. Physically qualified eligible officers are assigned by the Public Health Service to active duty with the Coast Guard and may be assigned anywhere the American flag flies.

Q Why have so many practitioners who are capable of serving long hours in civilian practice been disqualified for military service?

A The exigencies of service in combat areas are such that civilian practice is no criterion of physical qualification. The services at the present time have a full quota of those whom they can accept for limited duty. They are being forced to discharge some at present. Certain individual physicians who still will be able to undertake heavy civilian duties are no longer able to cope with the needs of combat troops.

Q Why is it necessary for a physician to take an indoctrination course after becoming a medical officer?

A The reason for this is that a physician becomes a medical officer, which means that he is at all times an officer subject to the duties of officers in other branches of the service. He must be responsible for those under his command and must be entirely capable of meeting any situation that confronts such personnel as is under his direct supervision whether it be in open field duty requiring the setting up of field hospitals or the maintenance of food supply and shelter for his personnel as well as a correlation of the activities of his group with the other services under the same command.

Q Is it true that the armed forces are not making efficient use of their medical personnel?

A There have been many occasions in the past when appearances would lead one to believe that they were not. At the present time efficient use is being made of such personnel and it must always be remembered in this connection that a reserve supply of such personnel must be maintained for immediate assignment to duty. Such a group must have been trained together to meet the situations that it will face immediately after assignment and cannot be gathered together at the last minute to be assigned to some specific post.

Furthermore, the planning of any military campaign requires a complete line-up of all services. If reverses are suffered such men who are held in preparation of projected positions may not be able to fill such positions and must be held for further plans. War, by its very nature, is not essentially efficient, but the lack of medical personnel in the various branches of the armed forces has resulted in a high increase in their efficient use.

Q On the basis of present ratios of physicians to total personnel, which service has the greatest need at the present time?

A The Army ratio is slightly over 5 per 1000, whereas the Navy is somewhat under 4 per 1000. Therefore, the Navy needs men somewhat more than the Army.

Q Why is any man under thirty-eight ever classified as essential?

A He is only essential if he were to leave his community or his institution and there were no replacement for him. No man under thirty-eight is, as a general rule, considered permanently essential, but only essential until he can be replaced by another physician who is not eligible for service with the armed forces.

Q Has not the civilian population been endangered by the number of physicians who have entered the armed forces?

A Not for the Nation at large. There are various problems of redistribution that have been partially or completely solved and some that will be difficult to solve, but if such distribution is equitable there is no shortage at present for minimal adequate civilian care.

Q Will not the needs of the services continue and require that additional personnel leave civilian life?

A To some extent, this is true, but primarily the services will be able to meet their own needs for replacement from the students they are training at present. The Navy may need some additional personnel even though they are also training students. The Public Health Service will continue to have needs since they do not have any students in training.

Q Why do not the armed forces adopt the liberalization of qualifications that exist in England and elsewhere?

A Because it is essential that American standards be maintained for the men in the armed forces as well as on the home front. Comparisons with the armed forces of other nations are not in order any more than comparisons of physician-population ratios on the home front are with those of other nations. The mortality in the armed forces at the present time is astoundingly low and every effort will be made to keep it at that level. This will obviously require further sacrifices on the part of those on the home front, but the Procurement and Assignment Service is constantly aware of the fact that supplies of all kinds must continue to flow to those who are on active duty and that the health of the home front is therefore as much a part of the war effort as is the health of the soldier.

Q. What action does Selective Service take on physicians?

A. Although local boards differ somewhat in their actions, in general, no action is taken at present on physicians or others over thirty-eight. Reclassification of those under thirty-eight is going on constantly and dependency is not considered to the same extent as it was in the past.

Dr. Barton, before the close of the meeting, again stated that the reviewing committee of which he was a member would meet for about ten consecutive days at the Boston Medical Library and was anxious to help all physicians seeking enlistment.

BOOK REVIEW

Diagnosis of Uterine Cancer by the Vaginal Smear. By George N. Papanicolaou, M.D., Ph.D., and Herbert F. Traut, M.D. 4th ed., cloth, 46 pp., with 11 color plates. New York: The Commonwealth Fund, 1943. \$5.00.

In this well-written and beautifully illustrated atlas, the authors have elaborated another method of making the diagnosis of early carcinoma of the uterus and lower genital tract. Virchow believed that the only absolute means of knowing whether a tissue was malignant was by demonstrating its invasion of other surrounding structures. This view was accepted until recent times, when the diagnosis of cancer in its preinvasive stage was accepted. The study of the cells desquamated from the superficial layers of the malignant neoplasms of the uterus and found in the vaginal secretions, makes, in the hands of those so trained, such a diagnosis possible—that is, the recognition of cancer in areas removed from its origin.

The preparation of the vaginal smear and its staining are taken up in the first chapter, whereas the general classification of the epithelial cells of the vagina and cervix found in the vaginal fluid makes up the subject matter of the second chapter. Six pages are devoted to the cellular contents of the vaginal fluid at different periods of the normal sex cycle, and an equal number of pages to the effect of modified physiologic and of pathologic conditions of the cellular elements of the vaginal fluid. The characteristics of vaginal smears in cancer of the cervix, adenoma malignum of the cervix and adenocarcinoma of the cervix are freely discussed. The characteristics of vaginal smears in cancer of the uterine fundus, adenoma malignum of the uterine fundus and adenoacanthoma of the uterine fundus form the subject matter of an entire chapter. The narrative part of the book is closed by a discussion of the use of the vaginal smear as a diagnostic procedure.

There follow eleven plates showing the various types of cells found in the smears under physiologic and pathologic conditions, with clear and understandable legends. The preparation of these plates must have involved a tremendous amount of painstaking work. The authors offer this method, which, in their hands, has proved to be helpful in the diagnosis of early cancer of the uterus, but they do not advocate it at the exclusion of all others that have given satisfactory results.

The student of uterine cancer, whether working in the laboratory or in the operating room, will find this book a distinct addition to his library.

CERVICAL-CORD INJURIES*

A Study of 101 Cases

DONALD MUNRO, M.D.†

BOSTON

EVERY discussion of any level of spinal cord injury should be based on two fundamental concepts. These are that spinal cord injuries are different from spinal column injuries without cord involvement, and that all significant spinal-cord injuries are accompanied by spinal shock and its effects. One has only to refer to the literature to discover many authors who draw conclusions concerning the diagnosis, treatment and prognosis of a neurologic injury from a mixed series of both cord and vertebral injury cases. Wegner and I¹ drew attention to this in 1939 in relation to a study we made at that time of the bone lesions accompanying cervical spinal cord injuries. When a spinal cord injury is present, any associated bone injury is secondary and of relatively little importance. Under such circumstances, diagnosis, therapy and prognosis are all primarily problems of the cord injury, and the bone damage is from every point of view subordinate. Only when there is a back or neck injury in which the spinal cord has been undamaged do the bony structures and any changes in them properly assume first place in the consideration of the case. Until this is generally recognized and acted on but little improvement can be expected in the functional end results of spinal cord injuries.

This report deals only with acute injuries to that part of the spinal cord that is enclosed within the seven cervical vertebrae. As a necessary part of the study, however, consideration has also been given to any associated bony and ligamentous damage done to the cervical spine. There are 101 cases in this series. Fifty-five patients survived, and 47 of these have been followed to an end result for periods varying from six months to fifteen years. Forty-six died, a mortality of 46

per cent. Autopsies were obtained and the cords studied in 17 cases.

Spinal Shock

Spinal shock is a constant accompaniment of significant spinal cord injuries. It is recognized by its effects and is known to occur at once after the infliction of the injury and to last for periods varying from a few hours to months. It has nothing to do with surgical shock. As the result of its presence, all reflex activity below the level of the injury becomes chaotic, unpredictably variable and devoid of any diagnostic or prognostic significance. The deleterious effect of spinal shock is greatest on those reflexes mediated by the spinal segments immediately below the level of injury and decreases proportionately as lower segments are reached. As the location of the injury descends, bladder difficulties and bedsores, for example, become increasingly common because of the closer approximation of the segments controlling these reflexes to the level of injury.

Nature of the Accident

The commonest cause of a cervical-cord injury in this series was by all odds a fall, usually on stairs. Fifty or nearly half of the patients were injured by a fall, in 34 cases on stairs (Table 1). Twenty-four of them died. The next commonest cause was diving, with 8 cases. Only 2 of these patients died. It was not possible to learn the nature of the accident in 16 cases, in 12 of which the patients died. Alcohol is evidently a factor in the production of this kind of injury. Acute alcoholism was present in 23 cases and was almost three times as common in the fatal accidents (17 cases) as in the nonfatal (6 cases). In 15 cases it was associated with the fall that caused the injury. In the other 8 cases the kind of accident could not be determined because of its presence.

Bony and Ligamentous Injuries

Although bony and ligamentous injuries are of less importance than cord injuries, it is more

convenient to deal with them first (Table 2). It is apparent that the commonest injury to the cervical spine is one that involves multiple vertebrae. An analysis of the 36 cases of multiple injury shows that 26 centered about the fifth vertebra and 2 others included it. Nineteen patients recovered and 17 died. More than half these injuries caused a dislocation as well as a fracture

determined it proved to be centered around the fifth and sixth cervical vertebrae, with the greater number involving the fifth.

Forty-four cases with bone injury had an associated dislocation and in all but 1 case the dislocation was anterior (Fig. 1). It is probable that with the exception of the first and second vertebrae a true posterior dislocation of the cervical vertebrae (Fig. 2) almost never occurs, and then only rarely in an acute form. This group includes one such case. The patient was struck on the forehead, his head was driven backward, the odontoid was broken, and a posterior dislocation of the skull and atlas on the axis was produced. Fortunately the dislocation was not lethal. Despite its rarity a diagnosis of posterior dislocation is frequently made by x-ray. In this case the mobilized part of the column moved backward in relation to the immobilized part. In the common anterior dislocation the mobilized part of the column moves forward in relation to the immobilized part. If all other factors are omitted, the presence of a dislocation in addition to a fracture increases the chance of death slightly, the mortality being 52 per cent in this group as opposed to 44 per cent in the non-dislocation group.

The ligamentous cases deserve special emphasis. It has been shown that it is possible and must be fairly common for adjacent cervical vertebrae to be dislocated either partially or completely

of the involved vertebrae. In the single fractures, whether with or without dislocation, the same preponderance of location appears, 21 involving the fifth and 18 the sixth vertebra. Moreover, in the one patient who had a rupture of a cervical intervertebral disk with an immediate and acute extrusion of the nucleus pulposus, the involved disk was that which separated the fourth and fifth vertebrae. Thus in 60 of the 93 patients in whom the site of the bone injury was certainly

without bone injury and by virtue of a tearing of the capsular and other ligaments that surround the articular facets.¹ This series includes 11 such patients, none of whom had any demonstrable injury of the vertebral column. The cord injuries included among other diagnoses classic cervical hematomyelia and transection. This has convinced me that it is possible for cervical vertebrae to be momentarily dislocated sufficiently far to damage the cervical cord, even to the point

of transection, only to return to apparent normality long before the physician sees the patient. None of these 11 patients died. The location of the injury as evidenced by the segmental level of the symptoms was again concentrated around the

tion or sufficient clinical observation to be unmistakable in 68 of the 101 cases.

There were 13 transections. All the patients died except 2, who were living six months and three years, respectively, after the accident. In one case the transection developed ten days after injury. In this interval a diagnosis of mild contusion had been made and was thought to have been confirmed by operation. The transection developed suddenly and is believed to have been

FIGURE 1. *Anterior Dislocation of Cervical Spine (lateral view).*

fifth cervical vertebra, with a tendency to move downward, particularly in the transected cases. As has been pointed out,¹ it is these injuries that are apt not to unite until late, because healing depends solely on ligamentous repair.

One should not jump to the conclusion from these figures that the preponderance of acute cervical vertebral injuries involve the fifth vertebra. Indeed, it can be easily demonstrated that they do not. The present figures apply only to the patients with acute cervical cord injuries. A realization that any significant acute injury to the cervical cord at or above the fourth cervical segment produces complete respiratory paralysis will explain why cases of damage to the higher cervical vertebrae were so rare in this series. Either the patient was dead before arrival at the hospital and was taken directly to the morgue or was not suffering from involvement of the cord as the result of the accident.

Pathology of Cord Injuries

The pathologic changes produced in the cord by the injury were confirmed by autopsy, opera-

FIGURE 2. *Posterior Dislocation of Lumbar Spine (lateral view).*

caused by interference with the cord circulation locally, resulting in something of the nature of a thrombomyelitis. Respiration was entirely diaphragmatic, and what little motion remained in the arms and shoulders was entirely useless. Of the remaining 11 cases the diagnosis was confirmed clinically in 2, by operation in 1, and by autopsy in 8. In all, the damage lay between the fifth and eighth cervical segments.

There were 6 contusions of the cord. Two were verified by operation, 2 by clinical observation.

and 2 at autopsy. Only 1 patient survived. Six cases originally diagnosed clinically as contusion proved to have transections at autopsy (5 cases) or at operation (1 case). No patient originally diagnosed as having contusion was discharged with that diagnosis. There were 6 cases with pure compression of the cord, without other myelogenous damage. Two patients survived, with clinical confirmation in one case and operative confirmation in the other. In the 4 fatal cases, the diagnosis was confirmed by operation in 2 and by autopsy in 2. The presence of edema of the cord was never confirmed by either operation or autopsy. There were 5 cases in which the clinical findings justified this diagnosis. All except one of the patients survived.

The commonest pathologic condition was hematomyelia, with or without edema. It is possible that some of the surviving cases classed as hematomyelia actually had a mild contusion. Short of microscopic examination such a differentiation is impossible. Because the symptoms and course were analogous to those of proved cases of hematomyelia, however, they have been classified in the latter group. There were 35 of these cases. Twenty-nine were confirmed clinically, 3 by operation, and 3 by autopsy. Twenty-six patients survived.

Two cases of stab wounds and 1 of radiculitis were confirmed clinically, and all the patients survived. In 3 cases the diagnosis was not certainly known and in 30 it could not be verified. Because the cord lesion has necessarily to be located below the fourth segment if a patient with any significant acute cervical-cord injury is to live long enough to be hospitalized before he dies of respiratory failure, and because the area of cervical cord below this point is so small that an estimate of the differential effects of injury at different segmental levels within this region is impossible, no effort has been made to study the distribution of the cord injury in more detail.

Diagnosis

It seems certain that the best one can do in making a diagnosis at or close to the time of the sustaining of a cord injury is to determine the approximate upper level of the damage by a sensory examination. Except for this information the doctor is limited to the decision whether the lesion is of the type that causes a block of the flow of the cerebrospinal fluid. The lesions that cause such a block are edema, with or without hematomyelia, contusion, compression and concussion of the cord. The compression may be caused by a meningeal clot, a fragment of fractured bone, the crushing of a vertebral body, a dislocation of a vertebra or an extrusion of a nucleus pulposus. Contusion is self-explanatory and may be com-

bined with compression. Concussion is associated only with bullet wounds of the bony wall of the canal. The lesions that do not cause a block of the flow of the cerebrospinal fluid are hematomyelia without edema, anatomical transection and rarely an overlapping tear in the dura and arachnoid with an undetermined amount of cord injury. This last permits cerebrospinal fluid to be diverted to the extradural or subdural space and thus prevents filling of the subarachnoid space below the point of injury. Such findings may lead to the diagnosis of cerebrospinal-fluid block when none is actually present. Conditions that produce no block may be present as a complication of any of those that do cause a block and, of course, be unrecognizable, but the reverse is never true. Final differentiation between pathologic entities within these two classifications must await the final outcome of the case and may not be possible for months or even years. Even then it may be impossible unless major sepsis is not present, the patient is not suffering from hypoproteinemia, the bladder has reached a satisfactory functional end point, and proper physiotherapy and splinting have been practiced.

Disagreement between the immediate and final diagnoses is common in all cord injuries. Even observations made of the exposed cord at operation are not necessarily accurate or dependable. This is particularly true when the cord looks as though it had sustained little or no damage so far as its surface goes. Because the vascular supply to the cord is minimal and so constructed as to produce a bottleneck^{2,3} in both the arterial and venous channels, its tissue is particularly vulnerable should damage to the arteries or venous thrombosis occur. Cells that would not have sustained lethal damage in any other tissues do not recover, and a spreading myelomalacia may develop in the presence of damage to a single artery or of thrombosis of a single vein at certain levels on account of the lack of collateral circulation. A detailed study of this series has demonstrated that in 32 cases the immediate and final diagnoses agreed and in 36 they did not agree. Whether there was agreement or disagreement could not be determined in 33 cases (Table 3). Agreement and disagreement were determined by autopsy, by operation provided the patient lived more than forty-eight hours or by clinical observation provided he lived one year or longer after the accident. The immediate diagnosis was that made as soon after the accident as adequate studies had been completed. Under these conditions agreement was held to be present in 3 cases of transection, 22 cases of hematomyelia, 3 cases of compression without other pathology, 1 case of edema, 2 cases of stab wounds and 1 case of radiculitis

A preliminary diagnosis of contusion of the cord was never verified. Thus, only 28 of 54 cases were correctly diagnosed when first seen. Only 1 of the 11 diagnoses made at operation was confirmed

In the light of this evidence it cannot any longer be seriously contended that either the rapidity of onset or the amount of paralysis following an injury to the cervical levels of the spinal cord is of

TABLE 3. *Difference between Immediate and Final Diagnoses.*

later. This was in a case of compression. Of those cases in which the two diagnoses did not agree the patient's condition was worse at discharge than it was at admission in 26 cases.

In summary, it seems reasonable to conclude that a diagnosis of hematomyelia is the most apt to be correct, and if wrong is least liable to turn out to be something more serious. On the other hand, contusion, compression and edema are the conditions least apt to be correctly diagnosed and the most likely to be finally diagnosed as a condition that is much more serious than the original one was thought to be. This last is true not so much because of inaccuracies at the time the first observations are made as because of the progressive disintegration in the cord tissue that goes with compression of the cord. This compression may come from within and be traceable to edema, large hemorrhages or the results of altered circulation, or from without because of the effect of bone fragments, meningeal clots and the like. This fact has its practical aspect in that it points to the desirability of relieving extraneous pressure as early as possible, and at the same time emphasizes the danger attendant on operative procedures that are carried out in the face of a cord already damaged by edema or by hemorrhage within its substance. In particular it indicates the folly of splitting the cord and thus running the risk of producing damage that might not otherwise occur.

Diagnostic and prognostic conclusions based on the onset, type and extent of motor and reflex disability are never justified. Recognition of this fact is extremely important. It comes about because of the changes wrought by spinal shock. Fifty-five of the patients in this series could be studied in detail from this point of view (Table 4).

any diagnostic or prognostic significance whatsoever.

The demonstration of the presence or absence of a block of the flow of cerebrospinal fluid is made by a study of the total protein content of the fluid

TABLE 4. *Onset and Type of Paralysis.*

below the block and the performance of a fractional Queckenstedt test. Evidence of block consisting in an increase in total protein frequently appears before the evidence of dynamic block, and always outlasts it. The fractional Queckenstedt test is best done by compressing the jugular veins, not by hand but by inflation and deflation of a blood-pressure cuff wrapped around the patient's neck. Observations on the intraspinal pressure are made and recorded with every 10 mm. increase of pressure in the cuff from 0 to 40 and similarly with every 10 mm. decrease from 40 to 0. Partial dynamic blocks are recognizable by this method when every other has failed. As has been pointed out above, if a block is present, the patient is suffering from either edema, with or without hematomyelia, contusion, compression or concussion of the cord. If a block is absent, he is suffering from either hematomyelia without edema or an anatomical transection. The only source of diag-

nostic error lies in the rare possibility of the patient's having coincidental tears in the dura and arachnoid and presenting signs that superficially appear to indicate a block when there is actually none present. Further diagnostic differentiation is unjustified and impossible until the lesion has reached an end point.

Nonoperative Treatment

Certain general principles of treatment must be adhered to if the end results that the patient has a

other method that aims to accomplish rapid hyperextension are also contraindicated. Sufficient protein must be given in the diet or by transfusions or other means to maintain the serum protein at 6.0 gm. per 100 cc. or better. The salt intake must usually be increased also, and the patient should be started at once on large amounts of all the vitamins. While he remains on tidal drainage the fluid intake should never be allowed to fall below 4000 cc. per twenty-four hours for an adult with a normal cardiorenal system. Care

FIGURE 3. *Bridle Made from Folded Flannel Bandages.*

right to expect are to be obtained. In every case of spinal-cord injury the bladder should be emptied and an inlying catheter fastened in place at the earliest possible moment. As soon afterward as it can be done this catheter should be attached to a tidal-drainage apparatus properly adjusted by cystometry to the needs of the bladder. Simultaneously the patient should be treated for surgical shock if and when it is present. Both steps should precede all but the most superficial diagnostic measures. The demonstration of the presence or absence of a block should always follow the above and come before all other measures. Splints, no matter what their material, that are fixed in relation to the patient must never be used in spinal-cord injuries, especially in thoracic and lumbosacral ones. In particular the application of plaster of Paris is contraindicated regardless of the amount of padding used. So, too, are rubber and other rings or doughnuts, Bradford or other frames and water or air mattresses. Metal frames and any

must be taken to keep the bowels open and prevent the development of fecal impactions. All patients must be moved off the back and onto one or the other side every two hours, day and night, during their stay in bed. They should never be allowed to lie in a wet bed for even as little time as fifteen minutes. These are general measures that apply to all patients with spinal-cord injuries until such time as anatomical and functional end results have been reached, regardless of the diagnosis. Other procedures depend on the presence or absence of a positive Queckenstedt test. This reaction must be determined in every case without exception, and the test should be made after the patient is out of surgical shock and on tidal drainage.

It is vitally important in all patients with cervical-cord injuries that the head be not accidentally flexed. This control of the movements of the head on the spine is equally essential whether or not there is a cerebrospinal fluid block. It is

best accomplished by traction of the head in extension with a bridle. It can be achieved by the application of some form of fixed splint, such as a Thomas collar or a plaster cuirasse, with or without a jury mast, but my experience has shown

In general and unless there is some special indication, traction in all cases of cervical cord injury should be parallel to the long axis of that part of the cervical spine that has not been dislocated or moved. Under such circumstances it is

FIGURE 4 Moving a Patient in Bed with the Aid of a Drawsheet
Note the sheet stretched tightly beneath the patient

that these applications can do no more than traction does, usually do not do so much, and are much more difficult and dangerous to use. Under the circumstances the best apparatus is the one that is simplest and easiest to apply. As can be seen in Figure 3, such an apparatus can be made from two flannel bandages each folded lengthwise a number of times until an appropriate length is reached. One of these bandages is looped around the chin and its free end attached to a spreader, which in its turn has a piece of rope hung from its center point. This rope passes over the pulley of an ordinary Buck's extension apparatus that is attached to the bed, and terminates in a loop that supports a 5 pound weight. The other bandage is looped about the occiput and the free ends are pinned to those parts of the first bandage that are opposite the ears. The head of the bed should be slightly elevated. By adjusting the relative lengths of the bandage loops and the height of the pulley in relation to the line of pull, traction can be exerted on the head with simultaneous control of the flexion and extension of the neck. Commercial bridles have no advantage and offer many disadvantages compared with this simpler one.

well to put a soft pillow under the head. If extension is required, a small hard pillow should be put under the shoulders. I have not used tongs but have used piano wire looped through adjoining trephines on either side of the vertex of the skull as a means of applying traction and using greater weights than are possible with the flannel bandage bridle. I have been unable to accomplish anything more by this method than I was able to do with the bridle. Regardless of the weight applied, all that traction can do is to stretch the muscles and ligaments of the neck and tire out the former. The constant application of 5 pounds of traction will accomplish this as expeditiously and as efficiently as will a heavier weight. Neither method nor any amount of weight will relocate a locked dislocation without accompanying and proper adjustment of the line of traction. When this is provided, 5 pounds of traction will move the articulating facets as efficiently and more accurately than greater weights. This has been described in detail elsewhere.¹

If a block is absent there is no need for operation, and x-ray films should be postponed until they can be taken without risk to the patient. The patient should be placed on an

way. This brings a wide linen drawsheet beneath the buttocks and back (Fig. 4). It is this drawsheet that should be used to turn the patient at the end of every two-hour period. With an ordinary adult it requires at least three and better

The patient's feet should be supported at right angles, with the bedclothes held off them by a cradle, and the knees should be supported on pillows in slight flexion. Particular pains should be taken to see that the paralyzed hands and arms are

FIGURE 5. *Moving a Patient in Bed with the Aid of a Drawsheet.*

The patient is partially turned toward his left side. Note that the patient's head is rotated simultaneously.

five persons to do this. Each of the lateral edges of the drawsheet is grasped by one or two nurses and the sheet is pulled tight underneath the patient. Another nurse holds the patient's head face-up between her hands (Fig. 5). If the patient is to be turned from his back to his left side, the nurse or nurses holding the drawsheet edge to the right of the patient, bring it upward and toward the other side of the bed until it is in contact with the patient's back and side. The drawsheet is kept stretched tightly at all times. A continuation of the movement rolls the patient onto his left side. Simultaneously the nurse holding the patient's head turns the latter in concert with the body (Fig. 6). Once the rotation is accomplished, the drawsheet is used to lift and move the patient back to the middle of the bed (Fig. 7). The traction is not disturbed. To move the patient from his side to his back the sheet is brought to the last position described above, and with this as a starting point the rest of the process is done in reverse. Every patient with any kind of spinal-cord injury can be moved safely as often as need be by this method. It is much safer and more efficient than the use of Bradford frames or any similar apparatus.

not allowed to get into awkward or strained positions or to get beneath the body. They should also be kept off the chest and particularly the abdomen — not because of damage to the extremities but because their dead weight will seriously impede respiration. This is especially dangerous and may make the difference between life and death during the early period after the injury when respiration is either wholly or mostly diaphragmatic. Physiotherapy should be begun and maintained as long as the patient's muscles are not hypertonic. If they are, it is harmful and contraindicated. The latter situation, however, scarcely ever arises in cervical-cord injuries. When it does occur, it is usually a late manifestation of transection of the cord.

Care of the hands is particularly important in all these cases. In many it is also particularly difficult. This is especially true in alcoholic patients or others who have had an inadequate diet, in manual laborers and in patients over fifty years of age. In many of these patients the small muscles of the hand atrophy early, a general swelling of the subcutaneous tissues of the palm and back of the hand and the areas around the finger joints takes place, and stiffness and immobility of the

joints, and in some cases intra-articular adhesions, develop. These changes reach their maximum height in about three weeks after the injury. They make their appearance and persist in spite of adequate and early physiotherapy, although with

Three patients with the above signs, two of whom were alcoholic, over fifty five, manual laborers and suffering from hematomyelia, and who had had advanced and uncorrectable disability of this type for seven and three months respectively

FIGURE 6 Moving a Patient in Bed with the Aid of a Drawsheet
The patient has been turned so that he lies on his left side

out they appear earlier and are worse. The hands have a characteristic flat appearance and are best described by the appellation "flippers." As a result, although innervation of these small muscles is complete at the usual time and in accordance with the amount and degree of recovery from the cord injury, function fails to return—perhaps permanently—because of the soft tissue swelling and the immobility of the joints.

Because of my belief that this might be an arthritis problem, Dr. Francis C. Hall was asked to see certain patients suffering from this condition. It was his opinion that the lesion was neither arthritic nor periarthritic in the usual sense of the word. He suggested that it had its origin in a combination of subclinical avitaminosis and impairment of the circulation in the upper extremities. For the avitaminosis he suggested the following: eight yeast tablets or one teaspoonful of Vegex three times a day, 3 cc of crude liver extract twice a week, one tablet of Lederle's vitamin B complex every hour for twelve doses daily for two to three weeks and the avoidance of catharsis when possible. For the circulatory deficiency he suggested diathermy three times a week through the back over the origins of the brachial arteries.

were put on the above regime. The third patient was nonalcoholic, over sixty, a foreman, and was suffering from a cervicodorsal transection, he had had the same disability for three months but to a lesser degree than the others. Within a month the hands of all these patients had regained their normal appearance except for the atrophy of the small muscles, the swelling was completely gone, the local circulation was noticeably improved, and the mobility of the joints and consequent usefulness of the fingers had increased by 30 to 50 per cent. During this time every application of the diathermy had caused pain in the shoulders and down the arms. Since then the improvement has continued, but more slowly, and this pain has disappeared. One other patient—a woman of forty eight, alcoholic and a manual laborer with a hematomyelia—was treated in this way from the start. Four months after injury she had had no more than the expected trouble in regaining the usefulness of her hands and had never shown any of the signs listed above, although she was believed from the start to be a patient who under other circumstances would have certainly developed disability from this cause. Although many more observations must be made and many more of such patients seen

and studied before even tentative conclusions can be reached, the experience seems sufficiently striking so that the profession at large should have the benefit of it.

At the end of six weeks in a case in which there has been bone injury and there is adequate evi-

I have never seen any harm done by too prolonged splinting in cases of cervical-cord injury, but have seen unnecessary invalidism develop because of too short a period of both traction and splinting.

The problems inherent in transection of the cord arise only infrequently in cervical-cord in-

FIGURE 7. *Moving a Patient in Bed with the Aid of a Drawsheet.*
The patient is moved back to the center of the bed.

dence of repair by x-ray, or after eight weeks in those in which there has been minimal or no evidence of bone injury, the patients can be allowed out of bed after being fitted with a modified Zimmer brace (Fig. 8).⁴ Elderly patients can be allowed out of bed as early as two weeks after the injury if their general condition warrants it and they wear one of these braces. This practice is justifiable only under special circumstances, however, and should not be applied as a general rule. By the end of six or eight weeks and usually earlier, those patients who have had hematomyelia regain normal control of the bladder and bowels. Constant x-ray check should be made of their bone injury until such time as the physician is certain that it is completely healed. The splint should be worn constantly during this period. This is doubly important if the injury has been ligamentous. Check by x-ray for redislocation in such cases should be frequent and should be continued for four months after the splint has been removed. Evidence that redislocation is developing necessitates the return of the patient to traction in bed and more prolonged splinting. Practically all patients with transected

cervical cords die within the first week after their injury. This is particularly true with complete transections. I have never seen a patient with a complete cervical transection develop a mass reflex. As a result, tidal drainage has been adequate and efficient in the care of their bladders. The 2 patients with partial transections who have survived for a longer period have flexion and adductor spasm but none of the excessive motor response to minimal sensory stimuli that characterize the next stage in complete transections and that are the chief characteristic of the mass reflex. The greatest problem in these cervical transections has been caring for the distention that under other circumstances would do little or no harm. In these patients respiration is entirely diaphragmatic. The increased intra-abdominal pressure inherent in distention splints the diaphragm, with a resultant decrease in respiratory efficiency, the development of pulmonary disease and death. Avoidance of fluids, including water, by mouth for the first three to five days and the use of rectal tubes, milk and molasses enemas, physostigmine and similar drugs and procedures, repeated frequently or used constantly, are the best means of

combating this condition. Abdominal operation is contraindicated and will kill the patient if performed.

Operative Treatment

In patients who have a positive Queckenstedt test the question arises whether this block should

be justified, regardless of the symptoms and signs of block. During this period the surgeon must depend on properly adjusted traction and improvement in the oxygenation of the tissues to reduce to a minimum any permanent damage to the cord. If at the end of this time a complete block is still present or a partial one is increasing and the pa-

FIGURE 8. *The Modified Zimmer Brace*

be relieved by a decompressive laminectomy, and if so how soon after the injury. This procedure is not to be undertaken lightly. A comparative study of two similar groups of cervical-cord injuries demonstrated that in 30 patients 43 per cent of whom were operated on, the mortality was 63 per cent, whereas in 46 patients 15 per cent of whom were operated on it was only 33 per cent. In other words, when the number of decompressive laminectomies was reduced by 28 per cent the mortality was reduced by 30 per cent. All these patients are included in the present series. A study of the lesion, as noted above, points in the same direction. Those conditions (contusion, edema and compression of the cord) that at first sight are most in need of early decompression are the ones that end, whether operated on or not, with transection or at least a more serious pathologic condition than was originally believed to have been present. Operation therefore can only do harm unless it is postponed until the changes produced in the cord by the injury have become stabilized. This does not mean that other methods of treatment should be abandoned during this period, nor does it mean that decompression may not prove helpful after the period has passed. It does mean that operative decompression during the first five to seven days after the injury is not

justified, regardless of the symptoms and signs of block. It should be extensive enough to free the block completely and the operation should be limited to this procedure only.

I am strongly opposed in these cases of cervical cord injury to any attempt to manipulate the damaged bones as part of the operative procedure. The cord has been sufficiently endangered already without adding the chance of injury from a slipped instrument, a loose fragment that had not been seen or a redislocation during closure because of an unrecognized partial reduction. Any necessary and possible change in the bony alignment can be better accomplished by properly applied traction. I am opposed also to the use of silver wire or other material for the purpose of tying one spinous process to another in the belief that this will control the movements of the damaged vertebra or vertebrae. Any control comes from proper reduction and sufficient splinting, and in spite of and not because of a loop of wire. Furthermore, the presence of wire is not necessarily innocuous. I have removed one that was surrounded by dense fibrous tissue continuous with a scar in the canal that deformed the dura of the cord and the roots over three segments on one side. The resultant symptoms were disabling.

If possible it is best to use Avertin and local

apnea. If the condition of the patient is such as to preclude the use of local anesthesia, Avertin followed by Pentothal Sodium intravenously is the next choice and is preferable to an inhalation anesthetic. Its administration should not be attempted, however, unless a cannula is inserted and tied into an ankle vein and kept open by dripping 5 per cent glucose in salt solution into it. The Pentothal Sodium should be administered by puncturing the rubber tubing of this system close to the cannula with a needle attached to the syringe containing the drug. If the drug is given slowly and repeated often enough, there will be no trouble with the respiration.

Before a final decision can be made as to operability, information relative to the bone condition must be obtained. This should be done as soon as it is known that a block is present. Thus, in blocked cases x-ray examination is essential some time during the first seventy-two hours or as soon thereafter as it is possible and safe to make it. This should include a stereoscopic anteroposterior view and right and left stereoscopic oblique views. A single lateral view can be taken, but one should not expect a great deal from it, especially in the lower cervical injuries. It should never be forgotten that a negative x-ray finding in cervical-cord injuries is more important than a positive one in that it suggests ligamentous rather than bone damage. Bullet wounds and stab wounds are compound injuries and as a general rule should be débrided when it is safe to do so. Whether or not the wound is débrided, however, the sulfonamides should be administered by mouth or intravenously and applied locally to the wound. Beyond this, it is impossible to be more specific. Each case must be settled on its merits, always bearing in mind that the preservation of the patient's life is a necessary prerequisite to his recovery from any paralysis he may have. While the surgeon is reaching a decision as to whether and when to operate, or whenever the block is relieved, the care of the cord injury and the patient is the same as that outlined in the previous section.

Transportation

The problem of how and when to move patients with a cervical spinal-cord injury may arise at any time, and experience in relation to it is particularly apposite in view of the widespread public education in first aid. One fundamental factor governs. This is that the patient's head must under no circumstances be flexed on the chest. Pure extension within reason is harmless, and fixation in mild extension is ideal. Flexion is inexcusable, and denotes complete ignorance of the problem at hand. Patients who walked into

the hospital have been changed into bedridden invalids with paralysis of all four extremities after their necks have been flexed in the course of a clinical examination. In other cases flexing of the neck in the course of moving patients from the scene of the accident to a litter has resulted in instant death. The danger attendant on any flexion or any possibility of flexion of the head on the chest in actual or potential cervical-cord injuries cannot be emphasized too strongly in view of the directions for moving such patients given in the *American Red Cross First Aid Text-Book*⁵ and the sixth volume of *Military Surgical Manuals*, published under the auspices of the National Research Council.⁶ The former is the book used for the instruction of first-aid classes. Specific directions are given there, including a photograph, that a victim with an actual or suspected broken neck must be kept with his face up if lying on his back or turned to a face-up position if lying on his face previous to transportation. This is despite the fact that the directions for caring for a broken back call for transportation in the face-down position unless a combination of broken neck and back is suspected, in which case the victim must be carried with his face up. The latter, a recent publication, is intended for the use of the medical departments of the Army and Navy.

Transportation face up is dangerous for several obvious reasons. Many of these patients vomit. They are paralyzed and cannot move or be moved. When they vomit in this position, the vomitus necessarily gravitates to the back of the throat and is almost certain to be inhaled. This causes atelectasis or pneumonia at best and death by strangulation at worst. Attendants are of no help in preventing such a complication because with the patient in this position they cannot move his head without flexing his neck. This is recognized even by the Red Cross as being extremely dangerous. With the patient in the face-down position this situation can be avoided.

Another source of danger is the self-appointed assistant. He is ubiquitous, and his judgment is as bad as his intentions are good. A request by the patient for a drink of water or a more comfortable pillow, or that his head be moved, or similar suggestions by a bystander, will, if gratified, lead to flexion of the head on the chest when the patient is lying face up. In the face-down position, on the other hand, movement of the head is limited to turning or extension. Either one of these is relatively safe and is therapeutic in comparison to flexion. Many patients with cervical-cord injuries are unco-operative and confused, and persist in trying to get off the stretcher. If they are face up they can and may kill themselves in the course of such attempts, whereas

if they are face down their chances of doing themselves harm are much reduced.

Patients with broken necks who have to be moved before they can be laid face down must have some sort of temporary splint applied to the cervical spine. Such persons are those who are held erect or in a sitting position after the accident or who have to be brought out of a confined space. Among the latter are men injured in tanks or in single seated fighting planes. Attempts to extract these patients without such splinting almost inevitably leads to flexion of the neck and an increase of cord damage as the least serious result, and instant death as the most serious one. Any splint applied to prevent this development must be easily available, and of such a type that it can be wrapped around the neck before the patient is moved. It needs only enough body to give it stiffness for ten or fifteen minutes. A newspaper fulfills these requirements as well as anything else. It should be folded lengthwise in such a way that its width equals the distance between the angle of the lower jaw and the clavicle. It is wrapped around the patient's neck without moving him and held in place with a piece of string. This is a temporary arrangement, and should not be expected to do more than steady the head on the shoulders during the moving. Neither this nor any other kind of splint need be applied to such patients' necks when they are lying face down, and must not be put on when they are lying face up. For the rest, I am in agreement with the recommendations given in the Red Cross manual. They insist that such patients should always be rolled and never lifted, that they be carried on a solid litter or its equivalent that is longer and wider than the patient, and that the neck and head be supported on both sides by the equivalent of sandbags so that the head cannot roll. When the patient is carried face down, one of his arms should be placed in such a position that the forehead rests on the extensor surface of the forearm. To accomplish this the elbow must be bent at right angles and adjusted in such a position that the forearm lies at right angles to the long axis of the body. Unless and until these requirements can be fulfilled, it is much better and infinitely safer to leave the patient where he is, even if this necessitates standing guard over him, redirecting traffic and the like. Certainly these are no cases for amateur handling.

Complications

One of the commonest and usually forgotten or unrecognized complications of cervical spine and cervical-cord injuries is a craniocerebral injury. Nineteen patients in this series, or 19 per

cent, suffered from craniocerebral injuries, and 7 died. The lesion and treatment are no different from those of the craniocerebral injuries that are not complicated by injuries of the cervical spine or cord (Table 1).

Other significant complications of cervical cord injuries are interference with the return of function of the hands and the conditions traceable to impairment of respiration. The former has been discussed sufficiently above. Impairment of respiration is a necessary consequence of practically any cervical cord injury. Either the injury itself or spinal shock will at least reduce and may do away altogether with the usefulness of the costal muscles. As a result, all respiratory exchange must depend for a variable period of time on the diaphragm. This muscle is not equipped to carry such a load unaided and without a chance for adjustment. Respiratory irregularities and deficiency result and may go on to the point where death follows. Distention, restlessness, anoxemia, other injuries, necessary or unnecessary operative procedures and the like all further impede the action of the diaphragm. Unfortunately, the general bodily changes that may be associated with such conditions are not well understood. Treatment is therefore purely empirical and not of great avail. Investigation now going on in my clinic will—*I hope*—eventually settle some of these questions but it has not proceeded far enough to justify any final conclusions. At the moment we believe that in practically all cervical transections at any level and in most of the other more severe injuries that involve the cervical cord close to the fifth segment the diaphragm must provide the motive power for respiratory exchange for a variable period of time—from a few hours up to the rest of the patient's life. During the first week after the injury or until the first effects of spinal shock have worn off, the diaphragm attempts to adjust itself to this unaccustomed load. If this proves impossible, cyanosis, restlessness, an increase in respiratory rate with a decrease in amplitude and signs of fluid or consolidation in the lungs develop. In the later stages confusion and disorientation further complicate the picture, but whether these are caused by anoxemia or something else is not clear. This syndrome is probably traceable to tiring and consequent inefficiency of the diaphragm, with a resultant decrease in respiratory exchange. It usually but not always results in death. In our experience a respirator and other mechanical substitutes for costal breathing are not only of no help but are actually a hindrance because of the impossibility of adjusting the respirator rate to that of the patient. We have not, however, tried paralyzing the patient's respiration entirely and depending on

PURPURA FULMINANS (THE WATERHOUSE-FRIDERICHSEN SYNDROME)

Report of a Case with Recovery

STEPHEN D. PEABODY, M.D.*

NEWBURYPORT, MASSACHUSETTS

THE Waterhouse-Friderichsen syndrome — adrenal hemorrhage associated with purpura — is also known as acute hemorrhagic adrenalitis, suprarenal apoplexy and purpura fulminans. Although the clinical picture was first described in 1901, until recently it has been regarded a very rare condition, and one that is rapidly and invariably fatal.¹ The diagnosis is still not often made clinically.^{2,3} Until February, 1943, there were but 103 cases reported in the literature, and among these there were only 3 recoveries.³

With few exceptions the condition is observed in children between the ages of two months and two years. Seventy per cent of all cases fall within this age range, and 90 per cent of all patients are under nine years of age.^{3,4}

The similarity of the course of this disease to that of meningitis and the frequent finding of the meningococcus as the etiologic agent have given rise to a feeling that this is the only cause of the syndrome.³ Actually, although the meningococcus is the most commonly found agent, there are many possible etiologic factors. In newborn infants, trauma and asphyxia of long and difficult labor, hereditary syphilis and maternal eclampsia have been thought to be implicated.¹ In older children and adults, adrenal hemorrhage has been found to occur in the course of many acute infectious diseases, especially scarlet fever, diphtheria, pneumonia and meningococcal meningitis.³

The exact cause of adrenal hemorrhage is not known. Anatomically, the vessels of the adrenal glands are characterized by extremely thin sinusoidal walls in close contact with the parenchyma. It is believed that a toxic effect is exerted on the vessel walls, increasing their permeability and resulting in extravasation of blood.³ Venous thrombosis is also seen, but this is believed to be a secondary effect. The hemorrhage is located chiefly in the medullary portion of the gland and extends into the cortex, mostly by contiguity. Adrenal hemorrhage is bilateral in 95 per cent of cases, and when unilateral the right suprarenal is practically always involved. Grossly the gland may be enlarged in cases of severe hemorrhage, but its contour is usually not changed.¹ Variations in severity of hemorrhage from petechiae to

gross extravasation are directly correlated with the severity of the clinical picture.⁸

Previous to the last few years the clinical picture has not been well recognized,⁴ and the diagnosis has rarely been made before autopsy.^{1,2} Features described by observers reveal that the general picture varies considerably, but after the onset, with actual adrenal damage, the pattern becomes clearer and more typical and should be recognized, or at least suspected, oftener than it has been.

The initial symptoms are the nonspecific ones encountered at the onset of any infectious disease. Malaise, fatigue, headache, digestive disturbances and a slight rise in temperature are common. Frequently there is an accompanying upper-respiratory infection. A more suggestive but less frequently encountered train of symptoms is that which occurs when a previously well child awakens during the night with a cry and is seized with nausea, vomiting and pain, followed by mild diarrhea. These mild premonitory symptoms are usually not regarded seriously, but soon the fulminating course characteristic of adrenal hemorrhage appears, and this frequently proceeds rapidly to a fatal termination.

Cyanosis first appears. This may be constant or intermittent, and either generalized or limited to the lips and nails. Usually the appearance of this sign is accompanied by a rapid rise in temperature, but the temperature may not rise until later and may even be subnormal. Within a short time petechial mottling of any or all parts of the body appears. The petechiae are reddish and tend to increase and coalesce, especially about the hands and smaller joints of the body. Lesions of the mucous membrane and conjunctivas are often encountered. Frequently a post-mortem type of lividity is present in the dependent portions of the body. As the condition progresses the patient lapses into a state of profound shock, with a fast, irregular pulse, rapid respirations and a fall in blood pressure. A characteristic feature of shock of adrenal origin is that the extremities become cold whereas the body remains warm.¹ Commonly observed signs of the final phase consist of Cheyne-Stokes respiration, coma, delirium or convulsions, a sudden rise or fall in temperature and death, which may come on in twelve to

*Formerly, intern, Newton Hospital.

sulfadiazine level of the spinal fluid was 11.6 mg. per 100 cc. No organisms could be cultured.

On admission the blood chloride was 514 mg. per 100 cc., the glucose 94 mg., and the nonprotein nitrogen 116 mg. A blood culture showed meningococci.

The urinary output during the first 24 hours was 15 cc. despite a 4000-cc. fluid intake. Catheterization produced only another 90 cc. That night the subcutaneous tissues were turgid and edematous and the output for the day was only 180 cc. Urinalysis that evening showed a heavy trace of albumin and large numbers of red cells. The nonprotein nitrogen was 103 mg. per 100 cc. Because of the possibility of large amounts of adrenocortical extract in conjunction with large amounts of saline causing fluid retention, these were stopped. Sulfadiazine anuria could not be ruled out, although this was not thought to be likely, but sulfonamide therapy was discontinued. Cystoscopy and ureteral catheterizations were negative. Following this the patient was given 105 cc. of polyvalent antimeningococcus serum. She became more edematous during the night and had periods of apnea and cyanosis. For this Coramine and caffeine were given intramuscularly.

On the 3rd hospital day the patient had marked and generalized edema. The urinary output had been 180 cc. during the night. She was unable to hear and had bilateral internal strabismus. The urinary output improved that day. The petechial spots, which had become greatly enlarged and coalescent, began to fade at the periphery. The systolic blood pressure had risen to 140, and the pulse was 90.

The course from this time on was one of gradual improvement without further serious complications. Six days following the administration of the antimeningococcus serum, polyarticular hydrarthrosis involving the knees and elbows appeared. Culture of the joint fluid was negative. The only other complications were the development of deep pressure sores over some of the petechial eruption under the heels and buttocks.

The patient had some residual joint stiffness, which improved with physiotherapy. At the time of discharge, 6 weeks after admission, she still had some stiffness in the knees, a slight hearing impairment and a mild degree of myopia. The spinal fluid was normal aside from an elevated protein value—75 mg. per 100 cc. There were still two deep pressure sores on the heels that had not filled in. She felt well.

On June 9, the patient reported for a check on her spinal fluid. The cell count, glucose and protein were normal. The hearing and vision had improved. The pressure sores were well filled in and there were no more joint symptoms. The patient had been at work for a week, and looked and felt well.

SUMMARY AND CONCLUSIONS

A case of purpura fulminans has been reported because of its rarity and especially because of the extremely low incidence of recovery.

It is evident that the syndrome is being oftener recognized clinically. Any patient, especially a young child, who develops spontaneously or in the course of a contagious disease cyanosis, purpuric eruption, profound shock and hyperpyrexia should be regarded as manifesting the syndrome.

Since the course of this disease is often rapid and fulminating, it is imperative that a prompt diagnosis followed by early and active treatment be carried out. In view of the high mortality, heroic measures seem justified.

Since the infection is usually bacterial in origin, the sulfonamides seem to be the mainstay of therapy.

Hormonal replacement with both adrenocortical extract and adrenalin are indicated in the hope of carrying the patient along until a hoped-for resumption of adrenal function takes place.

Plasma, blood transfusions and other supportive therapy may be indicated.

INSTRUMENTAL REMOVAL OF A TWO AND A-HALF-POUND BLADDER CALCULUS, WITH RECOVERY*

FRANK J. LEPREAU, JR., M.D.,† AND RALPH H. JENKINS, M.D.‡

NEW HAVEN, CONNECTICUT

THE following case is reported because it records the largest bladder calculus ever removed with complete recovery. The dry weight of the calculus was 1134 gm (2½ pounds). It was composed of phosphates and carbonates.

The literature in regard to bladder calculus is copious, and only a few of the references¹ are appended. The search through it included the domestic and foreign literature and was conducted through the Yale Medical Library with microfilm material obtained from other sources notably the Army Medical Library and the New York Academy of Medicine.

The next largest stone reported is removed with survival is that of Smith,² which weighed 2 pounds, 6½ ounces. No follow up was given beyond the hospital stay. The 4 pound stone reported by Randall³ is the largest bladder calculus removed during life; the patient died thirty-six hours later.

CASE REPORT

The patient, a 34-year-old man, was admitted to the New Haven Hospital on October 28, 1940, with a chief complaint of pus in the urine. He had had urinary difficulty for the last 4 years characterized by hesitancy, slight dysuria, nocturia (one or two times), variation in the size of the stream, cloudy urine and occasional hematuria. He had recently lost 23 pounds in weight.

The past history was unimportant except that the patient had had weak kidneys as a child. He could recall no specific complaints. The family history was negative.

Physical examination on admission showed a man appearing slightly tired and rather old for his age. The temperature, pulse and respirations were normal. The blood pressure was 156/82. All the teeth were markedly carious. There was a stony, hard, rounded abdominal mass in the suprapubic region that extended almost to the umbilicus. On rectal examination the same mass was felt, as well as a small prostate just within the anus.

The urine was yellow and cloudy with a specific gravity of 1.015, a slight amount of albumin, no sugar and occasional red cells. It contained innumerable white cells with many cocci in clumps and many small rods in the methylene blue smear. In the only provocative determination of the reaction of the urine it was reported as being acid to litmus paper, one of us (R. H. J.)

however knew that the urine was alkaline on at least one occasion.

An intravenous phenolsulfonphthalein test was done. No dye appeared in the urine 10 minutes after injection; 45 per cent appeared in 1 hour and 10 minutes and

FIGURE 1 Interoposterior View of the Calcic Lith

30 per cent in 2 hours and 10 minutes. The total percentage of dye in 2 hours and 10 minutes was thus 75 per cent.

The blood was normal. A Kahn test was negative. The nonprotein nitrogen was 31 mg per 100 cc, the blood calcium 10.5 mg and the blood phosphorus 3.4 mg.

Intravenous urograms showed bilateral hydronephrosis and hydroureters. There was a huge laminated, calcific shadow in the bladder region (Figs 1 and 2), but no calcifications in the kidney and ureteral regions.

Eight days after admission a suprapubic cystolithotomy was done under Avertin, nitrous oxide and oxygen anesthesia. A large, friable, gray calculus was removed with the aid of obstetric forceps and a suprapubic tube was left in place. At the close of the procedure the blood pressure was 70/60 and the pulse 108. The patient responded well to a 500-cc blood transfusion and 5 per cent glucose given intravenously. Two grams of sulfathiazole was given daily for 2 weeks postoperatively, with blood levels between 0.5 and 2.3 mg per 100 cc. The oral temperature was never above 100.4°F.

The dry calculus was white and friable, weighed 1134 gm and was composed of phosphates and carbonates.

Cystoscopic examination 3 weeks after cystolithotomy showed a slightly constricted vesical neck, which was then resected with a Young's punch. The suprapubic tube was removed and a Foley indwelling catheter was left in place for 5 days. At discharge 10 weeks after

FIGURE 2. *Oblique View of the Calculus.*

operation, the suprapubic sinus was healed and the patient was symptom-free. There was 50-cc. residual urine, which contained many white cells and bacilli.

After discharge, the patient remained symptom-free and gained 30 pounds in weight. The urine was consistently infected with bacilli until a course of sulfadiazine cleared it in October, 1942, 2 years after removal of the calculus.

A complete cystoscopic examination with retrograde pyelograms later in the same month was entirely normal except for trabeculation of the bladder, which had been observed preoperatively. The urine was free from infection, and there was no residual urine. The blood pressure was 140/85. The urine was normal and without infection when the patient was last seen (December, 1942).

In view of the composition of the calculus (analyzed by the methods used by Higgins and Mendenhall¹), the reaction of the urine was somewhat of a puzzle. Three postoperative checks with nitrazene paper, while the patient was still in the hospital without medication and at various times of the day, showed the reaction to be pH 5.5. When the patient was last cystoscoped the reaction was pH 6.0, as tested with litmus, phenol red, brom-cresol green, brom-cresol purple and nitrazene paper. There is no explanation of this.

SUMMARY

A case report is presented of a thirty-four-year-old man from whom a 2½-pound bladder calculus composed of phosphates and carbonates was successfully removed. The hydronephrosis disappeared, the urinary-tract infection subsequently disappeared, and the patient became symptom-free.

This, to the best of our knowledge, is the largest bladder calculus removed with complete recovery that has been reported.

MEDICAL PROGRESS

CURABLE FORMS OF HEART DISEASE*

A. STONE FREEDBERG, M.D.,† AND HERRMAN L. BLUMGART, M.D.‡

BOSTON

PATIENTS with the conditions discussed in this report comprise only a minority of all those with heart disease. The correct diagnosis, however, is most important, since therapy is highly effective in the majority of cases, whereas in the commoner varieties of heart disease treatment is generally far less satisfactory.

PATENT DUCTUS ARTERIOSUS

In 1939, Gross and Hubbard¹ reported the first successful ligation of patent ductus arteriosus in man; ample confirmation of the usefulness of the procedure is now available.²⁻¹¹ In addition, the renewed interest in this condition resulting from Gross's work has stimulated study of the disease.

Etiology. The ductus arteriosus (normally) is patent during intrauterine life; its persistence after birth is therefore not the result of a bizarre congenital malformation.¹² Kennedy¹³ recently demonstrated that closure involves two phases previously postulated by Wells.¹⁴ The first is due to a muscular contraction of the wall of the ductus, requiring several minutes; the second phase, obliteration by fibrous tissue, requires approximately one month. Breathing stimulates closure, and Kennedy¹⁵ has shown that the onset of normal breathing in animals is followed by closure in three to ten minutes. Oxygen bubbled into the umbilical vein of fetuses also results in closure of the ductus. He therefore concludes that high concentrations of oxygen in the arterial blood and the beginning of vigorous respiration just after birth presumably combine to promote prompt closure.

Incidence. Patency of the ductus is not rare. In the course of a few years Gross¹⁶ has operated on 56 patients with this condition. Keys and Shapiro^{8,17} have studied 51 patients, and estimate that there are at least 20,000 persons with patent ductus arteriosus in the United States at the present time.

Clinical picture. Patent ductus arteriosus may be recognized clinically by the presence of a so-called "machinery" or constant murmur in the second left interspace, a systolic thrill in this area, dullness in the second or third left intercostal space and the peripheral signs of aortic insufficiency. X-ray study reveals a prominent conus shadow and, in almost all patients, some degree of dilatation of the left auricle, enlargement of the left ventricle, increased pulsations of the left ventricle and pulmonary artery, hilus dance and pulmonary congestion.^{4,18} Electrocardiograms may show left-axis or right-axis deviation or none; when right-axis deviation is present, one must exclude the presence of some other congenital lesion.

Dynamics of the circulation. In man the diastolic blood pressure is usually low and the pulse pressure wide; mild exercise results in a further decrease of the diastolic pressure.¹⁹ No change in mean blood pressure occurs in animals with a long-standing fistula between the aorta and pulmonary artery.²⁰ The venous pressure in man shows no constant changes.¹⁹ The circulation time is somewhat longer than would be expected in the absence of congestive failure, and is explained on the basis of an increased amount of blood in the lungs.¹⁹ The vital capacity is unchanged. In animals an increase in total circulating blood volume is observed after the establishment of an aortic-pulmonary artery fistula.¹⁹ The cardiac output is increased as a result of a left-ventricular output two to four times higher than the right-ventricular output.¹⁹⁻²¹ Since the flow of blood under ordinary conditions is entirely from the aorta into the pulmonary artery, cyanosis is absent. During coughing, laughing, crying, straining at stool and so forth, however, changes in pulmonary intravascular pressure may cause the flow through the ductus to be reversed, resulting in transitory cyanosis.

Results of surgery on dynamics of circulation. At the moment of closure of a patent ductus, the diastolic blood pressure immediately increases,^{18,22} probably owing to the diversion of the entire left-ventricular output into the aorta. The pulse rate slows, either because of increased vagal tone or, more likely, as a concomitant of the decrease in cardiac output.^{22,23} There is a decrease and equal

Associate professor of medicine, Harvard Medical School, and visiting physician and head of Medical Research Department, Beth Israel Hospital (on leave of absence).

ization of the cardiac output of both ventricles,¹⁹ lasting for at least twenty-seven minutes.²⁰ Blood samples taken from the pulmonary artery show a more marked degree of oxygen unsaturation than was present before closure.²⁰ The above-mentioned increases in circulation time and blood volume are restored toward normal following closure of the ductus.¹⁹

Clinical results of surgery. Reports by Burwell, Eppinger and Gross^{18, 19} indicate that enlargement of the heart due to dilatation, when present, disappears rapidly following surgery. Hypertrophic enlargement changes little in the immediate postoperative period. The cardiothoracic ratio, however, eventually becomes normal. Patients with definite congestive failure preoperatively show no symptoms of failure postoperatively despite a greatly increased physical activity.

The mortality of operation is low. Gross¹⁶ reported 2 surgical deaths in 56 operations. Complete division of the ductus, in addition to ligation, has been successfully accomplished in his last 14 cases. The advantage of division is the assurance of complete and permanent closure of the ductus.

Indications for surgical closure of patent ductus arteriosus. The majority of patients with patent ductus arteriosus die of cardiovascular complications; 25 per cent die with congestive failure, 25 to 33 per cent die with bacterial endarteritis, and 12 per cent die suddenly.²⁴

Burwell²⁵ has recently stated:

I think that any expression of opinion at this stage of our knowledge is bound to be tentative since we have been able to observe patients for only a few years after closure of the ductus arteriosus by operation. Two statements may be made:

First, the presence of important limitation or actual heart failure, the demonstration that the patent ductus is interfering with normal growth, or the presence of subacute bacterial endarteritis would seem to me to constitute firm indication for the operation.*

Second, because of the probable utility of the operation in preventing progressive overwork of the heart and in preventing bacterial endarteritis in a young person, I should consider the demonstration of uncomplicated patency to be in itself a strong suggestion that operation should be considered.

SUBACUTE BACTERIAL ENDARTERITIS SUPERIMPOSED ON PATENT DUCTUS ARTERIOSUS

Incidence. The occurrence of superimposed infection in patent ductus arteriosus is frequent. Reports^{8, 24, 29} indicate that from 20 to 40 per cent of all patients in whom the condition is recognized die with this complication.

*This statement is in agreement with the published reports of many observers.²⁹⁻³³

Diagnosis. The diagnosis is based on evidence pointing to the existence of patent ductus arteriosus: generalized evidence of toxemia, such as fever, tachycardia, leukocytosis, weakness and pallor³⁰; and the symptoms and signs of bacterial endocarditis—that is, splenomegaly and clubbing of the fingers. The course may be that of a protracted atypical pulmonary infection due to repeated small pulmonary emboli³¹ or may be characterized by manifestations of peripheral embolism, or both may occur. Peripheral blood cultures may be negative until the lungs are unable to filter out all the organisms, the pulmonary lesions break down and release organisms into the peripheral blood stream, and spread of the infection occurs to the greater circulation.

Therapy. Although it is not certain that surgical ligation or division of the ductus will prevent the subsequent development of bacterial endarteritis, this may well prove to be the case. To date there have been 3 cases of infection developing on a previously ligated ductus. One patient was reoperated on successfully³²; 2 died following the initial operation.^{4, 33} Graybiel et al.³⁴ reported the first attempt at surgical cure of subacute bacterial endarteritis complicating patent ductus arteriosus. At approximately the same time Keele³⁵ and Touroff³⁶ reported similar cases. Touroff has reported operations on 11 such patients thus far.^{27, 28, 37, 38} Of the 9 patients surviving the operation, 6 recovered from the infection. Burwell and Gross³⁰ have recorded the findings in 7 patients with patent ductus arteriosus and superimposed bacterial endarteritis. All were treated with chemotherapy—sulfapyridine, sulfathiazole or sulfadiazine—and with surgical closure of the ductus. One patient was cured on a medical regime before surgery was undertaken. The remaining 6 patients still had positive blood cultures when surgical closure of the ductus was performed. Two of these received no benefit from the combined medical and surgical therapy and subsequently died of their infection. The 4 remaining patients have apparently been completely cured, as evidenced by cessation of fever, repeatedly negative blood cultures, gain in weight and a resumption of normal activities. An additional case has been reported in which chemotherapy alone resulted in cure.⁴⁰ It is of interest that there have been several reports of cure of subacute *Streptococcus viridans* septicemia by excision of an arteriovenous fistula.^{41, 42}

It is evident that a higher percentage—approximately 67 per cent—of recoveries can be expected following chemotherapy and surgery together⁴³⁻⁴⁶ than has been reported from chemotherapy used alone or with heparin, or from any

other type of medical regime.^{42, 48} It may be concluded that when intensive treatment with the sulfonamides does not result in the disappearance of infection, both clinically and bacteriologically, within a short period of time—that is, approximately two weeks—surgical ligation of the ductus is indicated.

The contraindications to surgery are evidence that the patent ductus arteriosus compensates for another coexisting congenital cardiovascular anomaly, and evidence that the vegetations have already spread to the aortic or mitral valves. The presence of soft new murmurs or a positive peripheral blood culture (a few colonies) cannot, however, be accepted as absolute evidence of spread. It is clear that early recognition and prompt therapy will minimize its likelihood.

Mechanism of action of surgery. It has been shown that shortly after surgery blood cultures become sterile.^{27, 41} In some cases this has been true of the first blood culture taken ten minutes after ligation. It is possible that the lung acts normally as an efficient filter, since blood cultures from the pulmonary artery contain many more colonies than do those obtained from the aorta.⁴⁹ The efficiency of the lung as a filter may increase when the traumatizing effect of the higher aortic pressure on the lesion in the ductus or pulmonary artery is removed by ligation. It is also possible that the decrease in pulmonary-artery pressure, the slowing of the pulmonary-artery blood flow and the decrease in oxygen content of the pulmonary arterial blood are factors.

THE HEART IN NUTRITIONAL DEFICIENCY STATES

Although thiamine deficiency is a well-recognized cause of congestive heart failure,⁵⁰⁻⁵³ it is perhaps not so widely recognized that deficiency states may exist in patients with congestive heart failure due to intrinsic cardiac lesions. Anorexia, the dietary limitations, the anoxia and congestion of the gastrointestinal tract leading to impaired absorption and the possibly deficient storage and utilization of the substances comprising the vitamin B complex in the presence of impaired liver function combine to give rise to vitamin B deficiency in many cardiac patients with congestive failure. These patients exhibit a red tongue, cheilosis and absence or diminution of tendon reflexes and vibratory sense in the legs.

Pathologic physiology. Porter and Downs⁵⁴ recently pointed out that thiamine deficiency in man results in an increase in cardiac output, both absolute and in relation to the oxygen consumed, an increase in blood volume, a decrease in circulation time, an increase in oxygen consumption and elevation of the venous pressure. The decreased

arteriovenous oxygen difference and the decreased circulation time suggest the presence of an abnormally dilated peripheral vascular bed. The vital capacity is low and the blood pressure may be normal. Electrocardiographic changes are noted in almost all patients.⁵¹ These consist of tachycardia, a change in the direction of the T waves and a prolonged QT interval. These abnormalities tend to disappear after adequate administration of thiamine, suggesting the presence of a functional rather than an anatomic disturbance. It has, however, been shown that thiamine deficiency may be followed by focal myocardial necrosis^{55, 56} and cardiac hypertrophy.⁵⁷

Therapy. It has been pointed out by Hawes et al.⁵⁸ that effective therapy in oriental beriberi with cardiovascular dysfunction requires the use of large doses of vitamin B₁ parenterally. These authors stress the fact that in many cases enormous doses have been given by mouth with hardly any noticeable effect. Patients observed in this hospital support this contention. The following case is illustrative of the therapeutic effect of parenteral administration of thiamine chloride and vitamin B complex.

A. L., a 53-year-old man, entered the Beth Israel Hospital on June 27, 1943, with a history consistent with rheumatic fever at the age of 12. Twenty-seven years before entry he had been refused life insurance because of some cardiac abnormality. Ten years before entry he began to experience increasing fatigability, mild dyspnea on exertion and occasional edema of the ankles. About 1 year before admission these symptoms increased and during the previous 6 months dyspnea, both exertional and paroxysmal, orthopnea and peripheral edema became severe and progressive. Marked anorexia and a weight loss of 25 pounds were evident during the previous year. Treatment prior to hospitalization consisted of digitalization, intermittent bed rest and injections of Mercupurin. His condition, however, became so severe that he entered the hospital.

The essential findings were as follows: temperature, 99°F.; pulse, 70; respirations, 25; and blood pressure, 160/60. The patient was pale and cachectic, perspiring profusely, and exhibited severe dyspnea and orthopnea. Slight icterus, moderate cyanosis and marked venous engorgement with prominent venous pulsations were evident. There were redness and atrophy of the tongue as well as cheilosis. The anteroposterior thoracic diameter was increased, and diminished resonance, voice sounds and breath sounds, as well as fine crackling rales, were noted over both lung bases. The heart was tremendously enlarged to both left and right, with a widespread bounding apex impulse in the left axilla. The head bobbed and the chest wall heaved with each heartbeat. Characteristic murmurs of aortic and mitral stenosis and insufficiency were heard. The second aortic tone was almost inaudible. The liver was enlarged a handbreadth below the right costal margin and was firm and moderately tender. Slight clubbing of the fingers, bounding radial pulses and marked pitting edema of the legs, with a small amount of sacral edema, were apparent. The knee

jerk reflexes were sluggish. The Achilles tendon reflexes were not obtained.

Examination of the urine revealed normal findings, except for a slight trace to a trace of albumin during the first days. The blood counts were normal. The blood nonprotein nitrogen was 53 mg. per 100 cc. on admission, rising to 82 mg. during the next 3 days and subsequently returning to normal. The circulation time (calcium gluconate) was 60 seconds. The total blood protein was 6.9 gm. per 100 cc. A 7-foot roentgenogram showed the transverse diameter of the heart to be 21 cm. (twice the expected diameter for the patient's height and weight). The pulmonary arteries were prominent, the left auricle moderately dilated, and the pulmonary vessels dilated. Electrocardiograms showed left-axis deviation, a prolonged PR interval (0.22 seconds), depressed ST₁ and ST₂, inverted T₁ and T₂, and auricular and ventricular premature beats.

On admission oxygen was administered by mask, re-digitalization was accomplished, and ammonium chloride and vitamin B complex (6 capsules a day) were given. Dyspnea, marked heat intolerance and apprehension increased. Mercupurin, given intravenously on the 4th day, resulted in a diuresis of 4500 cc. in 24 hours. In spite of this, the course during the next 9 days was downhill. Increasing edema, severe dyspnea at rest, growing intolerance of the summer heat and several psychotic episodes were noted. There was no diuretic response or change in the clinical picture following the subsequent intravenous injection of Mercupurin. On the 13th day all oral vitamin B was omitted, and 100 mg. a day of intramuscular thiamine hydrochloride and 1 cc. of vitamin B complex were begun. Within 36 hours a striking change in the clinical picture took place. The dyspnea became minimal, the very severe heat intolerance disappeared although the weather was warmer, and the patient had no more psychotic episodes. During the course of the next 6 days the pulmonary rales disappeared and the peripheral edema became clinically undetectable following a favorable response to Mercupurin injection. The oxygen tent was omitted 2 days after institution of parenteral vitamin therapy. In addition the patient developed an appetite for food. The parenteral vitamin therapy was omitted after 8 days and vitamin B complex (6 capsules) and 15 mg. of thiamine hydrochloride were given orally. Mild to moderate dyspnea and slight to moderate pitting edema began to appear about 10 days after the omission of the parenteral vitamins. The patient was discharged on the 38th day much improved, but with slight dyspnea at rest and slight pitting edema of the ankles and sacrum.

Equally favorable effects on dyspnea and psychosis have been noted following administration of thiamine hydrochloride and vitamin B complex parenterally in other patients with vitamin B deficiency and severe organic heart disease causing long-standing decompensation with severe dyspnea after failure of the usual treatment with digitalis, diuretics and oxygen to secure improvement.^{59, 60} No striking benefit has been noted after the administration of large amounts of vitamin B complex, including thiamine, by mouth for periods from a few weeks to several months or more.⁵⁹

CHRONIC CONSTRICTIVE PERICARDITIS

Chronic constrictive pericarditis is recognized by the presence of a small or only slightly enlarged heart, diminished heart tones, markedly increased venous pressure and an enlarged liver with ascites. Blalock and Burwell⁶¹ and Harrison and White⁶² have recently reported follow-up studies on their series of cases of constrictive pericarditis, and conclude that approximately 60 per cent of all cases may be cured by surgical excision of portions of the scar. Although the surgical mortality rate is low,^{61, 63} it is of further interest that both groups of investigators stress the point that not all patients need surgery; if the disease is not progressive and the disability is mild, patients do well on salt restriction, diuretics and tapping of serous cavities. Digitalis is of no value except when myocardial weakness or auricular fibrillation is present.⁶¹

Pathologic physiology. Thickening and contraction of the pericardium or epicardium or both prevent the heart from dilating normally and therefore decrease the amount of blood received during diastole. There may also be some interference with emptying of the heart. It has recently been demonstrated that chronic compression of the heart results in atrophy of disuse, manifested by smaller muscle fibers.⁶⁴ The decreased filling, with increased venous pressure, results in an increase in pulse rate (Bainbridge reflex). The decreased output and inability to increase it normally result in weakness, fatigue, tachycardia, low pulse pressure and a diminished tolerance for exercise. The increase in venous pressure leads to the peripheral signs of venous congestion. The circulation time is prolonged and the arteriovenous oxygen difference⁶⁵ is increased. Hitzig⁶⁶ has recently offered an explanation of the occurrence of pulsus paradoxus in constrictive pericarditis: If the compression is predominantly right-sided, the phenomenon of pulsus paradoxus appears when there is a marked discrepancy between the pulmonary blood volume during expiration and the pulmonary vascular capacity during inspiration. This results in inadequate left ventricular filling and a decreased output with a weakened beat.

The electrocardiograms in White's⁶² series showed normal rhythm in 60 per cent and auricular fibrillation in 37 per cent of patients. Low voltage of the QRS complex was found in 60 per cent, with little change following surgery. Abnormal T waves in two or three of the classic leads were found in all cases; none of the T waves became normal in more than one lead following surgery. The electrocardiogram during pericardiectomy

has been studied by Stewart and Bailey.⁶⁷ Premature beats and paroxysms of abnormal rhythm, such as auricular fibrillation, auricular flutter and tachycardia, as well as ventricular tachycardia, were observed. The changes were of short duration and were similar to those previously recorded by Feil and Rossman.⁶⁸ Serial electrocardiograms taken for months after operation showed few changes in the form of the T waves or ST segments.⁶⁷

WOUNDS OF THE HEART AND VESSELS

Trauma to the heart. The war has resulted in increased interest in cardiac trauma.⁶⁹⁻⁷³ In such cases the early recognition of cardiac tamponade is most important. A large, quiet heart, an increase in venous pressure, or rapid pulse rate, a drop in blood pressure with a low pulse pressure, cyanosis and orthopnea are evidences of cardiac compression.

The Army⁷⁴ has recently formulated the treatment of penetrating heart wounds as follows: Blood must be aspirated from the pericardium by the costoxiphoid route, if possible within two hours of the onset of the tamponade. The advantages of the costoxiphoid route are that the needle avoids passing through both pleural leaves, that one cannot injure the lingula of the upper lobe if it is adherent, and that the pericardial sac can be more satisfactorily cleared of blood.⁷⁶ After anesthetizing—with 1 per cent novocain—the skin and underlying tissues, a 15-gauge, short-beveled needle is inserted at the left costoxiphoid junction and directed inward and slightly upward until blood escapes. Either a small syringe or no syringe should be attached to the needle. If the needle touches the heart, a scratching sensation is felt, and the needle must immediately be slightly withdrawn. Paracentesis may be done at the site of injury, if indicated, since even the withdrawal of a small amount of blood may be lifesaving. Several reports are available noting the beneficial effects of conservative treatment by means of aspiration and plasma, blood and saline infusions.⁷⁰⁻⁷⁸ Recurrence of tamponade is an indication for a second paracentesis. This should not be done less than fifteen minutes after the first in order that closure of the wound by a clot may be favored. If tamponade again recurs, extra-pleural cardiorrhaphy is indicated. The mortality rate from this operation in experienced hands varies from 26 to 50 per cent.^{71, 76}

It is now accepted that contusion of the heart may be consequent on nonpenetrating trauma to the chest wall. An interesting variant is afforded by a case of intrauterine cardiac injury produced by a nonpenetrating blow to the maternal abdomen, with the death of the fetus.⁷⁹ In addition,

Scherf and Terranova⁸⁰ have recently shown that displacement of the ST segment of the electrocardiogram occurs following blunt trauma to the precordium. The traumatic nonpenetrating wounds of the heart may present the following clinical features: absence of symptoms, with complete recovery; delayed, fatal rupture of the heart; myocardial failure, both transient and persistent; hemopericardium; ruptured valve; coronary thrombosis and acute myocardial infarction; angina pectoris, both transient and persistent; and arrhythmias, both transient and persistent, particularly auricular fibrillation.⁸¹⁻⁸⁴ The recognition of the possibility of cardiac damage after blunt trauma to the chest should be emphasized. The absence of bruising or other external evidence on the chest wall should not be construed as excluding cardiac trauma. Adequate treatment in the form of bed rest, oxygen administration, sedation and paracentesis may result in complete clinical recovery.

Traumatic arteriovenous aneurysms. The effects of an arteriovenous fistula on the circulation are similar to those noted above for patent ductus arteriosus. In arteriovenous fistula, however, since the systemic circulation is involved, the ventricular outputs are equal, and an increased blood flow is present in both the systemic and pulmonary circuits. Many case reports of successful repair of such fistulas have been published.⁸⁵⁻⁸⁷ Occasionally, however, spontaneous healing occurs.^{88, 89} It is important to remember in this connection that congestive heart failure may occur months or years after the establishment of an arteriovenous fistula.⁸⁷ Surgical removal of the fistula results in disappearance of the signs and symptoms of congestive failure.^{88, 87, 89} Reid and McGuire⁸⁸ emphasize the importance of prolonged bed rest with elevation of the affected part and postponement of surgery for three to six months. During this time hemorrhage becomes absorbed, the tissues are restored toward normal, the danger of infection is lessened, and collateral circulation develops.

There have been to date two reports of cures of subacute *Streptococcus viridans* septicemia due to an arteriovenous endarteritis by excision of the fistula.^{41, 42}

CARDIOVASCULAR SYPHILIS

Cardiovascular syphilis can be prevented in 99 per cent of patients by the prompt and energetic treatment of early syphilis.^{90, 91} It is important to recognize that adequate treatment of cardiovascular syphilis is effective only before serious complications arise. The criteria for the diagnosis of uncomplicated syphilitic aortitis are teleroentgenographic and fluoroscopic evidence of aortic dila-

jerk reflexes were sluggish. The Achilles tendon reflexes were not obtained.

Examination of the urine revealed normal findings, except for a slight trace to a trace of albumin during the first days. The blood counts were normal. The blood nonprotein nitrogen was 53 mg. per 100 cc. on admission, rising to 82 mg. during the next 3 days and subsequently returning to normal. The circulation time (calcium gluconate) was 60 seconds. The total blood protein was 6.9 gm. per 100 cc. A 7-foot roentgenogram showed the transverse diameter of the heart to be 21 cm. (twice the expected diameter for the patient's height and weight). The pulmonary arteries were prominent, the left auricle moderately dilated, and the pulmonary vessels dilated. Electrocardiograms showed left-axis deviation, a prolonged PR interval (0.22 seconds), depressed ST₁ and ST₂, inverted T₁ and T₂, and auricular and ventricular premature beats.

On admission oxygen was administered by mask, re-digitalization was accomplished, and ammonium chloride and vitamin B complex (6 capsules a day) were given. Dyspnea, marked heat intolerance and apprehension increased. Mercupurin, given intravenously on the 4th day, resulted in a diuresis of 4500 cc. in 24 hours. In spite of this, the course during the next 9 days was downhill. Increasing edema, severe dyspnea at rest, growing intolerance of the summer heat and several psychotic episodes were noted. There was no diuretic response or change in the clinical picture following the subsequent intravenous injection of Mercupurin. On the 13th day all oral vitamin B was omitted, and 100 mg. a day of intramuscular thiamine hydrochloride and 1 cc. of vitamin B complex were begun. Within 36 hours a striking change in the clinical picture took place. The dyspnea became minimal, the very severe heat intolerance disappeared although the weather was warmer, and the patient had no more psychotic episodes. During the course of the next 6 days the pulmonary rales disappeared and the peripheral edema became clinically undetectable following a favorable response to Mercupurin injection. The oxygen tent was omitted 2 days after institution of parenteral vitamin therapy. In addition the patient developed an appetite for food. The parenteral vitamin therapy was omitted after 8 days and vitamin B complex (6 capsules) and 15 mg. of thiamine hydrochloride were given orally. Mild to moderate dyspnea and slight to moderate pitting edema began to appear about 10 days after the omission of the parenteral vitamins. The patient was discharged on the 38th day much improved, but with slight dyspnea at rest and slight pitting edema of the ankles and sacrum.

Equally favorable effects on dyspnea and psychosis have been noted following administration of thiamine hydrochloride and vitamin B complex parenterally in other patients with vitamin B deficiency and severe organic heart disease causing long-standing decompensation with severe dyspnea after failure of the usual treatment with digitalis, diuretics and oxygen to secure improvement.^{59, 60} No striking benefit has been noted after the administration of large amounts of vitamin B complex, including thiamine, by mouth for periods from a few weeks to several months or more.⁵⁹

CHRONIC CONSTRICTIVE PERICARDITIS

Chronic constrictive pericarditis is recognized by the presence of a small or only slightly enlarged heart, diminished heart tones, markedly increased venous pressure and an enlarged liver with ascites. Blalock and Burwell⁶¹ and Harrison and White⁶² have recently reported follow-up studies on their series of cases of constrictive pericarditis, and conclude that approximately 60 per cent of all cases may be cured by surgical excision of portions of the scar. Although the surgical mortality rate is low,^{61, 63} it is of further interest that both groups of investigators stress the point that not all patients need surgery; if the disease is not progressive and the disability is mild, patients do well on salt restriction, diuretics and tapping of serous cavities. Digitalis is of no value except when myocardial weakness or auricular fibrillation is present.⁶¹

Pathologic physiology. Thickening and contraction of the pericardium or epicardium or both prevent the heart from dilating normally and therefore decrease the amount of blood received during diastole. There may also be some interference with emptying of the heart. It has recently been demonstrated that chronic compression of the heart results in atrophy of disuse, made manifest by smaller muscle fibers.⁶⁴ The decreased filling, with increased venous pressure, results in an increase in pulse rate (Bainbridge reflex). The decreased output and inability to increase it normally result in weakness, fatigue, tachycardia, low pulse pressure and a diminished tolerance for exercise. The increase in venous pressure leads to the peripheral signs of venous congestion. The circulation time is prolonged and the arteriovenous oxygen difference⁶⁵ is increased. Hitzig⁶⁶ has recently offered an explanation of the occurrence of pulsus paradoxus in constrictive pericarditis. If the compression is predominantly right-sided, the phenomenon of pulsus paradoxus appears when there is a marked discrepancy between the pulmonary blood volume during expiration and the pulmonary vascular capacity during inspiration. This results in inadequate left ventricular filling and a decreased output with a weakened beat.

The electrocardiograms in White's⁶² series showed normal rhythm in 60 per cent and auricular fibrillation in 37 per cent of patients. Low voltage of the QRS complex was found in 60 per cent, with little change following surgery. Abnormal T waves in two or three of the classic leads were found in all cases; none of the T waves became normal in more than one lead following surgery. The electrocardiogram during pericardiectomy

not revert may then be treated with quinidine. On the other hand, the Massachusetts General Hospital group¹⁰⁸ gives quinidine preoperatively, except to those patients with active auricular fibrillation, beginning twenty-four hours before surgery and continuing for twenty-four to thirty-six hours thereafter. They also stress the importance of reassuring the patient regarding the entire operative procedure, the anesthetic, the postoperative discomfort, intravenous injections and the oxygen tent.

ANEMIA AS A CAUSE OF CARDIAC PAIN AND CONGESTIVE FAILURE

An erroneous diagnosis of heart disease is often made in patients with anemia¹⁰⁹ because of dyspnea, easy fatigability, weakness, precordial pain,¹¹⁰ murmurs that simulate those of mitral stenosis¹¹¹ and edema. It is true, however, that severe anemia of any origin may have a harmful effect on a normal or diseased heart because of the persistent marked increase in cardiac work consequent on a decrease in the hemoglobin level below 50 per cent.¹¹²⁻¹¹⁴ It is sometimes difficult to differentiate dyspnea due solely to an inadequate amount of circulating hemoglobin from that consequent on congestive heart failure in a severely anemic patient. The presence of rales, orthopnea and venous engorgement in the latter condition and their absence in the former¹¹⁵ are very helpful.

Incidence. A recent study by Riseman¹¹⁶ has shown that anemia, thyrotoxicosis and polycythemia occurred in his clinic in a total of less than 1 per cent of patients with angina pectoris. There are, however, many patients with anemia whose presenting complaints are those of angina pectoris or congestive failure. Thus, from 1918 to 1937, Stalker¹¹⁷ collected 100 cases of angina pectoris and pernicious anemia. Since 1937, several reports indicate the not uncommon association of angina pectoris and hypochromic anemia.^{118, 119} Congestive failure precipitated by anemia appears to be less common, since only a small number of cases have been recorded.^{111, 116, 119}

Pathologic physiology of the circulation. The effects of anemia on the circulation resemble in some ways those produced by thyrotoxicosis or an arteriovenous shunt. The systolic and diastolic blood pressures are lowered,¹⁰⁹ with an increase in pulse pressure probably due to peripheral vasodilatation and a decreased blood viscosity. The circulation time is more rapid,^{120, 121} although it may be normal in the presence of congestive failure,¹²² and the cardiac output and oxygen utilization are increased.^{112, 114} Considerable cardiac enlargement occurs in approximately 50 per cent of

patients and is particularly common in the older age group.¹⁰⁹ Although most of the enlargement is due to dilatation, some hypertrophy apparently occurs.¹²³ The electrocardiograms may show flattened or inverted T waves, depression of the ST segments, particularly in Leads 1 and 2,^{109, 124} tachycardia, auricular ventricular nodal rhythm¹⁰⁸ and prolongation of the QT interval.¹¹⁵ These phenomena are responsible for the tachycardia, dyspnea, increased fatigability, weakness and edema noted in anemic patients. A contributory factor in the genesis of edema may be the decreased blood total protein with a reversal of the albumin-globulin ratio seen in some patients.¹¹⁵ Although most anemic patients with angina pectoris have underlying organic heart disease, several reports stress the normality of the coronary arteries in such patients.^{125, 126} The anemia, with its consequent reduction in oxygen capacity, results in myocardial anoxemia and chest pain.

Response to therapy. It is universally agreed that blood transfusions,¹¹⁸ iron, liver and bed rest result in cure in almost all cases, whether the symptoms are those of congestive failure or of angina pectoris. The changes in the circulation, size of the heart and electrocardiograms noted above are restored to normal. This of course indicates that the changes induced by anemia are functional rather than organic in nature. Although bed rest may not be necessary for all patients,¹²⁷ in some cases of congestive failure its use together with digitalis and diuretics may be required to tide the patient over until the hemoglobin level increases significantly in response to antianemic therapy.

CASE 29501

PRESENTATION OF CASE

A sixty-year-old housewife entered the hospital because of rectal bleeding.

The history was taken through an interpreter and was rather incomplete. The patient had been in good health until about one year prior to admission, when she had an episode of "moderate" rectal bleeding. There was no pain or "any other symptoms." It is not stated how long the bleeding lasted. Since that time she had had two similar episodes. At various other times she had noticed that her stools were blood streaked. Her bowels had always been regular. She had had no diarrhea and rarely took cathartics. Her appetite had been good. There was no vomiting, but occasional regurgitation of food after eating. There had been no weight loss. In the few months preceding entry she had a more or less constant ache in the right side of the abdomen, "just opposite the umbilicus," which was usually accompanied by gaseous distress. Two barium enemas performed at an outside hospital were said to have shown a polypoid filling defect in the lateral wall of the ascending colon just above the ileocecal valve.

She had had a hysterectomy eighteen years before entry, and a right nephrectomy sixteen years prior to admission following an attack of severe right flank pain. No diagnoses were recorded for either operation, and no additional information was available.

Physical examination showed a well-developed, rather obese woman in no distress. The lungs were clear. There was a Grade 2 aortic systolic murmur. The aortic second sound was greater than the pulmonic. The abdomen was not distended. Peristalsis was normal. No masses could be palpated. There was tenderness with some spasm deep in the right side of the abdomen at the level of the umbilicus. The scars of the previous operations were well healed. There were no hernias.

*On leave of absence.

The blood pressure was 140 systolic, 82 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood showed a white-cell count of 10,600, with 56 per cent neutrophils and 39 per cent lymphocytes. The hemoglobin was 13 gm. A blood Hinton test was negative. The urine was negative. The stools were guaiac negative. The blood sugar was 68 mg. per 100 cc., the nonprotein nitrogen 10 mg., and the total protein 7 gm.

An abdominal exploration was performed on the fifth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. RICHARD H. SWEET: I wonder if it was accurate to describe the filling defect as being polypoid. In examining an x-ray film Dr. Holmes has taught us to describe what we see and then go to the diagnosis. I assume there was more than one x-ray observation.

The record does not say whether this patient was admitted under the care of a medical service or under the care of the surgeons. I should not mention that except that a great deal of reliance must be placed in some of these histories on the interpretation of physical findings, and my medical friends are not always certain of their own evaluation of such things as tenderness and spasm in abdominal lesions. They sometimes call the surgeon in. The record does not say, furthermore, whether any x-ray films were taken in this hospital.

DR. BENJAMIN CASTLEMAN: We have the films from the other hospital. Perhaps Dr. Mueller will comment on them now.

DR. H. PETER MUELLER: I examined this patient in an outside hospital and found this lesion, which has the appearance of a polypoid mass (Fig 1). In addition to this round, filling defect, which appears to be opposite the ileocecal valve, the patient was definitely tender on palpation. I was not quite sure when I saw the films for the first time whether this meant anything, or whether it was just due to an enlarged ileocecal valve. I repeated the x-ray films a few days later and the same findings were observed. I had the impression that the filling defect seen in the spot films was too large for the ileocecal valve and that it was probably due to a polypoid mass.

DR. SWEET: What do you mean by "polypoid"? Do you refer to the configuration of the shadow, or to the fact that the lesion appears to hang from the wall of the bowel?

DR. MUELLER: I had the impression that a mass

with a broad base was projecting from the wall of the bowel into the lumen

DR SWEET Above the level of the cecum in the ascending colon?

DR MUELLER Yes

DR SWEET The record states that a mass was felt. The patient was an obese woman, hence it

health. Therefore, without much help from the history and little help from the physical examination, I must guess what this might have been.

If it were a mass, and from the x-ray findings, I assume it was, we are fortunate to have the roentgenologist here who did the examination. It is interesting that he was uncertain at first and re-

FIGURE 1 Spot Film Showing Filling Defect in Region of Ileocecal Valve

must have been quite a mass if they were able to feel it.

There is not much information in the record, and I can summarize it quickly. The patient had rectal bleeding, but there were periods when she had none. In this hospital the stools showed no blood on chemical examination. That is unlike a carcinoma. I should expect rather constant, at least microscopic or chemical, evidence of blood in the stools in a case of carcinoma of the colon. Furthermore, the history is not at all suggestive of carcinoma of the colon, except that the patient had had some bleeding. She could not have bled much because there was relatively no anemia.

On physical examination it is stated that the mass was tender. I am not accustomed to thinking of masses within the abdomen as being tender unless there is an inflammatory process, such as gangrene, inflammation from an ulcerated tumor or something of that sort. The normal blood chemistry, the general state of well being, the state of nutrition and the lack of weight loss seem to indicate that this woman was in remarkably good

health. To me it looks like a mass producing a filling defect in the ascending colon. Although I was prepared to appear before you and say that I could see no way of making a diagnosis in this case, after seeing the x-ray films, I am willing to say that the patient probably had a benign tumor of the ascending colon. The location is too high for a lesion around the appendix, a diagnosis that we occasionally make with a tender mass in the region of the cecum. Furthermore, to me it does not look like a tuberculous lesion. Those are the conditions that sometimes confuse us in the region of the right colon. I should say that this patient had a benign tumor in the ascending colon, the exact nature of which I do not know.

CLINICAL DIAGNOSIS

Polyp of ascending colon

DR. SWEET'S DIAGNOSIS

Benign tumor of ascending colon

ANATOMICAL DIAGNOSES

Submucous lipoma of ileocecal valve.
(Chronic intussusception.)

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: I am going to ask Dr. Allen to discuss his case and then take up the pathology of both cases together.

CASE 29502

PRESENTATION OF CASE

A forty-seven-year-old housewife was admitted to the hospital because of abdominal distress and vomiting of many years' duration.

During her childhood the patient was underweight and had occasional vomiting. At eighteen years of age she began to have attacks of distention, eructation, generalized abdominal pain, nausea and vomiting. The pain was most noticeable in the epigastric region and radiated through to the back and up and down the spine. The vomitus was never blood stained, nor did it contain coffee-grounds material. Vomiting occurred usually in the early evening but occasionally within five minutes of eating, especially after the ingestion of foods containing eggs and bananas. It was extreme and continued until dry retching occurred. The morning afterward she felt weak and dizzy, but there was no residual nausea. The bowel habits were regular but she was unable to describe their character. There was no change in the color of the urine. She had never been jaundiced. The attacks were not relieved by hot water or soda. She sometimes "lost as much as 12 pounds during a single attack." She had never been seen by a physician during an attack. About one month before entry she noticed severe right-sided abdominal pain, which was more prominent in the lower quadrant than in the upper and which apparently came on in the evening. "The pain felt like something would burst"; it was continuous for twenty-four hours and was associated with considerable vomiting. No medical advice was sought. It was not known whether she had had any more attacks. She remained in bed for the eighteen days before admission.

The patient was known to have had high blood pressure for many years. She had had occasional episodes of severe coughing productive of considerable sputum, which was occasionally blood tinged. Her mother was said to have had frequent "bilious attacks" with the vomiting of yellowish-green material. One sister had suffered from "stomach trouble."

Physical examination showed a slightly obese, well-developed woman in no distress. The heart

was slightly enlarged, with the sounds regular and of good quality; a systolic murmur was heard in the right third interspace. The lungs were clear. The liver edge was palpable three fingerbreadths below the costal margin and was quite tender.

FIGURE 1. Spot Film Showing Mass in Region of Ileocecal Valve.

Another point of tenderness was elicited by one examiner in the right lower quadrant. There were no masses, spasm or rebound tenderness in the abdomen. Examination was otherwise not remarkable.

The blood pressure was 210 systolic, 96 diastolic. The temperature was 97.4°F., the pulse 88, and the respirations 22.

Examination of the blood showed a red-cell count of 4,500,000, with a hemoglobin of 15.6 gm. The white-cell count was 8500, with 65 per cent neutrophils. The urine was negative. A phenol-sulfonephthalein test was normal. The stools were tan colored and guaiac negative. The blood nonprotein nitrogen was 19 mg. per 100 cc. A blood Hinton test was negative. A Graham test showed a 1.5-cm. area of calcification in the gall bladder, which had the appearance of a stone. The gall bladder failed to concentrate the dye.

A barium enema showed ready passage of the barium to the cecum. Arising from the lateral wall of the cecum, opposite the ileocecal valve, was a sharply defined, round mass, measuring 2 cm. in diameter (Fig. 1). The mass was constant and was well visualized after air injection. A gastrointestinal series and an intravenous pyelogram were negative.

On the fifth hospital day an abdominal exploration was performed.

DIFFERENTIAL DIAGNOSIS

DR. ARTHUR W. ALLEN: May we have the x-ray demonstration at this time?

DR. GEORGE W. HOLMES: The striking thing about this case, it seems to me, is a comparison of the films taken in the usual way, after the ingestion of barium with the colon filled, and the films taken after evacuation with air in the colon. When we carry the examination a little farther and use the pressure technic and spot film we begin to see something obviously wrong in this area here. This film was taken with the cecum distended with air; this film was taken with the cecum distended with barium; and this film (Fig. 1) shows the cecum partially empty. In the text it states that the lesion was opposite the ileocecal valve. The man who did the examination had a better opportunity to determine the position than I have, but I think that the important lesion is in the region of the ileocecal valve, not opposite it. If this is correct the shadow may be due to protrusion of the ileum into the cecum. If it is opposite the valve, it must be a mass arising from the wall of the cecum. One can get all the appearances of a filling defect from a slightly edematous ileocecal valve. In the July number of the *American Journal of Roentgenology*, Golden* illustrates cases that look not unlike this that were found to be due to edema of the ileocecal valve. There is no question about this lesion in the spot films. I do not believe this is a polyp protruding from the wall.

DR. ALLEN: The patient gives such a perfect story for cholelithiasis with acute inflammation and perforation into the hollow viscus, with the possibility of gallstone ileus, that I strongly suspect that there was something else the matter with her. Every time we see gallstone ileus in the ward we always say afterward that, had we been alert concerning the history of the case, we could have made the diagnosis without any question of doubt.

This woman of forty-seven had had a sensitive gastrointestinal tract since childhood. Her mother had had frequent bilious attacks, and her sister,

stomach trouble. Recently I was asked to operate on the wife of a physician for gallstones. I was told that no x-ray examination had been made and the husband of the patient said: "It is not necessary. You have already operated on her mother and two of her sisters for gallstones. Besides, she has a good clinical story." This woman's early attacks were very mild and not associated with cholecystic disease. Many children vomit periodically while they are growing up, and I thought that this mass might conceivably show calcified mesenteric nodes on the x-ray films. It would have been a good sequence for her childhood disorders. At the age of eighteen, however, she began to have attacks that sound more like gallstone colic, brought on by the ingestion of foods containing a high content of fat. It is interesting that at no time during her previous life when she had these episodes or at the time of her present illness, which started a month prior to admission, had she consulted a physician. Most people who have gallstone attacks do consult a physician, usually in the middle of the night during their acute distress. Perhaps the scarcity of doctors might have played a role in her not having a physician on the night that the last acute attack started. She was apparently quite ill at that time. She was conscious of a feeling of something being radically wrong. She felt as though "something was going to burst" which, incidentally, is an interesting statement and is perhaps leading me off "on a limb." She obviously was ill because she stayed in bed eighteen days after this episode, which is about the right time for a patient with gallstone ileus to appear in a hospital, usually with vomiting and usually with a gallstone stuck about 40 cm. from the ileocecal valve, in the portion of the ileum that is narrower than the rest of the small intestine. During its descent the gallstone collects a certain amount of fecal matter on the outside, and by the time it gets to this narrow segment it may produce obstruction of the small bowel. That is the story that these patients are most apt to give. We have no history here to indicate that at any time this affair caused small-bowel obstruction. According to the story the patient certainly did not have small-bowel obstruction when she entered the hospital, nor was she extremely ill. It is a little amazing that she had a normal temperature and pulse and did not have much in the way of physical signs, except for possible tenderness in two areas—one in the region of the right upper quadrant and one in the region of the right lower quadrant. So she could, I think, have had a gallstone that had left the gall bladder, had entered the gastrointestinal tract and was discovered

*Golden, R. Enlargement of ileocecal valve. *Am. J. Roentgenol.* 50:19, 1943.

in the region of the cecum at the time of admission.

There are a great many other things that might explain the local picture in this region. This woman had had no history of bleeding from the bowel. She was free from anemia—as a matter of fact she had 15.6 gm. of hemoglobin at entry, which is above normal. That brings up the question of tumors of the right bowel, which are supposed to cause anemia but which, as a matter of fact, only cause anemia in about 70 per cent of the cases. This could perfectly well have been a benign tumor, such as a lipoma, a lipofibroma or a true fibromyoma, or a benign polypoid lesion, although I strongly suspect that it was not of that type because she came to the hospital following an acute episode. This type of tumor does not cause an acute episode, except for intussusception, which does not permit a patient to stay in bed eighteen days prior to admission to the hospital; but an inflammatory lesion such as appendicitis could. That also could produce a defect similar to the one that we see here, but if the defect were still present from such cause I should expect that there would still be some leukocytic elevation, some elevation of temperature and some obvious tenderness in this region. Besides, in this film one sees a perfectly normal appendix. So I shall rule out appendicitis. Occasionally a single diverticulum of the intestine with diverticulitis occurs in this site. These cases produce symptoms and signs of acute appendicitis and are always diagnosed acute appendicitis preoperatively. The history is usually shorter than this and associated with a perfectly typical febrile reaction and a tender inflammatory mass. Therefore, I shall rule that out.

I am going to go back to the gallstones in this case: the history is so perfect for gallstone ileus, and about the right time had elapsed after the severe onset. One gallstone was left behind, and although the mass in the cecum does not look like a gallstone to me, I am going to assume that there was a gallstone in the cecum at the time of operation.

DR. HOLMES: The patient had a barium meal, and it went through without difficulty.

DR. ALLEN: I should expect a barium meal to show the biliary system if she had a fistula. Did you purposely keep back the gall-bladder films?

DR. HOLMES: No. I did not put them up because they do not show anything. If the patient had gallstone ileus, she should have shown some obstruction.

DR. ALLEN: Yes; I should assume there was no small bowel obstruction from the appearance of the flat film. No loops of small bowel are apparent.

DR. HOLMES: I should have put up the other film. I neglected to do so because it did not show anything. But you notice the barium passed through the ileum all right and entered the cecum.

DR. ALLEN: That would be expected if the gallstone had gone by, but I should like to see a little barium in the biliary tree.

CLINICAL DIAGNOSES

Cecal polyp.

Chronic cholecystitis and cholelithiasis.

DR. ALLEN'S DIAGNOSES

Gallstone in cecum.

Cholelithiasis.

ANATOMICAL DIAGNOSES

Hypertrophied ileocecal valve.

(Chronic intussusception.)

Cholelithiasis.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: In the case that Dr. Allen discussed the patient was operated on and the surgeon found the gall bladder filled with stones. There was no connection that he could make out between the gall bladder and the duodenum or the jejunum. When he felt the cecum he was able to palpate a definite mass. On opening the cecum he found a prolapse or protrusion of the mucosa (and possibly of the entire wall) of the terminal ileum into the cecum for a distance of 2.5 to 3.5 cm. The edge of the protruding tissue was everted. The whole mass of tissue resembled the end of a cornet horn. The examining finger passed freely through the lumen of the protruding tissue into the terminal ileum. No obstruction was felt. It was thought that any procedure toward removal of the lesion would necessitate an ileotransverse colostomy and right colectomy in a two-stage operation. Since the patient had hypertensive heart disease and since there was no obstruction in the ileocecal region no further surgery was deemed advisable at that time.

The patient left the hospital and was apparently free from symptoms for over two years, when she died of a cerebral hemorrhage.

In the case discussed by Dr. Sweet, the surgeon did not open the cecum. He felt the mass and resected the cecum and the terminal ileum. When the specimen was opened, the mass was found to be an ovoid, well-circumscribed, submucosal tumor involving about a third of the circumference of the ileocecal valve and projecting about 0.7 cm. above the rest of the valve. The mucosa over the lesion was definitely hemorrhagic. When sectioned the mass proved to be a lipoma. In

the serosa over both ileum and cecum there were many areas of fat necrosis. This, together with the mucosal inflammation, is evidence that something had been going on, and certainly the likeliest process is chronic intussusception.

The problem in Dr. Sweet's case is to decide whether the mass was a true lipoma or merely a hypertrophied ileocecal valve, with perhaps more than the usual amount of submucosal fat, similar to the one found in Dr. Allen's case. In going through some of our routine autopsies we have found hypertrophied ileocecal valves that had been removed from patients who had had no symptoms of chronic intussusception. These ileocecal valves are fatty and uniformly enlarged, unlike that in Dr. Sweet's case, in which the lesion was circumscribed and had produced a localized elevation of the mucosa. The case discussed by Dr. Sweet I think should be called a true lipoma, although I admit that I am not sure it could not have been merely a variation from the normal ileocecal valve. We have seen several other obvious submucosal lipomas in the intestinal tract, especially in the cecum and ascending colon. These were much larger than the one under discussion today and had produced intussusception. I believe that in the case discussed by Dr. Allen the patient had a hypertrophied ileocecal valve that also produced chronic intussusception.

Dr. ALLEN: I should like to ask Dr. Holmes if he considers the case I discussed as typical of

the cases Golden described. I think he spoke of mucosal edema and not of fat deposits.

Dr. HOLMES: That is correct.

Dr. ALLEN: It seems to me that these cases represent either an unusually large ileocecal valve or a small herniation of the terminal ileum through the valve. Is it not true that we may see a considerable variation? We have no good idea of what they are normally. How do you reconstruct the acute episode starting one month prior to entry?

Dr. CASTLEMAN: The patient probably was not sick because of her ileocecal intussusception. She was a severe cardiac and undoubtedly went to bed for any mild complaint. I believe that she had intussusception off and on, which reduced itself spontaneously. She remained free from symptoms for almost two years after operation.

Dr. HOLMES: The radiologist is more or less responsible for getting the surgeons into difficulties, and we must eventually be able to recognize this condition and to distinguish it from true tumor of the cecum.

Dr. CASTLEMAN: Does it matter whether you call it a true tumor or a variation from the normal? If it produces chronic intussusception, perhaps something should be done surgically.

Dr. HOLMES: The points are that the surgeon might not be in so much of a hurry to operate and that he would not take the cecum out if it were due to protrusion of the valve.

in the region of the cecum at the time of admission.

There are a great many other things that might explain the local picture in this region. This woman had had no history of bleeding from the bowel. She was free from anemia—as a matter of fact she had 15.6 gm. of hemoglobin at entry, which is above normal. diseases on the part of a better nourished population

To the medical profession much of the information in this report merely confirms what it well knows—that Boston continues to have an ably administered Health Department. A greater value, and one that the *Journal* hails, is that the report will be read in circles not usually reached by medical publications, and will take information on public health to places where it would not otherwise have been carried.

MEDICAL EPONYM

NEUFELD METHOD

A note on the observation of specific capsular swelling of pneumococci by Ferdinand Neufeld (b 1869) first appeared in *Zeitschrift für Hygiene und Infektionskrankheiten* (40 54-72, 1902) under the title "Über die Agglutination der Pneumokokken und über die Theorien der Agglutination [Agglutination of Pneumococci, and Theories of Agglutination]." A portion of the translation from page 57 follows:

If we mix equal parts of agglutinating serum and a bouillon culture of pneumococci, whether in the test tube or by intimate admixture on a coverslip of a loopful each of serum and culture, we observe in the hanging drop preparation distinct signs of swelling which in the case of a strongly potent serum appear immediately or after only a few minutes. The individual cocci swell up twice or three times their [normal] size and at the same time flatten out at their points of contact with each other, which are ordinarily pointed and their whole contour becomes indistinct and hazy.

Twenty nine years later, in an article with R. Ettinger-Tulczynska entitled "Nasale Pneumokokkeninfektionen und Pneumokokkenkeimträger im Tierversuch [Nasal Pneumococcal Infections and Pneumococcus Carriers in Animal Experiments]" which appeared in the same journal (112 492-526 1931), Professor Neufeld describes the inoculation of bouillon with nasal secretion. A portion of the translation from page 495 follows:

The serum bouillon growth usually does not show a pure culture of pneumococci but a mixture of various bacteria (among them frequently, streptococci). Notwithstanding it is possible quickly and with certainty to identify typical pneumococci if advantage is taken of the fact that they promptly swell markedly in homologous rabbit (not horse) serum.

And in a footnote on page 496 he observes:

The swelling phenomenon has furthermore proved its worth to us as a simpler and more reliable means of typing pneumococci than the usual agglutination method.

R W B

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

THE PHYSICIAN'S ROLE IN TUBERCULOSIS CASE FINDING IN INDUSTRY

Some Massachusetts physicians have received a letter from the Division of Tuberculosis stating that significant findings were noted in an x-ray film of the doctor's patient during an industrial survey of the plant where the patient is employed. A report of the x-ray findings is given together with the information that the employee has been notified to consult his family physician so they may talk over the results of the report.

Routine x-ray examination of the chest for the purpose of finding unsuspected pulmonary tuberculosis in apparently healthy people is not only being used in the induction centers for the Army and Navy, but also in pre-employment examination in large industries and in the case-finding programs of state health departments and the United States Public Health Service.

Efficiency of the x-ray. There is no question that the x-ray method is the most effective single means for finding unsuspected pulmonary tuberculosis. Its value is limited only by the extent to which it is used. A person may have pulmonary tuberculosis in any stage of the disease either without any symptoms or with symptoms that are not alarming enough to cause him to seek medical advice. In early cases of tuberculosis, the x-ray evidence may be present three to five years before the disease has progressed to the symptomatic stage.

The absence of symptoms does not mean that the disease is not in an infective stage. In a recent study of 160 Army rejectees for pulmonary tuberculosis at the Middlesex County Sanatorium, it was found that only 10 of these had been previously known to have tuberculosis, and all were classed 1A by their local draft boards. By stage of disease, these cases were 75 per cent minimal, 14 per cent moderately advanced and 11 per cent advanced. The most significant fact from the public health point of view is that over half the patients with moderately advanced and advanced cases had positive sputums, and even 8 per cent of those with minimal cases had positive sputums. Such unsuspected bacillary cases are continuously seeding their communities with tuberculosis and must be found and segregated if tuberculosis is to be eliminated or reduced to a low level.

New program of case finding. In order to pick up these undiagnosed cases the Massachusetts De-

partment of Public Health, in co-operation with the Massachusetts Tuberculosis League, inaugurated a program of pulmonary tuberculosis case-finding in industry on September 28, 1943. His Excellency, Governor Leverett Saltonstall, was the first to have an x-ray film of his chest, and he was followed by the State House employees. The x-raying is accomplished by means of a fully equipped mobile unit which takes a 4-by-10-inch stereoscopic photofluorogram at a cost of only 6 cents per film. The unit was purchased by the Christmas-Seal-supported tuberculosis associations of Massachusetts and is loaned to the department. X-ray surveys are conducted in industry on a voluntary basis and at the invitation of the plant management.

Follow-up of suspects. On the identification blanks that are being used, the employee is asked to name the physician to whom he wishes his x-ray report to be sent. If the x-ray findings are significant, a written report is sent to the physician and the employee notified by mail to see his doctor. It is hoped that when the latter presents himself to his physician for interpretation of the x-ray findings, he will be placed under careful clinical, laboratory and further x-ray studies to confirm or deny the impression gained from the first roentgenogram. If the diagnosis of pulmonary tuberculosis is confirmed, the physician should then report the case to the local board of health.

It is the responsibility of the district health officer to see that the employee found to have suspected tuberculosis presents himself to his physician for further studies and, if the diagnosis is confirmed, that the case is reported to the local board of health in the prescribed manner.

COMMUNICABLE DISEASES
IN MASSACHUSETTS FOR NOVEMBER, 1943

Whooping cough	407	952	710

*Pfeiffer-bacillus meningitis only other form reportable previous to 1941.

COMMENT

Anterior poliomyelitis, as might be expected, is now definitely on the downward grade. The meningococcal meningitis figure has remained in the forties for the last

four months. This is a decidedly high level compared with that of other years. Diphtheria has been creeping up since August; the November figure is the highest for this month since 1935, but this year's total probably will not exceed that of last year. Whooping cough, on the other hand, shows a 50 per cent decline over last November.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Actinomycosis was reported from: Springfield, 1; total, 1.

Anterior poliomyelitis was reported from: Adams, 2; Beverly, 2; Boston, 4; Cambridge, 1; Danvers, 1; Fall River, 3; Haverhill, 1; Lynn, 3; Natick, 1; New Bedford, 1; North Adams, 1; Norwood, 1; Pittsfield, 1; Saugus, 1; Seekonk, 1; Watertown, 1; total, 25.

Diphtheria was reported from: Boston, 12; Cambridge, 1; Chelsea, 1; Foxboro, 1; Gloucester, 1; Lowell, 4; New Bedford, 3; Salem, 1; Somerville, 4; Woburn, 3; total, 31.

Dysentery, bacillary, was reported from: Boston, 6; Brookline, 1; Cambridge, 2; Canton, 1; Hingham, 1; Ipswich, 1; Lowell, 4; Malden, 2; Melrose, 1; Quincy, 1; Stoneham, 1; Wellesley, 1; total, 22.

Encephalitis, infectious, was reported from: Braintree, 1; Brockton, 1; Fort Devens, 1; total, 3.

Malaria was reported from: Falmouth, 1; Fort Banks, 13; Fort Devens, 11; total, 25.

Meningitis, meningococcal, was reported from: Agawam, 1; Boston, 7; Brockton, 1; Cambridge, 1; Fall River, 5; Fitchburg, 2; Fort Banks, 1; Fort Devens, 1; Haverhill, 1; Holbrook, 1; Holden, 1; Leominster, 1; Lowell, 1; Lynn, 2; New Bedford, 1; Norwood, 1; Revere, 1; Saugus, 1; Somerville, 3; Southbridge, 1; Springfield, 2; Waltham, 1; Weymouth, 1; Worcester, 6; total, 44.

Meningitis, other forms, was reported from: Boston, 1; Holyoke, 1; Lawrence, 1; Malden, 1; Medford, 1; Milford, 1; Somerville, 1; Springfield, 1; Worcester, 1; total, 9.

Meningitis, undetermined, was reported from: Boston, 3; Cambridge, 3; Leominster, 1; total, 7.

Salmonella infections were reported from: Boston, 1; Cambridge, 2; Marblehead, 2; Wellesley, 2; total, 7.

Septic sore throat was reported from: Boston, 6; Clinton, 1; Malden, 1; Marion, 2; Milton, 1; New Bedford, 1; total, 12.

Trichinosis was reported from: Newton, 1; total, 1.

Typhoid fever was reported from: Lowell, 1; Malden, 1; North Attleboro, 1; total, 3.

Typhus fever was reported from: Williamstown, 1; total, 1.

Undulant fever was reported from: Dartmouth, 1; Easton, 2; Framingham, 1; Somerville, 1; Wareham, 1; total, 6.

WAR ACTIVITIES

CIVILIAN DEFENSE

OCD AFFILIATED UNITS

The United States Office of Civilian Defense has recently announced that ninety-three hospitals and medical schools scattered throughout the country have completed the formation of affiliated units of civilian physicians, which will be available to either OCD or the Army in the event of need for setting up emergency hospital facilities in their respective areas.

Each unit is composed of fifteen physicians, surgeons and other specialists and forms a balanced professional staff. OCD will use the units to supplement the staffs of emergency base hospitals located in relatively safe zones on the fringes of critical areas in case it is necessary to transfer civilian patients to these hospitals because of emergency in such areas. Furthermore, the units will be called on by the War Department to staff externalized hospitals should there be a sudden influx of battle-front casualties, or some other extraordinary military necessity, requiring hospitals and physicians beyond the immediate capacity of the Army in any particular locality. The affiliated units will be used for military emergency purposes only in or near the communities in which the staff resides. Their duties will be temporary and they will be replaced by Army medical officers as quickly as the Surgeon General of the Army can make the necessary assignments.

Normally, the fifteen doctors of a unit are associated with a single hospital. Each unit includes a chief and assistant chief of medical services, two general internists, a chief and assistant chief of surgical services, four general surgeons, two orthopedic surgeons, one dental surgeon, one pathologist and one radiologist. Physicians accepted for service in the units receive inactive reserve commissions in the United States Public Health Service, but will be called to active duty by the Surgeon General (USPHS) only at the request of OCD. When a unit is needed either to staff an emergency base hospital or to assist the Army temporarily in a military emergency, the physicians of the unit will be placed on active duty for the duration of that particular emergency.

Following is a list of units completed and commissioned by the Public Health Service up to October 30, 1943, in Region I, which includes all the New England States:

Boston University School of Medicine Boston
Cambridge Hospital Cambridge Mass
Columbia Hospital Brockton Mass
Harvard Medical School (A) Boston
St. Luke's Hospital Pittsfield Mass
Springfield Hospital Springfield Mass
Central Maine General Hospital Lewiston Maine
Eastern Maine General Hospital Bangor Maine
Maine General Hospital Portland Maine
Elliot Hospital Manchester New Hampshire
Lawrence and Memorial Associated Hospitals New London Conn
Meriden Hospital Meriden Conn
Stamford Hospital Stamford Conn
Waterbury Hospital Waterbury Conn
Yale University School of Medicine New Haven Conn
Rhode Island Hospital Providence Rhode Island
St. Joseph's Hospital Providence Rhode Island

MISCELLANY

CANCER OF THE LUNG— A GROWING PROBLEM

Until recently, primary carcinoma of the lung was regarded as a relatively rare type of cancer. We are now

recognizing that it is one of the commonest forms of neoplasm. It has been discovered that around 10 per cent of all cancers originate in the lung, that this organ is surpassed only by the stomach as the most frequent site of beginning malignancy, and that approximately 15,000 Americans succumb annually to carcinomas that arise from lung structures usually in the bronchi. Such stark statistics and the demonstrated fact that cancer of the lung like pulmonary tuberculosis can be found early by employment of readily available diagnostic facilities, provide all physicians with food for thought as they evaluate the chest complaints presented by patients, especially men and particularly those past forty years of age. Many of the pertinent points are discussed in a recent paper (Overholt, R. H. A common masquerading lung disease *Dis. of Chest* 9:197-210, 1943).

There is a masquerading lung disease which often gives quarter for a short time before the fatal issue and whose actions, in many ways, may simulate those of tuberculosis.

Both diseases are unique for they masquerade as other acute or chronic conditions of the lung. In neither are symptoms reliable in the early stages. Both diseases are marked by a lack of early reliable physical signs. Both are unique since in the early stages a single x-ray film will usually show some abnormality. Again, they are one and the other because in spite of obscure clinical factors the diagnosis can be accurately made in a high percentage of cases. Lastly, there is a similarity between tuberculosis and this masquerading disease: cancer of the lung is successful treatment depends to such a large degree on early discovery.

However, the two diseases differ in regards the predominant age groups affected. Tuberculosis concerns principally the age groups between fifteen and forty, whereas lung cancer usually affects those between the ages of forty and sixty-five. The diseases are totally different in respect to the matter of time. In tuberculosis, time plus rest is often a useful ally of the patient in regaining health. In cancer of the lung the element of time is always an enemy of the patient. Prolonged observation and rest treatment never improve the situation, but rob the patient of his only chance for possible cure.

In 165 cases of lung cancer it was found that the patients first consulted a doctor because of symptoms usually associated with almost any chronic chest condition. A review of these symptoms suggests it would be impossible to set apart any group of complaints that could be regarded as pathognomonic of pulmonary malignancy. Nevertheless, 82 per cent of all the patients reported chronic cough, whereas no less than 92 per cent had as a first symptom something that called for attention to be directed to the chest when first the physician was consulted. Besides cough, other common symptoms included chest pain, chills and fever, hemoptysis, dyspnea, loss of weight and weakness.

Reviewing the physical signs elicited it is again impossible to outline a specific and significant grouping any more suggestive of cancer than of other chronic pulmonary conditions. Cases examined in the early stages often presented no physical signs. When present, the signs were of considerable variety and frequently misleading. They included evidence of congestion, consolidation, fluid localized emphysema, cavitation, bronchial obstruction, mediastinal shift and other phenomena varying with the case, thus emphasizing the unreliability of simple physical signs in the differential diagnosis of this condition.

Of the 165 cases, 104 (63 per cent) were incorrectly diagnosed by the first doctor consulted. In view of the confused picture of misleading symptoms and physical findings, perhaps this majority in favor of error is not completely surprising, but the sobering thought emerges that treatment based on an erroneous diagnosis was maintained for long periods of time, aimed at such supposed conditions as tuberculosis, 40 cases; unresolved pneumonia, 18 cases; lung abscess, 13 cases; bronchitis, 11 cases; asthma, 5; heart disease, 4; pleurisy, 4; metastatic tumors, 2; and miscellaneous, 9 cases. The most notable fact was the high frequency of false diagnoses of tuberculosis.

Unfortunately, lung cancer was not unmasked in far too many cases until long after the patient first visited a physician. It was possible in the case histories of 125 patients to determine how speedily a verified diagnosis was reached. Two facts stood out boldly. First, 36 per cent of the patients placed themselves under medical supervision at onset or within one month of the onset of symptoms. Second, the average patient consulted a doctor within three months of onset but did not receive benefit of a chest x-ray film for an additional three months. The true diagnosis was not arrived at until nine months had elapsed from the time when the first doctor saw the patient.

The x-ray, without doubt, is by far the most valuable aid in apprehending pulmonary disease, but a distinction is necessary between its ability to yield presumptive and absolute evidence. In 98 per cent of this series of cases the initial film revealed that trouble was present. An explanation of the delay in reaching a final diagnosis may be found in the fact that in the majority of cases the primary pathologic process failed to produce on the film or the fluoroscopic screen a shadow of itself. Those abnormalities that did appear were secondary effects due to the presence of the neoplasm and were of such variability as to be susceptible of a wide range of interpretation.

In 95 per cent of the cases it was possible to establish an unequivocal diagnosis during life, bronchoscopy being the leading method of obtaining tissue, and having been employed in 103 cases. In 39 other cases surgical exploration was used. Metastases were sectioned in a few cases, aspiration was the method in another small group, whereas the remaining 5 per cent were diagnosed only after post-mortem examination.

For a decade, surgery has been available in the treatment of lung cancer. A creditable showing has been made during this pioneering period. For example, 2 out of every 5 cases surgically explored have been found to be free of extension of the cancer extrapulmonarily. In 20 per cent of the entire group of verified cases there was some hope of cure. This seems an encouraging ratio when we recall that prior to 1933 there was no reason to regard the condition as anything but incurable. As a reward for our efforts, 20 patients, or 13 per cent, remain as the net salvage from the entire series of 156 verified cases of primary lung cancer, out of 32 selected for an attempt at curative resection. These 20 patients are all reasonably well and devoid of evidence of metastatic disease, and 5 of them can be referred to as "cures" in so far as they have now passed the five-year mark.

In considering practical steps toward bringing cases of lung cancer to light during the curable stage we can

learn valuable lessons from the record on tuberculosis case finding. Physicians have been taught that if tuberculosis is to be discovered during its minimal stage it is not necessary to search for absent or insignificant symptoms and physical signs but to go immediately to the x-ray. The same can be said for the apprehension of early lung cancer.

How may the first doctor consulted set in motion this mechanism of early discovery? He may save valuable time for his patient if he remembers:

1. That cancer of the lung is now one of the most important diseases of the chest in patients within the age period from forty to sixty-five years, particularly in males.
 2. That many patients do seek help at a time when the lesion is still confined to the lung.
 3. That symptoms and signs are either lacking or misleading in the early stages.
 4. That the earliest lesions will in almost every case produce some telltale shadow on the x-ray film, and
 5. Finally, that there are two methods available for clinching the diagnosis: first, that the majority of lesions are visible bronchoscopically and accessible for biopsy, and second, that when the suspicion cannot be verified in this way, it is possible to explore the chest safely by surgical means, settle the diagnosis and carry out curative treatment if necessary.

NOTICES

BOSTON COUNCIL OF SOCIAL AGENCIES

The following series of lectures covering the problem of alcoholism from various aspects will be given at Zero Marlborough Street, Boston, on Friday evenings at 7:30 p.m. They are sponsored by the Committee on Alcoholism of the Boston Council of Social Agencies.

January 7 — The Heredity of the Inebriate. Dr. E. M. Jellinek, associate professor of applied physiology, Yale University.

February 11 — Alcohol and Public Opinion. Dr. Dwight Anderson, director, public relations, Medical Society of the State of New York.

March 10 — Effects of Alcohol: The evidence of physiological experiments. Dr. Howard W. Haggard, director, Laboratory of Applied Physiology, Yale University.

April 7 — The Treatment of Chronic Alcoholism. Dr. Robert Fleming.

Plan of Treatment at the Washingtonian Hospital with Special Consideration of the Conditioned Reflex Treatment. Dr. Joseph Thimann.

May 12 — Alcoholism, Criminology, and Parole. Reuben L. Lurie, chairman, parole board, Massachusetts Department of Correction.

These lectures will be open to the public.

THE RELATION OF PHYSICAL THERAPY TO ARTHRITIS*

WILLIAM BENHAM SNOW, M.D.†

NEW YORK CITY

TO cover adequately the major medical problem of the relation of physical therapy to arthritis, with all the finesse in selection of physical therapy and in the technical understanding necessary for its proper application, would require a book, not a paper. Again, arthritis itself presents diverse types of cases. On the one hand, one sees a patient who is not too uncomfortable, with low-grade arthritic changes occurring later in life. He philosophically accepts his aches and pains, goes along "moving his bones," and so, by this subtle form of physical therapy, maintains his mobility and suffers little. On the other hand, one sees another patient with a hypochondriacal tendency who cannot stand pain, slows up, and takes too much treatment, often of the wrong kind. He stiffens up and is soon semi-invalided mentally and physically. Lastly, there are the extremely malignant deforming types of arthritis. An extremely careful classification of arthritis has been formulated. Several types of the disease may exist in the same patient. Often differential classification in a given case can be only conjectured. Diagnosis, however, is imperative before treatment can be prescribed with any degree of assurance or prognosis can become possible. The diagnosis once made, certain routines become obvious.

GOVERNING FACTORS

The treatment of an arthritic patient cannot be entered on until certain other factors are considered. These are as follows:

Psychologic Status

Arthritic patients often develop an anxiety neurosis when they learn the diagnosis. The lay press and radio have been major factors in creating

a fear of being crippled to fix itself in their minds. They may be anxious because of the inability to carry on the ordinary responsibilities of life that to them is increasingly evident. Fear of complete and ultimate dependency worries and frightens them. This anxiety is often part of a vicious circle. Psychologic analysis in a series of arthritic patients has at least suggested that the hypotonic state that accompanies worry may be a factor influencing the progress of arthritis.

Mental depression is present in many arthritic patients owing to continuous nagging pain that the physician often cannot alleviate. Depression due to narrowing of the sphere of activity because of slowing up or pain is often seen. The patient fears the influence that his semi-invalidism may have on other members of his or her family. The inability of the husband to get about, the difficulty the wife has in taking care of her part of the family responsibilities ordinarily vested in her, are both extremely depressing and are likewise causes for anxiety.

The balance or stability of the patient must either enhance or handicap the physician's efforts in caring for him. He may not be able to stand pain, or may lose confidence in his physician, or the prescribed routine may be diverted by outside influence.

Pain and Disability

Pain and disability are the urgent and immediate reasons for the patient's consulting a physician. The latter must not take these lightly. Although long-range treatment may be indicated, something must be done at once for the pain and disability to lessen the prolonged need for the anodyne assistance that is immediately necessary.

Prognosis

The prognosis occupies a prominent place in the patient's thoughts, and some honest satisfaction must be given him as soon as the diagnosis is made

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 26, 1943.

†Associate in medicine, College of Physicians and Surgeons, Columbia University; director of physical therapy, Columbia Presbyterian Medical Center.

and future portents can be estimated. The estimated stability of the patient determines to what detail it is wise to discuss the subject with him. Some member of the family, however, should be told the facts. The diagnosis will probably demand certain alterations in customary habits. Immediate or prolonged hospitalization, orthopedic care in deforming types, even surgical intervention in some others, may be necessary. Such arrangements as have to be made should be entered into tactfully.

The Patient as a Whole

The most important psychologic attributes have been mentioned. The age, life expectancy, metabolic level, food habits, usual employment and the presence of other constitutional ailments, such as a cardiac condition in rheumatic fever and the presence of hypertension, gall-bladder disease, complicating peripheral vascular disease, alcoholism existing with gout, and pelvic inflammatory disease or chronic prostatitis associated with specific arthritis all enter into the treatment of arthritis, and may well influence the advisability or limitation of physical therapy in a given case.

METHODS OF TREATMENT

The importance of physical therapy in relation to arthritis varies within wide limits. It is of the utmost value under certain conditions, but has little bearing in some arthritic patients. Some of the available methods of treatment will now be discussed.

Moist heat is the first and most universally applicable modality. Certain chronic arthritics may be said to "live in bathtubs." Such low-grade, general heating is nothing less than fever therapy.¹ A patient submerged in a bath at a tolerance temperature (110°F.) for twenty minutes develops an oral temperature of about 102°F. If he crawls into bed and insulates himself against heat loss, the resulting increased metabolism may cause the generation of one or two degrees more of heat.

Generalized heat in cases with multiple joint pains is most acceptable and of distinct therapeutic value.² Locally, all sorts of hot fomentations, soaks, whirlpool and paraffin baths and steam jets are universally available.³

Dry heat by means of hot pads, radiant-heat lamps, infrared applicators, diathermy and short-wave radiation are acceptable methods for local application.

Massage is a highly useful type of treatment. The importance of the technic, however, is not generally appreciated.⁴ How many physicians who have written an order for massage have taken the time to watch the procedure being carried out and so have realized how varied may

be the technics and effects of this form of treatment.

Passive movement, manipulative procedures and therapeutic exercises are likewise of great value in maintaining and restoring functional joint movement in the arthritic patient.

Rest and restriction of activity as therapeutic measures, although perhaps not usually considered as physical therapy, are absolute requisites at some stages of arthritis.

Many patients are advised to "sit in the sun." The routine of rest, heat and ultraviolet rays, associated with a complete change of environment, does much for an arthritic patient, especially if carried out in a dry climate. Often at spas, this is combined with hydrotherapeutic routines, with excellent results. Unfortunately, only a limited number of patients can afford such luxurious treatment.

Various electrical applications, notably galvanic iontophoresis, by which various drugs are introduced into the tissues by way of the skin, are sometimes indicated. Application of static electricity has a certain proved value in reducing the swelling present in arthritic inflammations.

The least expensive type of physical therapy, and an intensely valuable form, is exercise. Unfortunately, however, this involves home routines. As such, it requires much patience, time and perseverance on the part of the physician to see that such exercises are carried out.

CHOICE OF METHODS

With this armamentarium of physical therapy at hand, the next problem is for whom, when, where, how and to what extent and in what combinations, to use these modalities. The employment of any form of physical therapy in a case of arthritis represents an expenditure of energy by someone, and often requires special apparatus or a setup to make it available. Physical therapy is time consuming, and when done by paid personnel it is expensive. For these reasons, it should not be prescribed unless there are definite indications for its use.

Roughly stated, the indications for physical therapy in arthritis are as follows: to improve the general condition, to reduce joint swelling, to relieve pain, to improve function, and to preserve function and lessen deformity. It should not be used for its psychologic effect or as a sign to the patient that something is being done for him.

From the viewpoint of physical therapy, arthritic patients may be divided into six classes: those with rheumatic fever, septic arthritis, gonococcal arthritis, gouty arthritis, rheumatoid arthritis (atrophic) and osteoarthritis (hypertrophic). A.

discussion of each of these types will suggest the reasonable approach to the problems of the application of physical therapy in other miscellaneous cases. The treatment must always be individualized, and must be fitted to the needs according to the symptom complex that each case presents.

Rheumatic Fever

Patients with rheumatic fever are constitutionally ill. The cardia is threatened. Rest is paramount. Salicylates are indicated. Any physical therapy must be administered at the bedside. The extremely sensitive joints should be splinted⁵ to prevent jarring, pain and irritation and to offset the development of a deformity. A cradle with continuous low-grade heat and the gentle, persistent use of hot fomentations to affected joints are gratefully accepted by these sufferers. Their posture in bed has much to do with their comfort. As soon as joint sensitiveness becomes less acute, they should be encouraged to move their joints within the limits of moderate pain. When the temperature subsides and convalescence is established, extreme care in ambulation should be exercised and special care taken when the patients are placed on their feet. Slippers with heels, strapping of the feet or soft arch supports may be required. The patients should not be waited on too much during their convalescence, since their extreme lack of activity during the acute illness greatly depletes their muscular strength. They need as much voluntary exercise as ordinary guided activity will ordain to counteract the generalized atrophy present in their skeletal muscles.

Septic Arthritis

The cases with specific joint infections, such as tuberculous, post-traumatic, and other septic infections, are not physical-therapy problems until surgical care has rendered them fit for mobilization. Physical therapy instituted while wounds are draining, such as active movement with or without associated traction suspension and massage when the danger of spreading infection has passed, together with the use of radiant heat, will do much to hasten functional return by reducing swelling and preventing contractures. The early use of this procedure in infections of the hand has a pertinent industrial significance. In these cases the infection has probably also involved the tendon sheaths—fibrositis often accompanies the arthritis. Whirlpool baths, massage and passive motion should be carefully applied. Active exercises including functional types of occupational therapy⁶ speed up and amplify recovery.

Gonococcal Arthritis

The day of the rigidly ankylosed joint due to Neisserian infection has passed. Arthritic complications with gonorrhea have become far less frequent since the introduction of the sulfonamides. Occasional resistive cases do develop gonococcal joints. There are two methods of handling these, induced fever and diathermy.

Physically induced fever adequately given produces a dramatic result.⁷ If fever therapy is not available, diathermy may be given through and through the affected joint in the subacute stage, with positive passive manipulation of the joints. This is probably the one instance where the patient's sensibilities are to a large extent to be overlooked in giving passive motion. Massage and active exercises within the increasing range of movement will prevent an ankylosis from occurring in a joint, even though extreme clouding and loss of joint definition may be demonstrable on x-ray examination. The assumption is that the source of the infection as well as the affected joint receives adequate treatment.⁸

Gouty Arthritis

Dietary restriction, wet dressings, elevation, colchicine, salicylates, elimination and alkalization represent the accepted forms of treatment of gouty arthritis.⁹ Patients with acute joints should be encouraged to move their joints within the limits of swelling and pain. Hot applications and exercise will in themselves do much to reduce the swelling. Local spraying with ethyl chloride, together with the institution of exercise, is one method of initiating such movement painlessly, and may be a means of encouraging the patient to observe the beneficial effect of active movement in enhancing the assimilation of joint fluid.¹⁰

If the static brush discharge is available, it may also be useful in reducing swelling in acute gout. The patient should be cautioned regarding the future regulation of his exercises when recovery is complete.

Rheumatoid Arthritis

Patients with rheumatoid arthritis are constitutionally ill. They represent that type of arthritis in which the greatest involvement is in the soft tissues, and consequently physical therapy can have a definitely beneficial effect if properly applied. Aside from the general care of rest, a high-calorie, high-vitamin diet and forced fluids, physical therapy can do much for these patients. How to bring this treatment to the patient and not drain his financial resources completely is one of the gravest physical-therapy problems. The difficulty is that these patients need much time-

consuming, carefully guided, often changed physical therapy, which becomes extremely expensive.

The undulating course that these cases pursue creates a constantly recurring problem. Gold salts in selected cases have proved helpful, although inconsistent in their effects.¹¹ Being a heavy metal, gold must be given under well-controlled conditions. This form of treatment is definitely not the answer to the rheumatoid-arthritis problem.

The patient with an acute case without deformity should be kept at rest in bed, without lavatory privileges if possible, even if the lower extremities are not the major involvement. If swelling of the joints of the lower extremities is present to any extent, bivalved casts should be applied to immobilize the extremities, lessen joint irritation, and relieve the pain attendant to being moved during nursing care. These casts should be formed with joints in position to offset the development of flexor contractions or eversion of the feet. If the hips are involved and adductor spasm is present, the thighs should be held in abduction of 45° with an arrangement for preventing external rotation of the thighs. Later, casts or caliper splints may be necessary for ambulation.⁵ If only the knees and ankles are involved, molded splints should be applied for immobilization. In cases with marked swelling of the upper extremities, molded splints on the forearms, wrists and hands to prevent flexion deformity, eversion at the wrists, and disalignment of the finger digits should be applied. With this immobilization, various forms of gentle heat may be tried and will often alleviate pain and hasten reduction in swelling. The heat must not be intense, or the pain and swelling may be aggravated. Patients should be impressed with the importance of elevation of the extremities in lessening edema and the importance of the early reduction of swelling.

Each day the extremities should be removed from the casts and passive motion within limits of pain be given. Active exercises when the sedimentation rate is above 35 mm. per minute is apt to cause an exacerbation of symptoms in a case in which there has been a previous recession. With a lowering of the sedimentation rate and a diminution in swelling and protective spasm, the patient may be given a stroking massage and a graduated exercise program may be instituted.

In the case of hips and shoulders, exercises under water, preferably in a large therapeutic tank in which the temperature may be elevated to 100 or 102°F., are helpful early in the exercise routine. Such tanks often provide whirlpool arrangements that, when directed to the painful joint, relieve pain and, with the buoyancy of the water, en-

courage active movement. When exercises are once begun, they must be progressively increased as regards effort and range, but kept within the limits of fatigue and pain.

Deep breathing and bed calisthenics for the general condition occupy a prominent place in such a routine. In bed, patients should be encouraged to do moderate exercises, often with the assistance of weight-and-pulley arrangements. Care must be exercised while these patients are bedridden to prevent the friction of linen at the elbows, heels and buttocks. Body radiation with ultraviolet rays¹² will assist in overcoming the secondary anemia present in these cases. Small transfusions may give a sharp boost to severely debilitated patients.

Ambulation, as in the case of rheumatic fever, must be carefully and progressively carried forward. Crutches, walkers, supporting casts and caliper braces on the knees all have their place in treatment. Persistent accumulation of fluid in the knees may indicate synovectomy before ambulation can be successfully carried out. Splints must be worn well into convalescence, at night and in periods of relaxation during the day.

The hands tend to flatten and lose their normal lateral flexibility. This is usually due to lack of movement at the metacarpocarpal articulations. Manipulation of the bones in this area may be necessary before mobilization of the palm can be effected.¹³ Fibrositis is usually present in the fingers if edema and swelling have been prolonged. This requires rigorous and at times painful treatment if it is to be successfully combated. Manipulation of the phalangeal joints once a week and active and passive exercises daily following hot applications form the method of choice.¹³

The removal of persistent edema about the wrists and ankles may be expedited by the use of the static-wave current if available. It may also be accomplished by mild graduated exercises made possible through the prevention of pain by an ethyl chloride spray or iontophoresis with novocain.¹⁴

To pass over the subject of rheumatoid arthritis without mention of Still's disease would be a grave omission. Treatment of these unfortunate children should stress the prevention of deformities due to joint destruction and flexion contracture. Progressive casts seem more logical than arrangements for suspension traction. A mechanical pull slightly misdirected or of too great intensity may produce abnormal angulations at the epiphyses of the long bones. Since investigating Kenny packs, I have discovered that intensive packing relieves pain, diminishes swelling, releases protective spasm, and prepares the patient

for the application of casts in a position of minimal deformity.

Patients with Strümpell-Marie arthritis should be kept on an exercise routine from the time the diagnosis is made. This should include thoracic and breathing exercises. By such care, ultimate deformity may be lessened. Radiotherapy has to date exerted the next most beneficial results in these cases.

Osteoarthritis

The large group of cases of osteoarthritis may be divided roughly into traumatic and metabolic. Some cases represent combinations of both, as in the trauma to the joints of the lower extremities and back that is present in fat, middle-aged patients. In the cases due to direct trauma to a joint or to fracture involving the joint surface, the success of the treatment depends on the institution of physical therapy as early as possible to reduce synovial accumulation, relieve pain, and permit active movement of the joint involved.¹³ The greatest factor in treatment is to prevent progressive fixation.

Deep heat, not too intense, is used to improve the circulation within the joint capsules and less penetrating forms of heat for reflex circulation and relaxation of the protective spasm. The heat applications available for this purpose range from hot soaks, contrast baths and other forms of hydrotherapy to paraffin baths, mud packs, electric pads and radiant-heat lamps.¹⁰ Exercises further reduce muscle spasm if they are done within the limits of pain and are properly directed and stepped up progressively along with increased flexibility in joint movement.

Pain comes with prolonged lack of movement and pressure on opposed joint surfaces where the cartilaginous insulation is gradually disappearing. This pain is lessened through activity if carried out without weight-bearing.

In certain areas, special problems present themselves for consideration in the treatment of the osteoarthritic patient.

Cervical arthritis often exists without any notable subjective symptoms. It may, however, be the cause of a diverse array of both subjective and objective symptoms based directly on the progressive pathologic changes taking place.

The earliest pathologic manifestation is a synovial irritation with a tendency to calcification at the ligamentous attachments to the vertebrae. This is followed by definite osteoarthritic lippling and the intrusion of new bone about the foramina through which pass the spinal nerves. A narrowing of the intervertebral spaces occurs, with mechanical condensation in the neck and poor mechanics of head carriage.

The symptoms produced are largely mechanical, with increasing limitation of range of movement of the neck. Pain, at first only on movement of the head and neck in certain positions, but later with pressure developing about the cervical nerves, is radicular in type. This pain is directly related to posturing of the neck, and segmental distribution of pain has reference to the anatomical distribution of the cervical nerves. Pain is often more pronounced on one side than on the other. It may simulate bursitis, myositis or the true neuritis so common to this area. Mild cervical bony disarrangements may give similar symptoms. An exact differential diagnosis must be made before prognosis or proper treatment can be instituted.

The application of physical therapy varies considerably with the diagnosis. In true cervical arthritis, diathermy, massage and graduated exercise are indicated. Manual traction or suspension¹⁷ accompanied by gentle rotation are helpful in overcoming the crowding of structures in the neck that occurs with pain, protective spasm, bony hypertrophy and thinning of the intervertebral disks. Marked thinning of but one disk with arthritic changes in the presence of a history of trauma or acute snapping of the neck may be the cause for further studies to eliminate disk herniation, with its surgical indication for laminectomy.

Arthritis in the thoracic spine may be the result of poor posture, often occupational. A wedging round back or structural scoliosis may be the cause. Early discovery of bad posture and its correction will do much to prevent arthritis. Spinal fusion in structural scoliosis in children should be considered to offset pain, disability and semi-invalidism on reaching young adulthood.

Arthritis in the thoracic spine in women is often complicated by the undue strain of supporting abnormally large, fat or pendulous breasts. In these cases, relief will be accelerated if a brassière is constructed that distributes the support of these structures more evenly over a larger area of the back and shoulders.

Osteoarthritis of the lumbar spine has to do with old strains and injuries, metabolic causes, altered mechanics of weight bearing in middle-aged persons due to abdominal adiposity and loss of tone in the back muscles because of lack of exercise. The arthritis may be superimposed on a spine with asymmetrical or oblique unstable facets, often involving several vertebrae. As in the cervical region, the differential diagnosis must be carefully made, since there is much to be considered before all the symptoms can be made to repose on an arthritic diagnosis. Time does not permit discussing the differential diagnoses possi-

ble in this area. It will suffice to recall the various cases constantly seen of traumatic strains, tuberculosis, carcinomatous metastasis, myositis, disk herniation, functional, structural or referred back pains, osteomalacia and spondylolisthesis.

The arthritis may be superimposed on or exist with some of these other conditions, and so the treatment must be made to fit the case. Some cases of lumbar arthritis require mobilization. In others this is contraindicated or is advisable only after the acute symptoms have subsided. In structurally weak backs, exercise aggravates the symptoms. A period of limitation of movement may be advisable with curtailment of activities, even of golf playing, which delivers much torsion strain to the lumbar and lower dorsal spine. The age of the patient, the extent of the arthritis, the amount of thinning of the disk or of flexibility retained in the back and the presence of other complications, together with experience, are guides to the proper advising of these patients. As mentioned previously, however, efforts to increase the functional motility of the arthritic joints should be carried out, provided no apparent contraindication exists. Marked arthritic hypertrophic changes and marked thinning of a disk or disks should be considered as absolute contraindications to passive manipulations of the lumbar spine or straight leg-raising exercises.

In arthritis of the lumbar spine, obesity must be treated when present. High back corsets or braces with inclusion of arrangements for abdominal support must be given to stout patients with abdominal sag. It is impossible to relieve back pain until this weight has been taken away from an overburdened, acutely angulated lumbosacral joint and distributed over a wider longitudinal area of the back. Heat, massage, static electricity, exercise, a flat or firm bed, and supports are the forms of physical therapy indicated.

Consideration of *arthritis of the legs and of the knees and ankles* always involves the problem of supporting superimposed weight. Limitation of the patient's sphere of activity is another problem. These patients must all be treated as potential invalids, and every prophylactic means should be employed to prevent such a catastrophe. A few considerations are weight reduction to lessen the load and the early use of crutches to assist in weight-bearing, especially when synovial irritation is acute. Patients with mild symptoms do not relish being advised to wear crutches. Nevertheless crutches if used early are most valuable. The use of canes throws too much strain on the wrist and elbow joints, and the canes are often not of proper length, causing the patient to walk in the position of hip and lumbar-spine flexion. Also, canes tend to encourage the development of

flexion deformity, and often reactivate an arthritic lumbar spine. A general limitation in weight-bearing, with rest off the feet for a fixed period each day, should be advised.

These patients get much relief from diathermy applied directly through the hip joint, massage,—especially to the adductors of the thigh,—exercises to be done by the patient at home at least two times daily, and passive stretching of the hip joint and fascia of the thigh to maintain as much motion as possible. It should be explained to patients with rheumatoid arthritis or osteoarthritis that physical therapy is not going to cure their arthritis but that a course of physical therapy periodically will do much to make possible the maintenance of their activities. As soon as the patient's symptoms permit, physical therapy should become less frequent and should eventually be stopped entirely in favor of home routines, to prevent the patient from depending too much on such treatment.

The possibility of performing a hip fusion in cases with extreme degeneration should be kept in mind. Such an operation, provided the lumbar spine is flexible, leaves the patient quite capable of attending to any of his normal duties and, if successfully completed, removes the constant pain such patients suffer.

Arthroplasty of the hip by the Smith-Petersen¹⁸ method or variations of this procedure may offer the patient a chance of hip function when the restriction of movement is extremely advanced, although the results of this operation have been disappointing in some series of cases. The success of the procedure depends entirely on the use of physical therapy as soon as possible postoperatively along the lines recommended by Smith-Petersen. Unless the patient has sufficient fortitude to tolerate some pain during this period, he himself may ruin an otherwise skillfully performed operative procedure.

The use of any mechanical device that will prevent the pain of weight-bearing is indicated in the care of an arthritic patient.

Traumatic arthritis of the cuneiform navicular articulation is commonly seen in heavy, flabby patients, both young and old. These cases require foot support in addition to physical therapy. If these methods do not reduce the pain of weight-bearing, the patient may require orthopedic surgery until walking becomes less of an ordeal.

SUMMARY AND CONCLUSIONS

Physical therapy has a distinct place in the treatment of various forms of arthritis.

The use of physical therapy is varied with different types and in different stages of arthritis.

When physical therapy is prescribed, the routine should be rational.

Physical therapy should not be promiscuously prescribed or be continued indefinitely when prescribed.

The actual physical therapy must be done by skilled technicians who are familiar with the disease that they are treating.

Care should be taken that the patient does not get a false impression that physical therapy will cure his arthritis, except in the case of Neisserian arthritis.

Injudicious physical therapy may be a large factor in complicating an arthritis with a superimposed neurosis.

COEXISTING INTRAUTERINE AND EXTRAUTERINE PREGNANCIES*

A Review with the Report of a Case

SAMUEL J. KING, M.D.†

FARMINGTON, NEW HAMPSHIRE

THIS paper was prompted by the occurrence in my experience of an obstetric situation that need not be considered a rarity but that may be regarded as an unusual combination—namely, the coexistence of an extrauterine with an intrauterine pregnancy. The extrauterine aspect itself was typical in detail to that of any other pregnancy occurring within a fallopian tube and therein developing to the stage when the symptoms and signs suggested internal hemorrhage, and possibly tubal rupture, making prompt surgical therapy imperative. The other feature—that is, the intrauterine pregnancy—by itself was also completely normal in that the prenatal course, after the above surgery, was uneventful and that a simple, in fact precipitous, pelvic delivery of a normal female infant occurred. The unusual aspect was the coexistence of the extrauterine and intrauterine pregnancies, each having been treated separately, with a living infant resulting from the intrauterine implantation.

CASE REPORT

Mrs. H., a 33-year-old quartipara, consulted me on February 12, 1942, because of vaginal spotting and an associated persistent but slight pain in the right lower abdomen.

men for 5 days. Ordinarily the menstrual periods occurred every 28 days, lasting for about 5 days without pain and with an average flow. The last normal catamenia had occurred on December 20 to 25, 1941. The previous pregnancies were all normal except the fourth, which occurred in 1939. This pregnancy produced symptoms much like her current apparent gestation and was diagnosed elsewhere as a tubal pregnancy. She was not operated on, however, and at 5 months she miscarried. She had had no operations or serious illnesses, and there was no family history of multiple pregnancy.

Physical examination revealed a somewhat thin, palish woman. The temperature was 98°F., the pulse 80, (the blood pressure 125/75, and the weight 102 pounds (the average nonpregnant weight was 100 pounds). There was slight tenderness in the right lower quadrant of the abdomen, and a detectable mass the size of an orange was palpated just above the symphysis, which was assumed to be a pregnant uterus. A differential diagnosis of threatened abortion, appendicitis or tubal pregnancy was considered, with the first thought the likeliest. The patient was put to bed under observation, with conservative treatment.

On February 23, the patient had sudden, severe pain in the right lower quadrant, which persisted. The vaginal spotting had neither disappeared nor increased. There was no elevation of temperature, the pulse was 100 and was of good quality, and the abdomen, especially in the right lower area, was markedly tender both by palpation and by rectal examination. Although the only palpable mass was the one in the lower midline, a diagnosis of ectopic pregnancy with hemorrhage and possible tubal rupture was tentatively made and the patient was hospitalized.

*Awarded the second prize in the competition for the Gray and Burnham Awards offered by the Trustees of the New Hampshire Medical Society Physician, Fribble Memorial Hospital, Rochester, New Hampshire

Blood studies showed a red-cell count of 3,100,000, with a hemoglobin of 9 gm. (Sahli), or 58 per cent, and a white-cell count of 7200, with 65 per cent neutrophils. Urinalysis of a noncatheterized specimen was negative except for the slightest possible trace of albumin and occasional white blood and epithelial cells. Although the surgical consultant and I agreed concerning the probable diagnosis of tubal pregnancy, we were unable to account for the lower midline mass, the size of a large orange and itself nontender, except that it was possibly a pregnant uterus in the process of aborting. The patient was closely observed for another 15 hours, at the end of which time, there being no essential change, an exploratory laparotomy was done. The report of the surgeon was as follows:

A lower median incision revealed a bluish-appearing peritoneum, which when opened showed many old blood clots and a mass in the right pelvic region consisting of a tubal pregnancy. This had apparently bled through the fimbriated end of the tube but showed no evidence of rupture. The entire right tube was removed. The left tube was cystic and was also removed. Both ovaries appeared normal. The uterus was about the size of a 3-month pregnancy. The appendix was small and cordlike, with firm adhesions holding down the terminal third, which was freed. The appendix was removed in the usual manner, the stump was buried, and the wound was closed tightly in anatomical layers after inserting about a pint of normal saline solution in the peritoneal cavity.

The report of the pathologist was as follows:

Three specimens were received. The first consists of a fallopian tube, 10 cm. long and swollen to a diameter of 4 cm. in its proximal third. It is deeply congested and tense but intact. Section shows that the patent portion is filled with blood, but that the swollen portion is occupied by a swollen deep-red mass oozing blood when cut, which in its center has a tiny sac filled with clear fluid and showing a 3-mm. fetus. Soft, blood clots are adherent to the fimbriated end. The second is a small tortuous fallopian tube showing some congestion. The third is an appendix 5 cm. long and 4 mm. wide, with a little fat attached to it; on section there is thickening of the walls with partial occlusion. *Gross diagnoses:* tubal pregnancy (unruptured), fallopian tube and healed appendicitis.

On microscopical examination the first fallopian tube shows some thinning of the wall and plicae, with capillary engorgement, which appears to be a pressure phenomenon due to the presence of considerable fresh blood, as well as chorionic villi, in the lumen; the serosal vessels also show engorgement. In the second fallopian tube there is thickening of the walls and plicae, accompanied by vascular engorgement and lymphatic infiltration. The appendix shows marked fibrous proliferation of the submucosa, with replacement of the lymphoid tissue and mucosa and obliteration of the lumen. *Microscopic diagnoses:* tubal pregnancy, chronic salpingitis and healed appendicitis, with obliteration of the lumen.

Although both the surgeon and I commented on the uterine enlargement, we assumed that such enlargement was concomitant with the ectopic pregnancy. The patient had an uneventful recovery and was discharged from the hospital on the 13th day.

Several weeks later, the patient's husband stated that she was doing well, carrying on her household duties, but that she was "bloating." He was urged to bring her to the office for a complete checkup, but this was not done until August 6, or 5 months after the operation and 7½ months after the last normal menstrual period.

Examination at that time showed the weight to be 109 pounds (the most that the patient had weighed during her previous pregnancies was 115 pounds). There was no detectable edema. The urine was essentially negative and the circulatory system showed evidence of good function. However, there was a mass in the abdomen that extended slightly above the umbilicus, and a fetal heart rate of 140 was detected in the left lower quadrant of the abdomen. A uterine pregnancy, apparently the second half of a combined intrauterine and extrauterine pregnancy, was diagnosed. With the last normal catamenia occurring on December 20, 1941, the patient was told that her probable date of confinement was September 27, 1942. Owing to transportation problems she was unable to return for further prenatal observation, but on August 15 her husband reported that the membranes had ruptured, with the escape of 1000 cc. of fluid. He was advised to report further if labor commenced or if further symptoms developed. Not until September 2, or approximately 2 weeks after rupture of the membranes, did definite labor commence. The patient was then hospitalized, and 4 hours later, after variable pains, she spontaneously delivered a normal 4-pound, 6-ounce female infant before she could be transferred from the labor to the delivery room. The post-partum courses of the mother and baby were normal in every respect.

This case illustrates combined intrauterine and extrauterine pregnancies in which an early bleeding, nonruptured tubal gestation was treated by surgical removal and the intrauterine pregnancy proceeded to near term, with the pelvic delivery of a slightly premature but normal infant, who survived. This case and others like it suggest several practical points in the diagnosis and management of such an obstetric situation.

First of all, the lives of the mother and of the intrauterine fetus are particularly dependent on the correct treatment of the extrauterine aspect. Thus, in early prenatal care when the mother complains of pain in either vault, the physician in his differential diagnosis should consider not only the commoner types of pelvic disease, appendicitis and so forth, but also the possibility of extrauterine pregnancy. In a fair proportion of patients with this condition, there is no vaginal bleeding or spotting but evidence of internal hemorrhage. When once diagnosed in early gestation, an extrauterine pregnancy should be terminated forthwith by surgical means.

On the other hand, when a patient presents herself primarily with the clinical picture of an early ectopic pregnancy, irrespective of its activity, she should also be considered as a candidate for combined intrauterine and extrauterine pregnancies. This is especially true if there is a family or

personal history of multiple pregnancy. Although the diagnosis of an associated intrauterine pregnancy is oftener than not overlooked or not thought of, there is one common finding—namely, a uterus whose size and consistence as felt preoperatively and as seen and felt during laparotomy suggest that it carries a fetus. It is true that hypertrophy and hyperemia are also evident in a non-pregnant uterus associated with an extrauterine gestation, but to a less extent. In this case, the enlarged uterus as felt preoperatively was largely responsible for the period of conservative treatment, since a threatened abortion could not be ruled out. Because both the amount of hemorrhage and the surgical trauma are probable factors in precipitating a spontaneous evacuation of the intrauterine contents, early diagnosis prior to much hemorrhage and surgical treatment with minimal trauma are helpful in saving the intrauterine fetus.

Discussion

Definition of Terms

Coexisting intrauterine and extrauterine pregnancies may properly be subdivided into two groups: combined or simultaneous; and compound. Much of the literature has failed to differentiate these types.

In the compound type the intrauterine pregnancy becomes superimposed on an already existing extrauterine implantation. The latter may have been present for a variable time and in some cases for several years. As a rule the extrauterine pregnancy of this category is quiescent and nonproductive of symptoms but may be detected by physical examination. It may exist in a chemically altered state ranging from saponification to mummification or to calcification or the lithopedion stage. Repeated intrauterine implantations with normal development to term may be superimposed on an existing dormant extrauterine pregnancy. The quiescent extrauterine product of conception may be discovered during a normal intrauterine pregnancy when a prenatal or postpartum examination discloses an unexplained mass, or at operation for a suspected abdominal neoplasm, or during the post-mortem examination of a patient whose death may have been due to an unrelated cause.

Combined intrauterine and extrauterine pregnancies, including the case reported above, present a different situation. This combination is probably identical with a multiple pregnancy except that instead of the implantations occurring normally within the uterine cavity, one or more of the fertilized ova reach the intrauterine spaces,

where they commence normal development, whereas the remaining one or more become simultaneously implanted outside the uterus—that is, in the fallopian tubes or in the ovary or at some site within the abdominal cavity. (The expression "one or more" is used because a limited number of cases have been reported where co-existing intrauterine and extrauterine pregnancies have occurred in which more than one fertilized ovum has become implanted either within or without the uterine cavity.) The extrauterine pregnancy may produce the typical symptoms and signs of early ectopic pregnancy at four to twelve weeks, usually at about eight weeks, when internal hemorrhage or tubal rupture occurs, suggesting the necessity of prompt surgical relief; or the extrauterine pregnancy may fail to cause the classic syndrome of the early weeks and proceed to develop to term or near term and even be productive of a viable, not necessarily normal, fetus. The intrauterine pregnancy of this combination, for the most part, is no different from any other such gestation; it may abort or miscarry, with or without apparent cause, or it may proceed to term with the delivery of a normal living infant.

Compound Type

The compound type generally lacks the dramatic character of the combined one because, as a rule, the extrauterine feature is dormant and nonproductive of symptoms. Moreover, the apparent rarity of compound intrauterine and extrauterine pregnancies is due not to the intrauterine aspect but rather to the scarcity or nondiscovery of an extrauterine product of conception of a kind to make this combination possible. There is apparently no physiologic or anatomic reason why a normal intrauterine pregnancy may not superimpose itself on an already existing dead or chemically changed extrauterine fetus and develop normally. Incidentally, the converse is not true; namely, there is no convincing evidence that an extrauterine pregnancy ever superimposes itself on an already existent intrauterine pregnancy.

Bland, Goldstein and Bolton¹ in 1933 stated that the calcified fetus was recognized as early as 1595, and they were able to collect an aggregate of 197 reported cases. Although all these cases with extrauterine products of conception did not at the same time produce normal intrauterine pregnancies, a fair number went through one or more full-term pregnancies resulting in the birth of healthy children without the extrauterine gestation's giving rise to difficulty. Bland and his associates report a case in which a mummified fetus was carried by a patient for fifteen years, and states that at operation this fetus showed evidence of having had developed approximately to the eighth

month. Moreover, the patient, prior to operation for the removal of the mummified fetus, had uneventfully passed through three full-term intrauterine pregnancies.

The quiescent extrauterine gestation may show various chemical alterations, dependent on its duration. Thus, there is first a saponification, then a drying-out process or mummification and finally the calcified stage. These changes obviously require considerable time and are without apparent clinical symptoms. Perusal of the literature fails to show evidence of endocrine imbalance owing to the presence of a quiescent extrauterine pregnancy.

Combined Type

The first report of combined intrauterine and extrauterine pregnancies was made by Duverney² in 1708. His observations were made post mortem on a patient who died of tubal rupture in the third month of pregnancy. In 1876, Parry³ stated that of 500 tubal pregnancies, 22 had combined extrauterine and intrauterine pregnancies. Marten and Meyer⁴ estimate the occurrence of combined intrauterine and extrauterine pregnancies as 1 in 105 ectopic pregnancies. Since 1 ectopic pregnancy occurs for approximately 300 normal pregnancies, the rough incidence of this combined type is apparent. Bernstein⁵ states that Strauss in 1898 had collected 32 cases of the combined type. From this date on, several authors summarized the literature, and in 1940 Bernstein, excluding the obvious compound type, collected 294 authentic cases. Ludwig⁶ in the same year collected a total of 353 cases, but he probably had not excluded the compound type. Of this number, 16 were diagnosed post mortem and of these all but 1 were recorded prior to 1897 or before the era of abdominal surgery.

Nonpregnant Uterine Changes in Association with Ectopic Pregnancy

An effort was made to correlate the changes apparent in the nonpregnant uterus with an associated ectopic pregnancy. Perusal of the literature leads one to the conclusion that the cervix softens and the uterus enlarges. Preoperative clinical examination in some cases of ectopic pregnancy failed to reveal evidence of definite uterine enlargement, but bimanual examination was not always satisfactory owing to obesity or to excessive abdominal tenderness. The increased size of the uterus, when detected, did not, however, equal the size to be expected if it were pregnant. In reports of cases in which the extrauterine pregnancy reached term (Woods,⁷ Hamblen⁸ and others), the nonpregnant uterus was generally no larger than a two-month pregnant uterus. Surgeons operating on ectopic pregnancies generally

report that the uterus is enlarged and soft but usually no larger than a two-month or two-and-a-half-month gestation, irrespective of the duration of the extrauterine aspect. In some cases the uterus is said to be normal in size.

DeLee⁹ summarizes this subject as follows:

In response to the stimulus of pregnancy the uterus hypertrophies, but not as much as it would if it were carrying the ovum itself, and it exhibits intermittent contractions. A decidua develops in it and this may be as much as 1 cm. in thickness, presenting all the characters of an intrauterine pregnancy decidua, except that it contains no chorionic villi. At the time of spurious labor or spurious abortion the decidua is cast off, either in one piece, as a cast of the uterine cavity or in large shreds or plaques, sometimes accompanied by feto. With death of the fetus the uterus shrinks.

When the uterus is definitely enlarged and irregular uterine hemorrhage occurs, it is suggested that an analysis of this discharge should be made for the presence of particles of tissue. The presence of decidual particles with complete absence of fetal villi indicates an ectopic pregnancy; the presence of both decidual particles and fetal villi indicates the abortion of a uterine pregnancy, with or without an associated extrauterine pregnancy.

Age, Parity and Multiplicity

Based on the reported cases, the maximum incidence of combined pregnancies, or 60 per cent, occurred in women from twenty-six to thirty-five years of age with a tendency to fall in the latter years. None are reported in mothers under twenty years of age, and 8 mothers were past forty-one years, with the oldest aged fifty-four. Multiparity tended to predispose to the condition, and of the 178 patients whose parity was known, 11 per cent were nulliparas and 89 per cent were multiparas, with biparas predominating. Six patients had previous multiple pregnancies; data in the published case reports pertaining to the family history of multiple pregnancies are incomplete.

Duration of Intrauterine Pregnancy

There are various important factors in the duration of intrauterine pregnancy. First of all, there is the group of patients, irrespective of extrauterine complications, who abort or miscarry from endocrine, physiologic or anatomic reasons. As part of the therapy associated with an abdominal operation for ectopic pregnancy the surgeon may do a dilatation and curettage, with or without knowledge of a possible intrauterine pregnancy. At least 6 cases in this series were so aborted. The influence of excessive intraperitoneal hemorrhage and of trauma incident to operation may enhance a spontaneous uterine evacuation. Of the 221

cases in which the duration of the intrauterine pregnancy was recorded, 92, or 35 per cent, terminated in the first trimester, 35 or 15 per cent in the second trimester, and 104 or 44 per cent, in the third trimester. Of the latter, 88, or 35 per cent, went to term.

Duration of Extrauterine Pregnancy

The duration of extrauterine pregnancy is recorded for 125 cases, of which 107, or 85 per cent, were terminated in the first trimester, with 56 so treated at eight weeks. Seven, or 6 per cent, were terminated in the second trimester and 11, or 9 per cent, in the third trimester, with 8 patients, or 6 per cent, going to term.

Diagnosis, Treatment and Mortality

If the condition was diagnosed early, the symptoms and signs were those of an ectopic pregnancy, if late, the picture was primarily that of an intrauterine pregnancy. Two hundred and nineteen cases, or 75 per cent, were diagnosed in the first half of pregnancy, with a total of 16 deaths, or a mortality of 7 per cent. Hemorrhage and peritonitis were the chief causes of death. Twenty cases were diagnosed in the second half of pregnancy, with 7 deaths, or a mortality of 35 per cent. This is the dangerous period. All the patients who died were operated on. The deaths were due to hemorrhage, septicemia, pulmonary embolism and pulmonary edema.

Operation during the late stage, although advised, involves certain technical considerations. Walling off, as in a cesarean section, is necessary in order to minimize the escape of amniotic fluid, if possible, because the fluid is an active peritoneal irritant. If the placenta is implanted on the broad ligament, it may be removed and possibly hemostasis effected without complications, but if the implantation is on the aorta, the liver or parts of the gastrointestinal tract, it seems wisest to cut the cord close to the placenta, leaving the secundines intact to resolve, as they promptly do if there is no infection. Institution of drainage is a matter to be decided in each case. If the fetus is dead, the secundines can be removed from any site without difficulty.

Thirty-six, or 12 per cent, of the cases were diagnosed at labor. About half of these had a mass so symptomless that no operation was done. Eight patients passed the fetus piecemeal through a fistula, and 1 of them died. The other half gave evidence of infection or intestinal irritation, or both. A live child was removed in 5 cases, one to twenty-three days after the intrauterine labor.

The maternal mortality of the whole series was 21 per cent, or 14 per cent if those cases are excluded in which the diagnosis was made post

mortem and the patients did not receive treatment. Fetal mortality from the intrauterine implantation was 54 per cent,—that is, 103 of the 226 fetuses survived,—whereas the fetal mortality from the extrauterine gestation was approximately 90 per cent, 11 of 215 fetuses surviving.

Extrauterine Fetal Abnormalities

The fetus that develops to term in an extrauterine pregnancy tends to have malformations, contractures, a flattened head and so forth. The reasons advanced for this are a scarcity of amniotic fluid, the lack of uterine protection, the pressure of surrounding structures and a concurrently developing uterus. Moore and Sile¹⁰ in 1870 reported the first case in which both extrauterine and intrauterine fetuses were delivered alive. An interesting case report is that of a Negress who simultaneously produced viable fetuses within and without the uterus.¹¹ She had a strongly positive Kahn reaction. The intrauterine infant had congenital syphilis, whereas the extrauterine one did not. The paternal history was not given. A few case reports include multiple pregnancies in which more than one fetus was present, either in the intrauterine or the extrauterine site.

SUMMARY AND CONCLUSIONS

An original case illustrating coexisting intrauterine and extrauterine pregnancies with appropriate treatment of each phase is reported and discussed.

A review of the literature covering both the compound and combined types of coexisting intrauterine and extrauterine pregnancies is given.

It is not so much the intrauterine aspect that makes this obstetric situation unusual as the coexisting extrauterine pregnancy. In the compound type the extrauterine pregnancy is quiescent whereas in the combined type the extrauterine gestation, most often a tubal pregnancy with its various manifestations, actually or potentially presents a clinical emergency.

Correct treatment at the right time is important in order to save the life of the mother and possibly that of the intrauterine fetus as well.

CLINICAL NOTE

A NEW METHOD OF GIVING
POTASSIUM IODIDE*

WALTER T. GARFIELD, M.D.†

BOSTON

POTASSIUM iodide has been used for many years in medicine as an alterative and in the treatment of syphilis. It has been employed in pills, capsules and saturated solution. All these are more or less irritating to the stomach. The

I have used these pills in a number of cases in which potassium iodide was indicated. All these patients responded as expected, showing that the iodide was absorbed. Tests were made to determine the rate of absorption and to determine whether the weight of the patient had any relation to the tolerance of the drug. The elapsed time between the ingestion of the enteric-coated pill and the appearance of iodine in the saliva was about one and a half hours, whereas the elapsed time between the ingestion of potassium iodide in capsule form or solution and the appearance of

TABLE I. Summary of Data.

PATIENT	AGE Yr.	TYPE OF SYPHILIS	SIGNS	QUANTITY OF TREATMENT	RESULT OF TREATMENT	REMARKS
P. S.	8	Congenital	Keratitus	1 wk.	Lesion subsiding	Lesion resistant to bismuth and arsenicals
C. M.	18	Congenital	Keratitus	3 wk.	Lesion healed	
G. H.	21	Secondary (recurrent malignant)		1 mo.	Lesions healed	Lesions resistant to bismuth, mercury and arsenicals
P. W.	21	Late	Gumma on right side of chin	1 mo.	Gumma healed	
A. C.	38	Late	Gumma on right thigh	1½ mo.	Gumma healed	
M. C.	58	Late	Multiple gummas	2 wk.	Gumma healed	
T. M.	60	Late	Multiple gummas	2 wk.	Gumma healed	
C. S.	60	Late	Gumma on right thigh, eczema of liver, with fluid in abdomen	4½ mo.	Gumma healed, fluid in abdomen absorbed	Metallic taste
L. S.	53	Late	Gumma on right lower leg	1 mo.	Gumma healed	
P. M.	47	Late	Gumma on chest	1½ mo.	Gumma healed	Furuncle on face
A. Mel.	72	Late	Gumma on right foot	2 mo.	Gumma healed	
Q. J.	65	Late	Tubercles dorsalis	2 mo.	No change in symptoms	Metallic taste

saturated solution, in which form the drug is most commonly given, is considered to be the equivalent of 1 gr. per drop. The size of the drop, however, varies with that of the dropper and usually contains somewhat below this amount. It was therefore suggested that if an enteric-coated pill were used, both these objections could be eliminated.

Such a pill, containing 1 gm. (15 gr.) of potassium iodide,† was obtained. The enteric coating on these tablets does not dissolve until it comes in contact with the bile in the intestinal tract; it is insoluble in alkaline or acid solutions alone. This especially designed coating contains cetyl alcohol, gum mastic, balsam tolu, gelatin and sugar. Acetone and alcohol are used as solvents. Samples were tested in vivo and in vitro to determine their solubility.

iodine in the saliva was half an hour. Thus it can be seen that the absorption time of iodine was greater in the enteric-coated pill than in capsule form or solution. The tolerance to potassium iodide did not seem to depend so much on the weight of the patient as on his idiosyncrasy to potassium iodide.

The enteric-coated pill was given in 12 cases of syphilis in varying amounts (Table I). All the patients started with one tablet three times a day. Only 1 patient developed an iodide eruption. Two patients complained of a metallic taste. These reactions were considered to be due to idiosyncrasies. No patient complained of a stomach upset. There were 2 cases of congenital syphilis, 1 of which was a malignant type that had not responded to arsenical and bismuth therapy. One patient had recurrent malignant secondary syphilis, and 8 had late cases with gummas. All responded well to treatment. One was a case of tubercles dorsalis in which the dose was increased

to four tablets three times a day without any gastric symptoms that could be attributed to the potassium iodide.

SUMMARY

The use of potassium iodide in the form of an enteric-coated pill is described. Twelve cases so

treated responded well, and none complained of a gastric upset. Three patients evidenced idiosyncrasies to the drug. In view of the lack of gastric disturbances and the accuracy of dosage, further trial of this method of therapy is recommended.

MEDICAL PROGRESS

UROLOGY*

WILLIAM C. QUINBY, M.D.†

BOSTON

THE SULFONAMIDES

DURING the past year the knowledge of the great importance of the various sulfonamide drugs has become more crystallized. A noteworthy review and summary is that of Janeway,¹ with which every physician should be familiar. Written by an eminent authority on the treatment of infectious diseases, it is a comprehensive study based on his own large experience, as well as on the many articles in the literature bearing on this subject. The various forms of the sulfonamide drugs now in use are compared concerning action, dosage and toxic manifestations. There follows a discussion of their clinical use and what may be accomplished in the control of the various forms of bacterial infection. Being in itself a review, this article does not lend itself to summary.

In infections of the urinary tract, the sulfonamide drug that is today the one of choice is sulfadiazine. All types of urinary infection except those due to the enterococcus respond to its use. In most cases relatively small doses (2 to 4 gm. daily) are needed to attain the desired result, and thus good toleration and freedom from untoward manifestation are the rule. The outstanding drawback to sulfadiazine, however, is its low solubility and therefore slow excretion. Sulfathiazole is also well tolerated and is more soluble than sulfadiazine, but there is evidence that it is a fairly toxic drug, acting on the kidney parenchyma to depress renal function. Low solubility causes the precipitation of crystals in the renal tubules and ureters, with resultant hematuria or obstruction, reaching anuria in extreme cases. Indeed, there are reports of several deaths following such a sequence. It is imperative, therefore, that patients taking these drugs receive sufficient fluids to ensure a daily out-

put of urine of at least 2 liters. Blockage of the renal pelvis and ureters, should it occur, can generally be relieved by lavage through ureteral catheters, using a solution of bicarbonate of moderate strength. Both sulfathiazole and sulfadiazine are more soluble in an alkaline than in an acid urine, so that it is always wise to accompany their use by the administration of moderate amounts of sodium bicarbonate.

A more important manifestation of the toxicity of sulfonamide drugs is found in patients who have become sensitized by a previous administration of them. Such cases are not uncommon, and in view of the extensive use of the sulfonamides today, the recognition that such reactions may occur is certainly not sufficiently kept in mind by the physician in general practice. The following case is an example:

A 55-year-old man (PBBH S-71418) underwent the perineal removal of a benign prostatic enlargement. Because of a moderate amount of cystitis he received 2 gm. of sulfathiazole daily, beginning on the 3rd day after operation. The temperature, which had previously been normal, rose on the 8th day of this treatment to 101.5°F., when the drug was immediately discontinued, with a resultant return of the temperature to normal. The patient was discharged on the 14th day after operation, having good bladder function and a well-healed wound but still showing a mild cystitis, for the treatment of which he was referred to the Out-Door Department.

On the 12th day following discharge he was returned by ambulance to the hospital. The pulse was 120 and weak and thready, the respirations 20, and the temperature 103.2°F. The face was flushed and the eyes were bloodshot. The sensorium was much clouded, almost to coma. The blood pressure was 80/40 and the skin, especially of the back, shoulders and face, was a brilliant red. No adequate history was obtainable, but search of the Out-Door Department records showed that 4 days previously the patient had made a visit, at which time he had complained of dull pain in the right calf that made walking somewhat difficult. There was also a tender area on the inside of the calf. A diagnosis of mild thrombophlebitis of the leg was made. The patient was given a bandage and told to rest the leg at home. With this history in mind and the fear that the patient was suffer-

The articles in the medical-progress series of 1941 have been published in book form (*Medical Progress Annual*, Volume III, 678 pp. Springfield, Illinois: Charles C. Thomas, 1942, \$5.00).

†Clinical professor of genitourinary surgery, Harvard Medical School; urological surgeon, Peter Bent Brigham Hospital.

ing from a blood stream infection, he was given immediately on entrance 1 gm of sulfathiazole together with parenteral fluid and the next morning, 8 hours later, he was given another gram of sulfathiazole. This was followed almost immediately by a severe chill lasting for 45 minutes, with a temperature of 106°F and an alarming fall in blood pressure (to 70/40). It became immediately evident that the patient's condition was due to drug sensitivity, and a detailed history obtained from his physician brought forth the fact that on the day before the patient's collapse the latter had prescribed sulfathiazole in an effort to clear up the infection in the urine. Two grams at once, followed by 0.5 gm doses every 2 hours, was prescribed. This medication was followed by vomiting on several occasions and cessation of urination, only 60 cc of urine being passed during the whole day.

Further physical examination showed the white cell count to be elevated to 16,600. The level of sulfathiazole in the serum was 4.1 mg per 100 cc, and the urine was concentrated and filled with sulfathiazole crystals. Treatment consisted of parenteral fluids in liberal amount and 1 unit (500 cc.) of plasma. After 2 days the blood pressure became stabilized at 120/80 and the urinary output rose to 350 cc. The blood urea nitrogen, however, was still high, reaching 51 mg per 100 cc. The patient was still actively ill and disoriented. By the 5th day, however, the output of urine rose to 1800 cc, after which convalescence was continuous, although complicated by a slight pulmonary atelectasis and marked peripheral neuritis of the external peroneal nerve. The signs of acute nephritis slowly improved, and 5 weeks later the patient was discharged well.

It is evident that sensitivity to the sulfonamides has thus become a possibility that, because of their extensive use, must always be taken into consideration in acute febrile conditions associated with prostration. It is also true that such sensitivity may persist for at least as long as six months. In this regard the advice of Janeway cannot be too often repeated: "After the patient is cured, tell him which sulfonamide drug he has received; if he has had a reaction instruct him to inform any physician about it before taking sulfonamides again."

URINARY CALCULI

In order to facilitate the operative removal of small single or multiple calculi from the renal pelvis and its branches, Dees² suggests the formation of an intrapelvic clot that on removal contains any small concretions within itself. The clot is formed from a solution of human fibrinogen that is caused to coagulate by the simultaneous injection of a "clotting globulin" derived from rabbit plasma. These substances are injected simultaneously into the kidney pelvis after its capacity has been measured. The clot forms immediately, and at the end of five minutes has acquired sufficient tensile strength to make it possible to withdraw the mass as a cast of the pelvis and calyces through the usual pyelotomy incision.

It is pointed out that a suitable coagulating substance should have the following properties: it should be fluid so that it can be injected into the renal pelvis and fill it completely, it should coagulate uniformly and completely within a short period of time, but not until after a latent period sufficiently long to assure the complete filling of all calyces before coagulation, the strength of the coagulum should be sufficiently great within a short time after injection of the substance to permit its withdrawal intact and to deliver any calculi contained within it, the coagulum should be malleable and elastic enough to permit withdrawal of the mold of each calyx through its narrower infundibulum, and also to allow removal of the entire clot through a short incision in the renal pelvis, it should be noninjurious to the kidney, the coagulum should spontaneously dissolve or disintegrate so that if a fragment is accidentally left within the pelvis, it will not remain as a foreign body to cause further stone formation, and the properties of the coagulable substance should be unaffected by contact or mixture with small amounts of urine or blood. Dees finds that clotted fibrinogen, the properties and preparation of which he^{3,4} describes in two earlier papers, fulfills these requirements.

There is no doubt that the ability to produce such a coagulum within the pelvis and calyces offers the urologic surgeon a new method of much promise in the extraction of small fugitive concretions well known to be extremely difficult to locate or reach during the usual operative attack. Only too often irrigation, suction and stone forceps fail to rid the kidney pelvis and calyces of all such concretions, some of which must thus perforce be left, to cause further difficulty. The entire innocuousness of the fibrinogen coagulum seems to have been well proved by its discoverer. A difficulty remains, however, for it is stated that 1 liter of human blood plasma yields only 40 to 50 cc of fibrinogen solution. It is to be hoped, therefore, that the present efforts to substitute bovine fibrinogen will meet with success.

Another distinct aid in the attack on urinary calculi consists in the *in vivo* solution of the calculus by exposing it to the solvent action of a mixture of citric acid combined with magnesium oxide and sodium carbonate in water.* After ex-

* Solution C is so termed by its makers has the following formulae:

Citric acid (monohydrate)	33.3 gm
Sodium carbonate (anhydrous)	4.4 gm
Magnesium oxide (anhydrous)	3.8 gm
Distilled water	q. s. ad 1000 cc

Solution C has a pH of 4.0. Another formula with a pH of 4.5 is given if the more acid solution causes irritation or hemorrhage. The formula of Solution S is as follows:

Citric acid (monohydrate)	33.3 gm
Sodium carbonate (anhydrous)	4.4 gm
Magnesium oxide (anhydrous)	3.8 gm
Distilled water	q. s. ad 1000 cc

perimental observations using many substances, Albright and his associates⁵⁻⁷ have found it possible by using such a solution to cause the dissolution of such calculi as are composed largely of calcium phosphate, without at the same time causing any significant irritation or injury to the mucosa of either the renal pelvis or urinary bladder. In clinical cases in which the stone can be bathed in such solution as nearly continuously as circumstances will permit, its removal has been successfully accomplished. Naturally if the stone is not accessible to the action of the solution, and especially if it is composed of a dense matrix of organic material, its entire dissolution will be imperfect. The easiest and most direct application of the solution to the stone is by a two-way tube introduced into the renal pelvis through a nephrostomy wound. But in several cases the desired result has also been obtained by an intermittent current of solution introduced through an indwelling ureteral catheter connected to an appropriate apparatus to produce filling followed by emptying by siphonage. When the stone lies in the bladder, a double catheter through the urethra forms easy access.

The observations reported in these papers raise hope that still further investigations of this interesting problem of stone dissolution will be forthcoming, such as the finding of Keyser⁸ that the addition of an enzyme—a 0.5 per cent solution of urease—to the citric acid solution causes an increase in the speed with which the stone is dissolved. At the moment, of course, patients bearing renal stones for whom attempts to dissolve the calculus are wise or justifiable are seen relatively infrequently. For the usual renal calculus, early operation together with the correction of the underlying cause of the stone formation, such as obstruction, infection or metabolic fault, is unquestionably the best course. But for those patients who have bilateral calculi, for example, and in whom each kidney already shows marked lowering of its functional ability, operation is often either very hazardous or even out of the question. For such patients, if their stone is of the phosphatic variety, which is usually the case, the use of Solution G or some future modification of it may be of the greatest benefit.

Further observations on the use and properties of Solution G have been made by Sauer and Neter⁹ at the New York State Institute for the Study of Malignant Diseases. Continuous-drip irrigation of the bladder was used for patients having incrustated ulcers of the bladder following the use of radium. Such late reactions after radium are not uncommon and are well known to be resistant to treatment. The lime salts of the urine are deposited on the surface of the ulcer in

the presence of an alkaline cystitis. "In almost all of the cases treated," Sauer and Neter state, "continuous-drip irrigation of the bladder with Solution G resulted in disappearance of the incrustations within one to three weeks, followed by healing of the ulceration. In 2 patients incrustated ulcers had persisted for more than seven years in spite of the normal treatment." These favorable results led the authors to make observations on the possible bactericidal properties of Solution G in addition to its solvent action. Four varieties of bacteria common in cystitis were used: *Escherichia coli*, *Proteus vulgaris*, *Proteus morganii* and *Streptococcus faecalis*. Each organism was found to have lost its viability within seventy-two hours after exposure to Solution G (pH 4.0), whereas they remained viable for two weeks in physiologic saline solution (pH 6.8). Further tests, however, made it probable that this bactericidal action was largely due to the acidity of the solution and that its particular composition does not increase its antimicrobial properties beyond those of a buffer solution of identical reaction.

CASE RECORDS OF THE
MASSACHUSETTS GENERAL HOSPITAL

Weekly Clinicopathological Exercises

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., Editor*

BENJAMIN CASTLEMAN, M.D., Acting Editor

EDITH E. PARRIS, Assistant Editor

CASE 29511

PRESENTATION OF CASE

A seventy-seven year-old housewife was admitted to the hospital because of vomiting of one week's duration.

The patient was rather confused and could not give an accurate history. She had been in good health except that she had lost 50 pounds of weight during the preceding year in spite of a good appetite. Recently she had felt tired and rundown. Two or three weeks before admission she developed sudden abdominal pain. This was vaguely described as having started in the left lower quadrant or the right lower quadrant and became generalized. The pain was dull, severe and not colicky, and was accompanied by chills and fever. She was taken to a community hospital ten days before admission and given intravenous fluids for three days and then discharged against advice.

One week prior to entry she began to vomit constantly. No definite statement could be obtained regarding the character of the vomitus except that "after the first few days the material became progressively more fecal." The vomiting continued. She was unable to take anything by mouth. She was constipated and passed only small amounts of feces by rectum for the two days before entry; these were not "bloody." She had had no fever during the preceding week. She had always been somewhat constipated and took cathartics regularly. There was no history of jaundice or bloody, tarry or acholic stools. She had had no previous operations.

Physical examination showed a dehydrated woman retching and vomiting. She was not jaundiced. The lungs were clear. The heart was slightly enlarged, with the left border of cardiac dullness 2 cm. to the left of the midclavicular line. The sounds were of poor quality and very irregular; occasional dropped beats were present. There was a loud apical systolic murmur and a harsh high pitched aortic systolic murmur. The abdo-

*D. J. Leve of Aben e

men was somewhat distended and tympanic. There was dullness in the flanks, but no shifting dullness or fluid wave. Moderate tenderness was elicited in the right upper and lower quadrants, and rebound tenderness and spasm in the right lower quadrant. The psoas and obturator signs were negative. Peristalsis was hypoactive but some tinkling was heard. The liver edge was one fingerbreadth below the costal margin and was nontender. No masses were palpated on abdominal, rectal or pelvic examination. There was pitting edema of the ankles.

The blood pressure was 144 systolic, 80 diastolic. The temperature was 98.6°F, the pulse 76, and the respirations 18.

Examination of the blood showed a red-cell count of 4,370,000 with 90 per cent hemoglobin. The white-cell count was 13,800 with 78 per cent neutrophils. A blood Hinton test was negative. The urine showed a specific gravity of 1.010, with a + test for albumin. The sediment contained innumerable white cells and occasional red cells. The nonprotein nitrogen was 120 mg per 100 cc and the protein 6.2 gm.

A roentgenogram of the abdomen showed a dilated transverse colon and some gas and considerable fecal matter in the cecum. Several dilated loops of small bowel, probably ileum, were seen.

A Miller-Abbott tube was passed, and 1750 cc of "brown fecal fluid" was aspirated with considerable relief. The aspirated material was guaiac negative. The patient was given daily intravenous fluids and occasional transfusions of whole blood. A barium enema on the second day showed ready passage of the opaque material to the cecum. There were many diverticula in the descending colon and sigmoid but no evidence of diverticulitis. The cecum was high, almost fixed, and extending downward from it was the appendix, which seemed to be filled with barium. No barium could be forced into the terminal ileum. Considerable difficulty was encountered in the passage of the Miller-Abbott tube, which seemed to remain in the stomach.

The patient continued to vomit material that was definitely fecal in character. She was unable to take anything by mouth. A roentgenogram of the abdomen on the third day showed retention of a large amount of barium in the colon. The dilated loops of small intestine appeared increased. An ileostomy was performed on the fourth day, with considerable relief. On the fifth day no dilated gas-filled loops of bowel could be seen by x-ray; those that were dilated appeared to be full of fluid. There was a large

increase in density overlying the right half of the pelvis. The nonprotein nitrogen was 86 mg., and the protein 5 gm. per 100 cc.; the chloride was 97.5 milliequiv. per liter.

The patient's condition improved considerably. There was copious drainage from the nasal tube and the ileostomy. Repeated attempts to pass the Miller-Abbott tube beyond the pylorus were unsuccessful. In the next four or five days the abdomen became much softer. Peristalsis was normal, and she passed some gas by rectum. There was no vomiting.

On the tenth hospital day an exploratory laparotomy was performed.

DIFFERENTIAL DIAGNOSIS

DR. CARROLL C. MILLER: This conference today seems to be concerned with obstruction in the region of the ileocecal valve.* Frequently mistakes have been made in the past in the diagnosis of gallstone ileus. It seemed during this discussion that the three cases might all be due to gallstone ileus. As we have seen, however, the gallbladder and biliary system have not been implicated in either of the two preceding cases. In the present case we have not only an acute episode to consider, but also a period of one year during which the patient lost 50 pounds in weight. Before the onset of the acute episode there had been a tired, run-down feeling. Then suddenly an acute episode occurred, which was obviously due to acute, low obstruction of the small intestine. As we go through the data that are available we find no definite evidence of an acute inflammatory process. The symptoms first noted were pain in the lower abdomen, distention, some tenderness and vomiting. Although these suggest peritonitis at the start, the subsequent course, the lack of marked elevation in the white-cell count and a polymorphonuclear shift, the absence of fever and other toxic signs and the presence of tenderness lead me to believe that the obstruction was mechanical rather than inflammatory.

If we consider the causes for mechanical obstruction of the low ileum, we think of adhesive bands, volvulus and intussusception. The x-ray films should be of considerable help. They substantiate the diagnosis of obstruction of the small intestine by showing dilated loops of small bowel with some degree of distention of the transverse colon. Quite correctly no series of the upper gastrointestinal tract was done, because at that time the exact site of the obstruction was uncertain.

May we see the x-ray films?

DR. GEORGE W. HOLMES: This first film shows a shadow on the right side interpreted as transverse colon filled with gas. Then the patient was given a barium enema to determine how much gas was in the colon and how much in the small bowel. You can see that there are loops of small bowel that are definitely distended and filled with gas. It also shows multiple diverticula along the distal colon, and the appendix is visible. I think that this probably rules out appendiceal abscess as a cause of the obstruction. What part of the small bowel this represents, I am not certain; but I should think probably the ileum and not the jejunum. We also have several other films taken within a day or two that confirm these findings. All these films show a residual in the colon following the enema. The patient was unable to evacuate the enema completely, and you can still see dilated loops. Then the Miller-Abbott tube was passed. On this film it was in the stomach, and later on it passed beyond the stomach but appears to have tied itself in a knot as the Miller-Abbott tube sometimes does. That would explain why the Miller-Abbott procedure was not effective.

DR. MILLER: In the last film there is mention of hazy dullness in the right half of the pelvis. Is there any discrete mass?

DR. HOLMES: That probably is an artefact. This film was taken with the tube off center, which changes the density. I do not believe that it is of any clinical importance. Evidently the man who did the examination was interested in this loop of bowel, because he took a number of spot films of it.

DR. MILLER: Is that loop a part of the sigmoid?

DR. HOLMES: Yes.

DR. MILLER: Showing the diverticula?

DR. HOLMES: Yes; so far as I can see from these films there is nothing more than that.

DR. MILLER: No evidence of inflammation or diverticulitis?

DR. HOLMES: There is some evidence of spasm. There may be slight diverticulitis, but I am sure that there is no tumor in that region.

DR. MILLER: The cecum is described as being high and fixed. Is it out of the right lower quadrant?

DR. HOLMES: Yes; but "high and fixed" by x-ray examination is not an absolute finding. It depends on the patient; if the patient has a soft abdomen, palpation is easy; if there is resistance, palpation is unsatisfactory. One may not be able to move the colon during the time of examination.

DR. MILLER: It would be convenient to postulate a tumor in the pelvis, which would account for

*Case records of the Massachusetts General Hospital (Cases 29501 and 29502). *New Eng. J. Med.* 229:948-953, 1943.

the loss of weight, owing to malignant degeneration and diffuse spread, and also for an obstruction of the small bowel. No tumor, however, was felt by either abdominal or pelvic examination, nor is one visible in any of these films. It would also be convenient to postulate a carcinoma of the bowel that had caused sufficient contraction around the loops of terminal ileum to produce the acute episode of obstruction and also to account for the debility in the year before the patient came into the hospital. If we do postulate carcinoma, however, I think it is unrelated to the obstruction. It must be present simply as an explanation of the loss of weight and the downhill course.

It seems to me that the best condition to explain such a picture in a patient of this type is one of adhesive bands or a volvulus of the terminal loop of ileum, or an intussusception that was not seen in the x-ray films. It is mentioned that no barium could be forced back through the ileocecal valve. This might have been due to a distorted ileocecal valve or to a definite obstruction other than the folds of the valve in that area. We have recently seen several patients, especially older women, who have come in with a similar story. Some had had previous operations; others had not. They were found to have either an atypical adhesive condition between the loops of small bowel or a twist of the loops to account for the obstruction.

One condition that I have not mentioned but which one should think of is an acute perforation of the terminal ileum or cecum by a foreign body, such as a fishbone. This might account for the suddenness of the onset of abdominal pain. It would also account for the localized inflammatory reaction, but it would not account, of course, for the loss of weight and malaise prior to admission to the hospital.

I am going to rest my diagnosis with an adhesive band or adhesions between the ileum and cecum causing acute intestinal obstruction, with or without associated carcinoma of the abdomen.

CLINICAL DIAGNOSIS

Obstruction of small intestine, with perforation due to foreign body.

DR. MILLER'S DIAGNOSES

Obstruction of small intestine due to adhesive band or adhesions.
Carcinoma of abdomen?

ANATOMICAL DIAGNOSIS

Gallstone ileus, with obstruction of small intestine.

PATHOLOGICAL DISCUSSION

DR. DONALD N. SWEENEY: This patient was as confusing to us as she was to Dr. Miller. We were unable to explain the loss of weight without making a diagnosis of carcinoma. We could not pass a Miller-Abbott tube and had to do a Witzel ileostomy for decompression of the small bowel. We operated ten days after the ileostomy, with a diagnosis of perforation of the small bowel due to a foreign body, as Dr. Miller suggested. During the exploratory laparotomy the small bowel involved in the ileostomy was inadvertently torn from the abdominal wall. In closing the rent, the lumen was constricted and an enteroenterostomy was done. During this procedure three small gallstones were picked from the lumen of the small bowel. In the right upper quadrant there was an inflammatory mass that involved the hepatic flexure of the colon, the gall bladder and a loop of jejunum. In the cecum there was a large mass, thought to represent a gallstone, that I was unable to push back into the small bowel, and which I was loath to remove by opening the cecum. During the patient's subsequent convalescence we were able to obtain four or five small gallstones from the stools, but we never recovered the large gallstone, which probably disintegrated.

The patient did extremely well and is coming back at a later date for a cholecystectomy.

DR. BENJAMIN CASTLEMAN: Here is a postoperative film. Is this shadow the stone in the cecum?

DR. SWEENEY: That is what Dr. Schulz of the X-ray Department thinks is stone and accumulated harum. It was about the size of a plum and was partially fixed in the ileocecal valve. I could push it into the cecum but could not get it back.

DR. MILLER: You do not know whether she has carcinoma of the gall bladder?

DR. SWEENEY: I do not. She may have carcinoma but I doubt it, because she did so well postoperatively and has regained 10 of the 50 pound weight loss in the four weeks since she was operated on.

DR. MILLER: The fact that she had tenderness in the right upper quadrant should have made me think of an acute process going on there. The tenderness over the distended colon or small bowel was also confusing.

DR. CASTLEMAN: Do you think that that is a gallstone in the postoperative film, Dr. Holmes?

DR. HOLMES: Yes; it obviously was not in the cecum in the previous films.

DR. SWEENEY: There was some talk about air in the biliary tract. Now that we know the whole story we think that we can see air in the bile ducts

DR. CASTLEMAN: Do you agree with that, Dr. Holmes?

DR. HOLMES: I did not notice it in the films. There are shadows there that might possibly be due to that. To demonstrate air in the biliary tract one ought to take a film with the patient sitting up.

CASE 29512

PRESENTATION OF CASE

A forty-seven-year-old taxidriver was admitted to the hospital because of cough and weakness of six months' duration.

The patient was a chronic alcoholic, as well as a Seconal and paraldehyde addict. He had consumed large quantities of whisky since the age of twenty and had had repeated attacks of hallucinations and tremor, for which he had been hospitalized. About two years before entry he changed from whisky to ale, but he imbibed large amounts of the latter. There was a steady deterioration of memory, so that it was quite difficult to obtain a history and he was unable to give much information. His general condition had apparently been good until about two years before admission, when he noted episodes of fever as high as 102°F. associated with weakness and a cough productive of phlegm. The episodes of fever presumably continued until eight months before admission, when he started to feel tired and worn out, with progressively increasing weight loss and fatigue. There was some exertional dyspnea for the six weeks before entry, but no orthopnea, paroxysmal nocturnal dyspnea, hemoptysis, ankle edema or swelling of the abdomen. Three or four days before admission he developed a diarrhea consisting of eight or ten liquid, light-brown stools daily. There was no nausea, vomiting or bloody or tarry stools. During this period he had eaten little, subsisting on rather large quantities of ale. No other statement was made about his dietary habits.

Physical examination showed a well-developed man with evidence of recent weight loss. The skin was hot and moist. The mucous membranes were pale. The pupils were irregular but equal, and reacted sluggishly to light. The tongue was dry, the teeth dirty and carious, and the gums pyorrheic. The lungs were resonant throughout, but there were coarse rhonchi, squeals and groans, with a prolonged expiratory phase, throughout both fields. Patchy areas of diminished breath sounds were present, and moist rales were heard at both bases. The diaphragmatic excursion was poor on the right side. The heart was normal. The abdomen was distended, with the liver edge

palpable three fingerbreadths below the right costal margin. The spleen was felt five fingerbreadths below the left costal margin. The flanks were full, but no demonstrable fluid wave or shifting dullness was present. There was a coarse tremor of the outstretched hands, and minimal pitting edema of both ankles. Rectal examination showed palpable thrombosed external and internal hemorrhoids with one large external tab.

The blood pressure was 110 systolic, 65 diastolic. The temperature was 102°F., the pulse 120 and the respirations 30.

Examination of the blood showed a red-cell count of 3,750,000 with 9 gm. of hemoglobin. The white-cell count was 1500, with 55 per cent neutrophils, 34 per cent lymphocytes and 11 per cent monocytes. The platelets were diminished, and there was moderate anisocytosis and poikilocytosis. The urine showed a specific gravity of 1.015; the sediment showed 8 to 15 white cells and occasional red cells and coarse granular casts per high-power field. The sputum contained innumerable polymorphonuclears and moderate numbers of diplococci; it was culturally negative for beta-hemolytic streptococci and pneumococci. The stools were yellow, liquid and guaiac negative. No amebae were seen after "diligent search," and a culture was negative for pathogenic bacteria. The non-protein nitrogen was 22 mg. per 100 cc., and the chloride 95.5 milliequiv. per liter. The van den Bergh was 0.65 mg. direct, and 0.85 mg. indirect. The serum protein was 6 gm. per 100 cc. The cephalin flocculation test was ++ in twenty-four hours and ++++ in forty-eight hours.

An x-ray film of the chest showed several linear areas of increased density, probably atelectasis, in the right lung, but no areas of infiltration were apparent. The heart and aortic shadows were not unusual. Films of the abdomen showed the liver and the spleen to be enlarged. The entire abdomen was moderately and homogeneously clouded, probably because of ascites.

In the first four days the temperature showed one rise to 104 and one to 103, but fell gradually to 99.4°F. During that time the patient received three intravenous infusions of 1500 cc. of dextrose in water. He was given a high-calorie and high-vitamin diet. On the fifth day he had a mild attack of asthma lasting for about half an hour, which was relieved by ephedrine. His general condition seemed to improve, and by that time further information was obtained from one of the hospitals where he had been. It was stated that for the previous eight or ten months the patient had been having attacks of fever up to 103 or 104°F. that lasted several days, with afebrile in-

tervals of three or four weeks. He had been studied for malaria, but no malarial parasites had been found and no quinine had been given.

On the sixth, seventh and eighth hospital days the patient's temperature varied daily between 99 and 105°F. He had two chills. Three blood cultures were negative. A Widal test was negative. Additional information revealed that for the eight or ten months prior to admission, he had been taking sulfathiazole in doses of 1 or 2 tablets every hour for about three or four hours every time he had an episode of fever. In the past six weeks he had been receiving sulfadiazine intravenously, which was given by his physician each time he was called in for high fever.

An x-ray film of the chest on the thirteenth hospital day showed numerous fine linear areas of increased density in the right midchest, with some suggestion of honeycombing. There were no gross areas of consolidation or atelectasis, and no definite evidence of fluid. The white-cell count was 1600.

The patient's condition became steadily weaker, with a progressive rise of temperature to 106°F., and he died on the fifteenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. REED HARWOOD: In summary we have a chronic alcoholic with a deficient food and vitamin intake who developed cirrhosis of the liver and had chronic bronchitis and asthma. He also had a chronic infection characterized by severe exacerbations with fever and chills, and died with marked leukopenia.

I should like to look at the x-ray films at this point.

DR. GEORGE W. HOLMES: The first films were taken in July, and the second set in August. There is nothing striking or characteristic about either set of films. I am interested to know whether his heart was normal. It looks normal, although the left border does appear a little prominent. The diaphragm is in the usual position. In the second set of films, something that looks like dilated bronchi appears that was not present in the previous films; that is of considerable importance. If we did not have the previous films we might interpret this as being of no importance but since it appeared in a month I think it must mean something.

DR. HARWOOD: Do you think there is sufficient disease in the lungs to account for death?

DR. HOLMES: I do not believe this condition in the lungs had anything to do with his death.

In the film of the abdomen, you will notice that the film is rather thin, although the exposure was normal. Evidently there was some difficulty

in getting through the abdomen, which suggests the presence of fluid. Then we have the shadow of the liver and the shadow of the spleen, both of which are large. I think that I can say from the x-ray examination that the patient had an enlarged spleen and an enlarged liver; the shadow of the liver does not suggest the irregularity that may be present with a tumor.

DR. HARWOOD: As I went over the record, I came to the conclusion that this patient had a pulmonary infection, which was responsible for his final illness, but on rereading the x-ray report I wondered if enough had occurred in the chest to account for his death. I believed that Dr. Holmes would give the report that he has given, that is, that the lungs were not so striking as I had first thought. That leaves me "out on a limb" for a diagnosis, and I am going to beg your indulgence while I flounder around for a while and discuss the possible causes of fever.

It still is possible that the patient had an infection with its chief focus in the lung, but I am beginning to think that that is unlikely. Some of the conditions that I had thought of are pulmonary tuberculosis, carcinoma of the bronchus and bronchiectasis or other specific infections of the lungs, such as monilliasis, but there was no hemoptysis or organisms in the sputum. Bronchiectasis is unlikely because of the absence of foul sputum and clubbed fingers. Another relatively rare condition is chronic Friedländer's infection of the lungs, which occurs frequently in alcoholics, with a marked tendency to recur with severe exacerbations, responds somewhat to sulfadiazine, and can produce small cavities and bronchial dilatation. I am inclined to think now, however, that we shall have to consider something elsewhere in the body as the cause of this patient's death.

I interpret the leukopenia as evidence of bone-marrow depression, due to a combination of liver cirrhosis and acute infection. The possibility that the patient had a primary blood dyscrasia, such as aleukemic leukemia, seems highly unlikely in view of the normal smear. He has a moderate secondary anemia, which goes with any chronic sepsis, as well as with cirrhosis of the liver. The question of amebiasis was raised, but the story is not at all characteristic of amebic infection. The diarrhea developed late in the disease, no parasites were found, and the stools were not bloody. He might have had previous bouts of diarrhea that we do not know about. An amebic abscess of the liver is a possibility.

The question of malaria was raised. Again, the story does not seem good for malaria. Absence of parasites in the smear are the strongest bit of

evidence against such a diagnosis. He might at one time have developed central-nervous-system syphilis, for which he had been given malarial treatment. Even if this were so, at this late stage one would expect to find malarial parasites in the blood if his chills were due to this cause.

The question of a toxic reaction to sulfonamides comes up. I interpret this somewhat as follows.

dence to suggest it. The possibility of subacute bacterial endocarditis ought to be considered in any case of fever of unknown origin with leukopenia and a fatal termination. The patient, however, had no heart murmurs, and no physical signs suggesting embolic phenomena.

I must conclude, if one can call it a conclusion, that he died of some infection superimposed on

FIGURE 1. *Photograph of Section of Bone Marrow.*

The doctors who gave him sulfathiazole and sulfadiazine must have noted some response to the drug to justify their using it. In my original summing up of the case, I thought the patient had some chronic infection of the lung, with exacerbations that were relieved by sulfathiazole therapy, but now I am not so sure that the administration of sulfonamides had any bearing on the case or on the bacteriology. I do not believe it caused the leukopenia. It is more apt to cause a granulocytopenia, and this man had enough neutrophils in the differential count to make me think he did not have granulocytopenia.

He may have had some other type of infection to cause his chills. I cannot rule it out. He may have had peritoneal infection, such as tuberculous peritonitis. I do not see how I can exclude it. Fever and chills of this severity, however, are rather unusual in tuberculous peritonitis.

Did he have carcinoma somewhere in the liver or elsewhere in the abdomen? There is no evi-

cirrhosis of the liver. What it was, I really do not know.

DR. AUSTIN BRUES: Dr. Harwood will be glad to know that our clinical impression was also indefinite. One suggestion brought up by the service was that, in view of the leukopenia, anemia and thrombocytopenia, he might have disease invading the bone marrow, and the question of lymphoma was raised.

DR. JOSEPH AUB: What about the possibility of pylephlebitis?

DR. BENJAMIN CASTLEMAN: He did not have jaundice.

CLINICAL DIAGNOSES

Chronic alcoholism, with deterioration.
Alcoholic cirrhosis.
Bronchiectasis.

DR. HARWOOD'S DIAGNOSES

Chronic sepsis.
Alcoholic cirrhosis of liver.

ANATOMICAL DIAGNOSES

Bone-marrow hyperplasia of red-cell series, marked.

Hematopoiesis, marked: spleen, liver and lymph nodes.

Chronic benzol intoxication?

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The autopsy on this man showed an extremely large liver, which weighed over 2500 gm. It was smooth, purplish brown and rather firm and showed no evidence of cirrhosis. The spleen also was large, weighing 1010 gm., which is about five to six times the normal weight. This also was smooth and on section rather "meaty." From the gross examination we could definitely rule out cirrhosis of the liver as the primary cause of the large liver, and also the acute alcoholic liver, which is yellow and fatty. At the time of autopsy we were unable to make any definite diagnosis except enlarged liver and spleen; because of the marked anemia, the leukopenia and the meaty spleen, we thought the best diagnosis was some form of leukemia.

This man did have a bone-marrow biopsy before death, and this is the microscopical picture (Fig. 1). It shows extreme hyperplasia of the marrow. Normally this marrow should be made up predominantly of fat cells, but they are practically all replaced by marked hyperplasia of the marrow cells. Most of these cells are large stem cells and megaloblasts; there are a fair number of normoblasts and a few megakaryocytes, but the myeloid elements are scarce. In some places there is fibrosis of the marrow. The bone marrow from the material obtained at autopsy was the same. Sections of the spleen, liver and lymph nodes show these same cells of the red-cell series and also many multinucleated cells. The appearance is sim-

ilar to that reported a few years ago from this laboratory by Drs. Mallory, Gall and Brickley* in cases of chronic benzol poisoning. In some of their cases there were multinucleated cells that resembled the Sternberg-Reed cells seen in Hodgkin's disease, and a number of these cases have in the past been incorrectly called Hodgkin's disease. This man was a taxicab driver and may well have been exposed to benzene (benzol), although clinically they were unable to elicit any history of exposure.

I do not believe the sulfonamides had anything to do with his condition because there were plenty of polymorphonuclear cells in the bone marrow and in the peripheral blood.

DR. HOLMES: Did he have anything in the lungs?

DR. CASTLEMAN: The lungs showed bronchitis and mild bronchiectasis. Some of the bronchi, especially those in the right lower lobe, were moderately dilated.

DR. HOLMES: Were there any changes in the heart?

DR. CASTLEMAN: No.

DR. AUB: May I object very strenuously to a diagnosis of benzol poisoning? I think you have a right to say the patient died with a blood dyscrasia but have no right to say benzol poisoning unless you know he was exposed to benzol.

DR. CASTLEMAN: I agree. The pathologic picture is similar, and that is as far as one can go. Often, however, a history of benzol exposure is difficult to trace.

DR. BRUES: It is illuminating to note that this presumably toxic condition mimicked Hodgkin's disease in the type of fever as well as in the pathological findings.

VARIOUS FREEDOMS

THE enunciation of the Four Freedoms established a goal to thrill the hearts of free men and bring hope to the subject masses of less fortunate countries than our own. The thought of freedom has always been an inspiration to mankind—a torch that has lighted the steps of many millions of feet, regardless of where their path ended. Sought after by the majority of the world's inhabitants, freedom remains an elusive abstraction,—a will-o'-the-wisp,—the concept of which may assume as many forms as there are minds to entertain it.

It was a canny idea to enumerate certain free-

doms in the plural number for there is not and cannot be such a thing as pure, unmodified freedom; personal freedom must always be qualified by the right to freedom of others and must always be restricted by the natural boundaries that are set to our thoughts and to our enterprises. It is a bold stroke to promise even certain freedoms to others. It is something else to guarantee the survival of these freedoms, or even their temporary enjoyment.

In those shadowed sections of the globe where freedom has been totally eclipsed, any kind of an emancipation is going to seem, at first, a sufficient goal. Later on, when the eye has become accustomed to the initial light, the qualifications and restrictions will be seen, and it will be noted that liberty can appear in various shades and colors.

The people of the United States, having set out to assure at least four freedoms (including the freedom from fear, from which no one is free) to the stricken people of the world, might do well, without pausing in this task, to see how freedom is working out in our own country. It becomes increasingly apparent that we must learn, if we wish to consider ourselves as the exponents of democracy before the world, that true democracy can exist only where its benefits are considered as a sacred trust and are spread equally over all the people without regard to race, creed or color. In this we have failed in that we have allowed ourselves to develop and flourish feelings of class hatred, of race and color discrimination and of religious prejudice. Democracy, tough as it may be when faced with dangers from without, is highly susceptible to dangers from within, and we can flourish only when its freedoms are uniformly distributed.

It will require a consistent, conscious effort of all thoughtful people to overcome the prejudices on which they have been raised, and to measure each man by his own worth rather than by the color of his skin, the cast of his countenance, or the building in which he worships, but it is the task to which we must set ourselves, and it must

be reciprocal. These problems that we have allowed to develop will continue to rise and accuse us, and we are going to have our hands full with them.

Bureaucracy will try to keep its hand on the helm and increase its powers, as it has always done, and, since bureaucracy is essentially sadistic, it will constitute an ever-present threat to democracy and those freedoms that are still left after the fight for freedom is finished. Here, too, lies our own greatest danger, in the federalization of medical practice. If this comes in, individual enterprise goes out, and another freedom with it.

THE PROBLEMS OF LOCAL HEALTH OFFICERS

EVER since the General Court of 1849 authorized the appointment of a commission of three members to "prepare and report . . . a plan for a sanitary survey of the State"—an authorization that brought about the famous Lemuel Shattuck report—there have always been available in Massachusetts a number of codes, suggestions and recommendations for workers in the fields of public health. These various plans have generally outrun our actual performances, which makes us appear to be constantly lagging behind what we might or ought to be accomplishing.

Under the leadership of another Shattuck in 1943, the Massachusetts Central Health Council has recently adopted recommendations concerning the problems of local health officers that represent the combined thinking of an enlarged and representative committee of that organization. It is the opinion of this committee, "That all cities of 50,000 population or over be required, and that all communities over 25,000 be urged, to employ a full-time health officer." The committee's report then goes on to suggest ways in which a community whose financial status does not permit it to meet these standards may combine with other communities to secure effective health services. Towns and unions of towns may organize in this

way under Chapter 111, Section 27A, in the Commonwealth of Massachusetts, and may thus secure for themselves a health-department organization that possesses many of the advantages of a large city department.

That so many of the small communities have not organized their health activities on this basis again suggests that they may be lagging behind their opportunities. Some of them doubtless are, but others are faced with obstacles of a local nature that must be overcome before they can improve their health services. The resistance that can be offered by a politically entrenched individual or group may be formidable. In the United States such resistances must be overcome locally, and by the time they have been overcome at one point they may have reappeared at another. Town meetings are notoriously suspicious of blueprints. Improvements in public-health practice must continue to evolve slowly, as they have in the past, but it is nevertheless helpful to keep plans for the future in mind and ready to activate when the propitious moment arrives. It is in this way that such organizations as the Massachusetts Central Health Council are building for the future.

MEDICAL EPONYM

PANCOAST SYNDROME

In an article entitled "Importance of Careful Roentgen-Ray Investigations of Apical Chest Tumors," by Henry K. Pancoast (b. 1875) in the *Journal of the American Medical Association* (83: 1407-1411, 1924), the following is described:

There is an unusual but apparently infrequent type of intrathoracic growth occurring in the apical region, yet found with sufficient frequency in my experience to warrant a collective report of the cases encountered. . . .

An infiltrating growth, either endothelioma of the pleura or sarcoma, probably of bony origin, may occur in the apex of the thoracic cavity and produce a symptom complex of pain in the upper extremity and cervical sympathetic paralysis closely simulating that of many other conditions, such as spinal cord or meningeal tumors, neck tumors, cervical rib and vertebral neoplasms.

Dr. Pancoast amplifies this description and re-names the tumor in an article "Superior Pulmonary Sulcus Tumor: Tumor characterized by

pain, Horner's syndrome, destruction of bone and atrophy of hand muscles," which appeared in the same journal (99: 1391-1396, 1932).

R. W. B.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

FOSTER—CHARLES C. FOSTER, M.D., of Cambridge, died December 2. He was in his eighty-sixth year.

Dr. Foster received his degree from Harvard Medical School in 1883. He was a member of the Massachusetts Medical Society and the American Medical Association.

GEARY—CORNELIUS E. GEARY, M.D., of Fitchburg, died December 6. He was in his sixty-fourth year.

Dr. Geary received his degree from Harvard Medical School in 1907. He was a member of the Massachusetts Medical Society and the American Medical Association.

His widow, his mother, a daughter and two sons survive.

HARTWELL—HARRY F. HARTWELL, M.D., formerly of Newton, died December 7. He was in his seventy-first year.

Dr. Hartwell received his degree from Harvard Medical School in 1898. After a surgical internship at the Massachusetts General Hospital, he began the practice of surgery in Boston, and in 1904 was appointed assistant in orthopedic surgery at the Massachusetts General Hospital. In 1911, he became assistant surgical pathologist, and in 1916 gave up private practice to become surgical pathologist at the Massachusetts General Hospital, as well as a member of the Department of Pathology at Harvard Medical School. He served with the First Harvard Unit of the British Medical Corps during the early years of World War I, later enlisting as a surgeon in the United States Naval Reserve. He was a member of the Massachusetts Medical Society and the American Medical Association.

Two sons survive.

KENNEDY—EDWARD A. KENNEDY, M.D., of Pittsfield, died December 14. He was in his sixty-fourth year.

Dr. Kennedy received his degree from the University of Vermont College of Medicine in 1905. He was a member of the Massachusetts Medical Society and the American Medical Association.

His widow and three daughters survive.

TILTON—JOSIAH O. TILTON, M.D., of Lexington, died December 2. He was in his ninety-first year.

Dr. Tilton received his degree from the New York University Medical College in 1882. He was a member of the Massachusetts Medical Society and the American Medical Association.

WOOD—BENJAMIN E. WOOD, M.D., of Canton, died December 26. He was in his sixty-fourth year.

Dr. Wood received his degree from Harvard Medical School in 1906. He served his internship in the Children's Hospital, following which he was a surgeon on the staff of the Lawrence General Hospital, the Carney Hospital, and the Boston Dispensary. He was a member

of the Massachusetts Medical Society, the American Medical Association and the Orthopedic Club of Boston. His widow, two sons and a sister survive.

MISCELLANY

LYMPHOGRANULOMA VENEREUM

Noteworthy contributions to the detection and differential diagnosis of lymphogranuloma venereum are those of Rake, McKee and Shaffer, who have cultivated the agent in the yolk sac of the chick embryo and obtained concentrated suspensions of elementary bodies. In this manner a highly purified and specific skin-testing antigen, known as Lygranum S. T., has been prepared that is rapidly supplanting antigens prepared from either human pus or mouse brain. These workers alone, and in collaboration with Dr. A. W. Grace, have used the yolk-sac antigen for the complement-fixation testing of serum from suspected infected patients. The specificity and sensitivity of this antigen (Lygranum C. F.) provides an additional means of detecting early cases of lymphogranuloma venereum.

In the course of investigations involving these tests, there accumulated at the Squibb Institute for Medical Research a considerable mass of information concerning the properties of the causative agent and the epidemiology and clinical course of the disease. To facilitate the work of investigators and teachers in this field, and perhaps to encourage the interest of potential investigators, practicing physicians and health officers, it was decided to compile and publish the information at hand. The result is a 32-page monograph entitled *Lymphogranuloma Venereum*. The value of the book is enhanced by maps, charts and numerous illustrations in color.

The monograph is available gratis to physicians and to public-health officials, and should be a valuable addition to medical libraries. Those who request copies from E. R. Squibb and Sons, 745 Fifth Avenue, New York 22, New York, should enclose their professional card or use their professional letterhead.

ANNUAL PRIZE SUBSCRIPTION

The annual prize subscription offered by the *New England Journal of Medicine* for the best undergraduate contribution to the *Tufts Medical Journal* has been awarded to Roy Crosby, '44, for his paper "Medical Review: Recent advances in the diagnosis and treatment of prostatic carcinoma," which appeared in the October, 1943, issue. The paper "Medical Review: Gonorrhea in the adult female," by Alfred Agrin, '44, received honorable mention; it appeared in the August, 1943, issue. The basis of the award has been changed, allowing a two-year and one-year subscription to the *Journal*, respectively.

NOTES

On December 1, Dr. Harvey Spencer resigned as acting director of the Habit Clinic for Child Guidance and psychiatrist at the Judge Baker Guidance Center of Boston to become a member of the full-time psychiatric staff of the Austen Fox Riggs Foundation, Stockbridge.

At a recent meeting of the Board of Directors of the Washingtonian Hospital, Dr. Hilbert F. Day was elected

president, and Dr Norbert A. Wilhelm vice president, of the board

CORRESPONDENCE

PHYSICIANS AND BLOOD BANKS

To the Editor: The September 16, 1943, issue of the *Journal* contained an editorial entitled "Blood Plasma," wherein the lack of donors and the lack of physician co-operation were commented on in regard to blood banks in various hospitals. In contradistinction to this apathy noted, we, in Worcester, are enjoying an excellent spirit of co-operation with all physicians and donors. Since there is such a marked difference, it might be helpful to examine and discuss the reasons for it.

The Worcester Blood Bank (officially named the Worcester District Community Center for Aiding Transfusions, Incorporated) is sponsored by the Worcester District Medical Society and is aided by funds granted by the Worcester Chapter of the American Red Cross, the Worcester War Relief Fund, and the Community Chest of Worcester. The blood bank began to operate on October 12, 1942. It supplies whole blood and blood plasma to any hospital and to any physician in the entire Worcester district on request and without profit. In addition, it has already stored more than 2000 units of frozen blood plasma for any major catastrophe.

The blood bank is not located in a hospital but rather in a building of central location and actually a former private home. Here, blood is collected and processed and stored. Frozen blood plasma is also distributed to storage depots throughout the district, these depots being hospitals and establishments having the proper refrigerating facilities.

In this way it has been found possible to meet adequately the daily needs of the entire district at any time and at reasonable cost. This arrangement thus truly serves the community, a fact which the public has been quick to recognize and which is, without a doubt, a reason for the popular donor and physician support that has characterized the operation of the Worcester blood bank since its inception. In these times when people are increasingly alive to social betterment and improved medical and hospital care, the above fact might even be claimed to be a most potent one.

It is wondered if the chief defect in the administration of most blood banks is not that they are operated by hospitals. In the first place the cost of establishing and running a blood bank is such that only a large or financially well-endowed hospital can afford to have one. Here it must be pointed out that no matter how humanitarian the motives, in the minds of the people that blood bank serves a special group, that is, the patients in that institution and the staff of that institution. Consequently the blood bank tends to be supported mostly by those people who have special interest in that hospital. Since a blood bank for successful operation depends on a constant and satisfactory flow of donors, it is easy to envision that a hospital-operated blood bank will often be in difficulty in this respect. Especially is this true where the sole service running the blood bank does not enjoy the sole service to the community in which it is situated. Furthermore—and again no matter how humanitarian its motives in establishing the blood bank—a hospital cannot set up a bank of a size to meet much more than its own needs, because it is not in that business and because the cost is

prohibitive. Finally, it should also be remembered that the physicians most interested in a hospital-operated blood bank, namely, the staff, comprise but a small percentage of the practicing physicians in that community and consequently the staff's influence on prospective donors is correspondingly small. All these factors then, from within as well as from without, make one raise the question whether such an arrangement can ever call forth a great degree of popular support.

On the other hand, a blood bank managed as the one here in Worcester has intrinsically more with which to appeal to the public and elicit a satisfactory donor response. It is devoted to the needs of all physicians and not merely to a small and select group. It is large enough to meet the needs of all, whether the necessity for whole blood or blood plasma arises in the home, in the street, in the factory or in the hospital. Lastly, it does benefit all. In a little more than a year of operation, the services rendered by the Worcester blood bank to all institutions and all physicians in the district have multiplied almost ten fold. In terms of lives saved and the quicker recoveries effected, this is not an inconsiderable and unenviable record.

In conclusion may I say that the fine enthusiasm and active co-operation of physicians and public alike have more than compensated for the work and planning that went into the project, and have justified the hopes of the members of the Worcester District Medical Society. It has demonstrated what can be accomplished by the voluntary and co-operative effort of physicians in broadening the base of medical service without incorporating the inherent defects of governmental action.

WILLIAM FREEMAN, M.D.

Worcester, Massachusetts

TRANSFUSIONS WITH RED CELL SUSPENSIONS

To the Editor: Although whole-blood transfusions have been used as a therapeutic measure more and more in recent years, interest in plasma transfusions now seems to be paramount. Theories concerning the effect of plasma in shock and burns have focused attention to plasma in such a way that blood banks have been developed and the processing of plasma is a daily routine procedure. The latter, of course, leaves a portion of donors' blood—the red cells—that is usually discarded. Several investigators have demonstrated that it is practical to use these red cells, provided they are not over eight days old, for the treatment of anemic patients, these men, however, all deal with large blood banks having the advantage of a quick turnover. This letter deals with the problems of a bank in a small hospital, in which whole-blood transfusions average ten per month, with a much more frequent use of plasma.

In dealing with a bank in a small community, it is difficult to procure donors to build up an adequate plasma reserve, unless the hospital happens to be the official station for Red Cross donors. Furthermore, it is obvious that little whole blood can be kept on hand. Pooling is done within three or four days, and when occasion arises for using whole blood, the attending physician usually finds none available and is required to call for donors. This is time consuming, and the usefulness of the blood bank is thus diminished.

floor and roof of the subacromial bursa, and consequent loss of the gliding function normally present there. Instead, scapulothoracic motion results,

this basic etiology has been responsible for much ineffectual treatment.

CLINICAL FINDINGS

A patient with chronic adhesive subacromial bursitis seeks medical advice for persistent pain in the shoulder, oftentimes extending up into the neck as well as down the arm into the hand, marked loss of shoulder-joint function, or both. Not infrequently the latter complaint is the only cause of disability. Pain may have been of long duration, but by the time the patient is seen in consultation the pain has often largely disappeared, leaving the shoulder with marked limitation of motion.

Depending on the duration of symptoms, the patient reveals atrophy of the musculature of the shoulder region, to a greater or less degree. It is sometimes pronounced. Furthermore, some patients also complain of pronounced loss of finger joint function (Fig. 4). The hand is swollen and is similar in appearance to that seen in atrophic arthritis. In all our patients with this complication, the finger joints of the affected extremity were the only articulations that exhibited these changes, and therefore there was no question of a generalized rheumatoid arthritis.

The particular shoulder motion lost is that of external rotation and lateral abduction. Antero-posterior motion is usually of almost normal range. The patient can rotate the arm internally so that the forearm lies across the front of the body, but he can rarely pass the hand behind the low back or even place the hand on the hip.

Although local points of tenderness over the shoulder are present, they are less acute and less well localized than those exhibited by patients suffering from an acute subacromial bursitis with calcification. In patients with calcification and adhesive bursitis, local tenderness is more accurately defined. When requested to abduct the arm, the patient performs this motion by a combination of scapulothoracic motion and lifting the entire shoulder high on the affected side while the opposite shoulder is depressed (Fig. 5). On passive motion, assuming that the patient can be persuaded to relax, the humerus is abducted laterally from the side of the body, on the average 15 to 20°, at which point the scapula starts to move toward the axilla. If the scapula is held firmly, further passive or active lateral abduction of the arm is not possible.

The roentgenograms of the shoulder of a patient with chronic adhesive subacromial bursitis consistently reveal generalized atrophy of the bones of the shoulder girdle (Fig. 6), and in some cases this degree of decalcification of bone is pro-

FIGURE 1. Diagrammatic Representation of a Coronal Section of the Shoulder Joint.

This shows the relation of the subacromial bursa to the adjacent bone and muscle structures (reproduced from Codman⁷). A is the acromial process, and B, the great tuberosity of the humerus. In a the arm is dependent at the side of the body, whereas in b it is slightly beyond horizontal abduction.

as pointed out by Codman, with consequent restriction of the normal range of motion at the shoulder joint.

Although these patients frequently exhibit neuritic symptoms, especially pain radiating down the upper extremity and up into the neck and back of the shoulder, the symptoms are not the result of a true neuritis, a term so frequently employed, but of the bursitis. Lack of an understanding of

FIGURE 2. *Anatomical Drawing Made from a Dissected Specimen, Looking Down on the Shoulder from Above.*

This shows the origin and insertion of the short rotator muscles and their relation to the acromioclavicular joint. The subacromial bursa lies superior to these muscles, as shown in Figure 1.

restoring normal shoulder function in this difficult group of cases.
When the patient is first seen, it is particularly

ment and active supervision of the case will obviously depend on many factors, such as the initial degree of limitation of shoulder function, the ex-

a minimum of three to four and occasionally as long as twelve to sixteen months to restore normal function of the shoulder. The actual extent of treatment's willingness to co-operate in the program outlined. The duration of treatment is emphasized because repeatedly patients who have had ade

quate therapy elsewhere but who did not realize the long period required to obtain normal function of the shoulder have become discouraged, have discontinued treatment, and have then sought advice from other physicians.

The patient also must understand clearly the significant role played by adequate and well-

rapid progress, not the least effect of which is the pronounced improvement in mental attitude.

Where considerable limitation of motion and marked discomfort exist, the patient is put to bed and the arm suspended in a Balkan-frame apparatus, with—and this is significant—the extremity in the maximum degree of abduction than

FIGURE 10. Diagrams of Exercises.

These are important in the ambulatory stage of the treatment of chronic adhesive subacromial bursitis. Note that the pendulum type of exercise permits what amounts to normal range of shoulder-joint motion without the effect of gravity and hence with a minimum degree of effort and discomfort.

directed physiotherapy. We particularly refer to progressive, active exercises of the shoulder musculature, carried out under the direction of a competent physiotherapist. This part of the treatment is performed at home by the patient, following initial training either in the clinic or in the hospital. Without exception all the patients with an adhesive bursitis require this phase of treatment.

On admission a patient with chronic adhesive subacromial bursitis is given the usual general examination, with particular reference to the local findings in the shoulder. Roentgenograms are taken and an analysis of the case is made. If the degree of limitation of motion is marked and the patient suffers considerable pain, he is advised to enter the hospital, since this permits much more

does not cause increased discomfort. Then adhesive traction, averaging 6 to 8 pounds, is applied to the upper arm, utilizing the Blake board. Intensive local heat repeatedly applied to the shoulder is instituted, together with massage. The patient is encouraged to move the arm in the apparatus as much as he can comfortably do so. Every effort is made to achieve general relaxation, to make the patient sleep well, and in general to establish the maximum degree of comfort possible under the circumstances. Such a phase may require as long as a week, but is oftener a matter of three to five days.

With the patient well adjusted to his apparatus, intensive active exercises of the shoulder are instituted. We have repeatedly observed that on this simple program the range of active and, in

particular, of passive abduction is increased as much as 30 to 40° in seven to ten days. When the patient has reached a maximum amount of improvement, as judged by his ability to abduct the arm, a shoulder-joint manipulation is carried

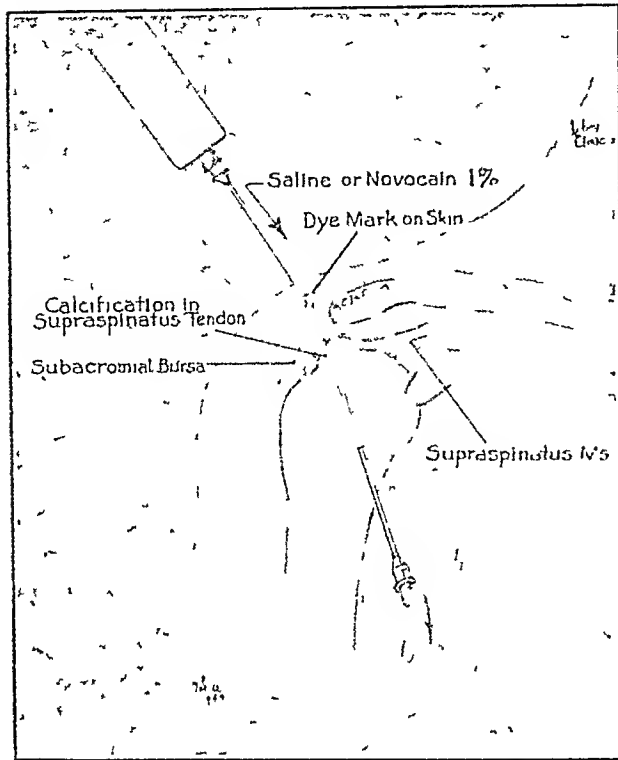

FIGURE 11. Removal of Calcified Deposits in the Tendon of the Supraspinatus Muscle.

This is accomplished by the "washing out" technic (Smith-Petersen¹¹). The dark area on the skin through which the superior needle has passed to enter the calcified deposit indicates the site of maximum tenderness on palpation. Localization by intermittent fluoroscopy permits accurate needling and washing out of the calcific material.

out under intravenous Pentothal Sodium anesthesia in the patient's room, with the arm in the apparatus.

Figures 7, 8 and 9 show the significant maneuvers in the actual manipulation. It should be noted that the scapula must be immobilized by one hand of the operator, while the other grasps the upper end of the humerus. In progressive stages the arm is moved laterally in abduction, during which maneuver numerous adhesions will be felt and heard to rupture. The significance of grasping the upper end of the humerus lies in the fact that this reduces the leverage action on that bone and hence it is less likely to fracture. No attempt is made to obtain a normal range of motion in the first manipulative procedure, because if this were done, frequently the resulting pain and discomfort would be so great that the patient would be unable to move the arm through the arc of mo-

tion that was present before the procedure. So in progressive stages the range of motion, both of lateral abduction and of rotation, is gradually increased. The actual extent of the manipulation is learned by experience, but a safe rule is to carry the arm through a lesser rather than a greater degree of motion.

With the manipulation completed, 1 per cent novocain is injected into the subacromial bursa, as well as into the periarticular structures of the shoulder joint. This idea, originally suggested by the work of Leriche and Policard⁹ in their treatment of sprains, has been of considerable aid in reducing the degree of discomfort that may follow the manipulation.

During the twenty-four hours after manipulation, no particular effort is made to have the patient move his arm unless he feels like doing so, but the intensive heat treatment is continued and sedatives are given as required to control discomfort. Beginning with the second postoperative day, active arm exercises are again instituted, in an attempt to increase the range of lateral abduction and of rotation. In practically every case the patient finds that he is able to move the arm through a wider arc of motion than was previously possible. Thereafter, the regimen as described is continued until further manipulation is indicated; this is performed after the patient again has reached a maximum degree of improvement.

As soon as the pain in the shoulder is less severe, the traction on the arm is progressively omitted, thus permitting much more active motion of the extremity. The patient then becomes ambulatory and begins pendulum exercises (Fig. 10), which are especially advantageous since the effect of gravity is eliminated and the patient can obtain normal motion at the shoulder joint with a minimum of effort. Likewise, in this same position the degree of pain caused by motion is considerably reduced.

In the ambulatory stage, the patient is discharged from the hospital and carries on his exercises at home, coming into the clinic on an average of two or three times a week for further physiotherapy, such as a combination of inductotherm, infrared radiation and massage, but always the main emphasis is placed on progressive active muscle exercises.

Thereafter the decision regarding further treatment depends on the patient's progress. If he is remiss in carrying out the active exercises and the adhesions recur, this negligence is emphasized, and he may then be readmitted for a few days in the hospital for further manipulative treatment. In the co-operative patient who continues under observation, however, this is usually unnecessary

A patient who lives at a distance is referred to his physician, and every effort is made to have him carry on treatment under the latter's active supervision.

In treatment of chronic adhesive subacromial

OPEN OPERATION

In one other group of patients, which includes two types, open operation is resorted to.

The most commonly encountered patient in this group is the one in whom the adhesions are

FIGURE 12. Tendons of the Shoulder Joint.

Through a small incision and with rotation of the arm, visualization not only of the subacromial bursa but also of the underlying tendons of the short rotator muscles is possible. The diagrams exhibit the tendons shown by the corresponding position of the arm.

bursitis with calcification in the bursa or in the tendon of the short rotator muscles, the foregoing program is also instituted with the following additions. The initial manipulation is done on the fluoroscopic table, again under intravenous Pentothal Sodium anesthesia. Needles are passed into the area of the calcification (Fig. 11), and as described in the article by Patterson,¹⁰ the technique of Smith-Petersen¹¹ is attempted—namely, the washing out of the calcified material. Before we were aware of this particular procedure, our practice had been to pierce the calcified deposit repeatedly with needles and inject novocain. This maneuver alone seems to encourage more rapid disappearance of the calcified deposit, but the washing-out technique has proved most efficacious.

so resistant to manipulative procedure that it is considered unwise to rupture them. The bursa is therefore explored (Fig. 12) and many of the adhesions are divided with a knife, and thereafter the usual manipulative maneuvers are performed. It should be emphasized that the decision to open a bursa of this type is made because of the dense, firm adhesions in the presence of extensive bone atrophy. In such a patient the manipulations may well cause fracture of the shaft of the humerus. This possibility is eliminated by open operation, since a considerable number of adhesions are divided and those that remain in the less accessible part of the bursa can be ruptured by manipulation without fear of humeral fracture.

The other type of operative case is the one with a large mass of calcification that we have not succeeded in removing by the needling technic. Here the subacromial bursa is explored, and the calcified deposit as it lies in the tendon is incised and curetted out as described by Codman.

STATISTICS AND RESULTS

The data presented in this paper are based on an analysis of the treatment of 100 consecutive patients admitted to the Lahey Clinic because of chronic adhesive subacromial bursitis. Of this number, 9 patients, although improved on discharge, have not had an adequate follow-up for evaluation of the end results. Forty patients have been followed for over two years, 27 for over one year, and 14 for six months to one year. In 10 cases the follow-up was less than six months, but the results were so satisfactory that it was thought that an end result could be reported.

These 100 patients were divided into five groups. Those in Group A (47 cases) — were completely relieved of all symptoms and disability. Those in Group B (34 cases) were markedly improved. They had no disability and acknowledged only occasional pain. All the patients in Groups A and B returned to their previous occupations, and their ability to carry out these activities was in no way impaired. The patients in Group C (5 cases) were followed from six months to two years. All of them exhibited improvement but not enough to be classified in either Group A or B. Each of these 5 patients had either normal motion and some discomfort, or better than 50 per cent normal shoulder motion and no pain. The patients in Group D (5 cases) were unimproved. Those in Group E (9 cases) were improved on discharge, but the follow-up was inadequate.

Of 100 patients, therefore, the majority of whom were followed a minimum of six months and in most cases over a year, 81 either were relieved completely of all symptoms or were markedly improved and remained without any disability, although they occasionally complained of some shoulder discomfort.

SUMMARY AND CONCLUSIONS

In summarizing the treatment of this difficult

problem, we wish to emphasize the following significant points:

The patient should be forewarned regarding the basis for his disability and the considerable length of time that is often required to achieve a return of normal shoulder-joint function, as well as the absolute necessity for his complete co-operation in carrying out the often extremely fatiguing and boring exercises.

An initial period of bed rest, the arm in suspension and traction, usually results in marked increase of shoulder-joint function.

Manipulative procedures designed to break up the adhesions in the bursa and about the soft parts in the shoulder should be done in stages, and no attempt should be made to obtain normal motion in the shoulder at the first manipulation.

In the case of extremely resistant adhesions, especially when present in frail, poorly muscled patients who have had the loss of shoulder function for some time, with accompanying marked bone atrophy, it is preferable to explore the bursa, divide firm, fibrous bands, and eliminate the remaining adhesions by manipulation.

In chronic adhesive subacromial bursitis with calcification, the latter is removed by the washing-out technic or by open operation. Thereafter the regimen for patients without such deposits is carried out.

A STUDY OF ERRORS IN THE DIAGNOSIS OF JAUNDICE*

FRANKLIN W. WHITE, M.D.†

BOSTON

ON ward rounds and in clinicopathological conferences, cases with jaundice, especially those in the early stage, call forth a diversity of diagnoses and frequent mistakes. In the last six years 500 cases have come under our observation on the Second and Fourth (Harvard) Medical Services at the Boston City Hospital. These included most types of jaundice: complete and partial biliary obstruction, acute and subacute infectious and toxic hepatitis, the cirrhotoses (portal, biliary, pigment, toxic and cardiac), fatty liver, tumors and syphilis of the liver and hemolytic jaundice. This paper is limited to 175 of these cases that came to operation or autopsy.

All known errors in diagnosis have been studied and classified. A statement of the number and kind of errors, showing which mistakes are commonest, may help to avoid them in the future. Errors are based on first-choice diagnoses only, and correct alternative diagnoses are not considered

METHODS OF STUDY

In addition to a careful history and a general physical examination, special attention was paid to the size of the liver, spleen and gall bladder, the presence of ascites or spider angiomas, the icteric index, the color of the stool, tests for urinary diastase and the roentgenologic examination (Graham test, barium meals and enemas). Several liver-function tests were used in serial observations in each case, chosen from the following group: the excretion of urobilinogen and hippuric acid in the urine, galactose tolerance, excretion of bromsulfalein, the phospholipids, total cholesterol and cholesterol-ester percentage in the blood, the blood prothrombin level and its response to vitamin K, the serum albumin and the albumin-globulin ratio. In a small number of cases, peritoneoscopy and medical biliary drainage were used; biopsies of lymph nodes and liver were done when possible. A considerable number of the patients were followed and studied for months or years after the attack of jaundice in order to discover residual liver damage

struction, hepatocellular jaundice‡ and hemolytic jaundice. McNee's¹ classification of jaundice was chosen as the most valuable clinical grouping, and obstruction was further divided, since it was found that complete obstructions were nearly all due to malignant neoplasms and partial obstructions were nearly all due to benign conditions. Rich's² classification into retention and regurgitation jaundice is important in showing the mechanism of jaundice, but has less clinical value than other classifications since there is rarely any difficulty in distinguishing these two types and since all the types of jaundice that are difficult to distinguish from one another are found in the regurgitation group.

The first two groups are essentially surgical with respect to treatment, and the last two essentially medical. The total group of 500 cases is listed in Table I to show the types. Almost one third of

CLASSIFICATION

The cases were classified in four groups, as a guide to medical or surgical treatment: namely, complete biliary obstruction, partial biliary ob-

struction, hepatocellular jaundice and hemolytic jaundice. About one third of the cases were chronic cirrhosis; about one third were toxic and infectious hepatitis; and about one third formed a group including gall-bladder disease, complete obstruction, tumors and syphilis of the liver and hemolytic jaundice. There was a surprisingly large proportion of cases of jaundice

*From the Thorndike Memorial Laboratory and the Second and Fourth Medical Services (Harvard) Boston City Hospital and the Department of Medicine Harvard University.

Presented in part at the annual meeting of the Association of American Physicians Atlantic City, May 3, 1939.

†Consulting physician Boston City Hospital.

on injury to liver cells

to produce liver cells

due to cirrhosis. The patients evidently enter the hospital when there is an attack of acute hepatic necrosis or decompensation. The percentage is greater in this hospital group than in the cases encountered in private practice.

In Table 1 are also listed 175 proved cases that came to operation or autopsy.

In Table 2 are given the proved errors in these 175 cases. They are classified in groups, with the correct diagnoses in one column and the erroneous diagnoses in the next column.

The proved errors in the 175 cases that came to operation or autopsy totaled 14, or 8 per cent. Needless to say, in many cases of jaundice that were easiest to diagnose the patients did not die and were not operated on. These included patients with acute toxic and infectious hepatitis

biliary passages. A man of fifty-two (Case 1) with a history of increasing painless jaundice for two months and a final icteric index of 100, gray stools and entire absence of urobilinogen in the urine on daily tests over a period of ten days showed at operation gall-bladder disease, with the hepatic and common ducts solidly plugged with puttylike material and gravel, causing complete obstruction.

Partial Obstruction

A man of seventy-seven (Case 2) with a known chronic genitourinary infection, pyuria, pyelitis and prostatic abscess also had empyema of the gall bladder, cholangitis and multiple liver abscesses, with slight obstruction of the biliary passages. The jaundice was slight and lasted only two days. The genitourinary infection masked the biliary-tract infection, which was not recognized.

A man of sixty (Case 3) of alcoholic habits had continuous deep, painless jaundice for six weeks, a large firm liver, a high urobilinogen falling to normal, stools yellowish to gray and possible slight ascites. Barium x-ray films were normal. It was difficult to decide between terminal chronic hepatitis with loss of function and partial external obstruction. A diagnosis of portal cirrhosis was made. The autopsy showed a primary cancer of the duodenum that gradually involved the ampulla and pancreas and that was missed by the roentgen ray, with a few metastases in the liver. The partial obstruction that was present when the diagnosis of cirrhosis was made became complete in the last two weeks of life, with clay-colored stools and absence of urobilinogen in the urine.

A fifty-one-year-old man (Case 4), moderately alcoholic, had dull pain in the region of the right scapula, deep jaundice for one week, slight hematemesis and a little irregular fever. The liver was slightly enlarged. There was a question of a palpable spleen and some ascites. The stools were light brown, the urobilinogen in the urine was increased (positive on four occasions in dilutions of 1:32, 1:16, 1:64 and 1:4 respectively), and roentgen-ray examination of the stomach and bowel was normal. The patient continued to be deeply jaundiced for two months and died in coma. A diagnosis of portal cirrhosis was made, with latent carcinoma causing partial obstruction as the second choice. Autopsy showed primary carcinoma, partially blocking both hepatic ducts, with metastases in the liver, lungs and adrenal glands.

A woman of seventy-six (Case 5) with an unusual small, soft adenocarcinomatous polyp in the common duct had epigastric pain, chills and irregular fever, moderately deep jaundice, some increase in the size of the liver, bile pigment in the

	13	Possible cardiac cirrhosis; infarcts	Secondary cancer of liver (stomach)
Hemolytic jaundice	14	Hepatorenal syndrome	Arteriosclerotic heart; infarcts of lungs and spleen; passive congestion.

-and hemolytic jaundice and many with chronic cirrhoses who had been under observation at the hospital for a long time, so that the actual percentage of erroneous diagnosis in the whole group was probably somewhat less than that given above.

KIND OF ERRORS

The known errors were in the chronic cases, with a single exception, a case of subacute yellow atrophy (Case 6).

Complete Obstruction

One case was diagnosed as cancer when it was absent, on the basis of complete obstruction of the

stool and increased urobilinogen in the urine, and was considered to have partial obstruction of the common duct due to stone, with infection of the bile passages and liver. At autopsy, in addition to the polyp in the common duct, there was extensive cholangitis with multiple abscesses of the liver.

Hepatocellular Jaundice

Acute hepatitis. A sixty-year-old man (Case 6) had two weeks of painless, steadily increasing deep jaundice (icteric index 100 to 200), complete absence of urobilinogen in the urine for ten days and normal galactose-tolerance tests. The diagnosis wavered between subacute hepatitis and obstruction of the common duct, and the patient was finally operated on. A longer period of observation and tests might have avoided this mistake. At autopsy, a healing acute yellow atrophy was found.

Cirrhosis. Two cases of pigment cirrhosis (Cases 7 and 8) were called portal. Neither patient had external pigmentation or glycosuria, and both were hard drinkers. One case of portal cirrhosis (Case 9) with accompanying cholecystitis was diagnosed as biliary cirrhosis.

Tumors of liver. Cancer was overlooked in 4 cases. Two of these patients had secondary cancer of the liver from a tiny primary focus, which caused no symptoms whatever and was discovered only at autopsy. One patient (Case 10) had a nodule in the breast the size of a small pea, and the other (Case 12) had a tiny nodule in the esophagus.

One patient (Case 11) had a latent cancer of the body of the pancreas not involving the common duct, with massive secondary cancer of the entire liver.

In 1 patient with chronic decompensated valvular heart disease (Case 13), the roentgen-ray examination of the stomach was unsatisfactory on account of weakness and vomiting. A cancer was suspected but not proved. Actually a medium-sized prepyloric cancer was present, with massive involvement of the liver.

Hemolytic jaundice. In a case of acquired hemolytic jaundice the diagnosis failed. A man of forty-one (Case 14) with chronic arteriosclerotic heart disease developed deep jaundice after ten days in the hospital (icteric index 40 to 100). He had multiple venous thromboses from venipuncture for the use of Mercupurin, signs of multiple infarcts in the lungs, moderate uremia (anuric for one day, with the nonprotein nitrogen 70, 82, 50, 60 and 30 mg. per 100 cc. in five successive samples of blood), some bile in the urine and evidence of liver damage (the urobilinogen in the urine rising and remaining positive in a dilution of 1:128). The liver was 2 to 3 cm. below the costal margin.

The vague diagnosis of hepatorenal syndrome was made on the basis of combined hepatic and renal damage. The autopsy showed, in addition to the above, infarcts in the spleen, a pathologic gall bladder containing two stones, with the large patent bile ducts, and passive congestion of the liver and kidneys. This confusing picture of multiple disease was dominated by hemolytic jaundice from the multiple infarcts in the lungs and spleen, to which insufficient attention was paid.

DISCUSSION

Errors of Diagnosis

Of 29 proved cases of complete obstruction, 28 (97 per cent) were due to cancer, and of 61 proved cases of partial obstruction of the common or hepatic ducts, 56 (92 per cent) were due to benign conditions. The 5 cases of cancers with partial obstruction of the external biliary passages comprised the following: 1 case (Case 3) of cancer of the duodenum with extension to the pancreas in which partial obstruction became complete in the last two weeks of life, 3 cases of almost complete obstruction—namely, 2 cases of cancer of the head of the pancreas correctly diagnosed and 1 (Case 4) of cancer of the hepatic ducts—and 1 unusual case (Case 5) of a soft pedunculated adenocarcinoma of the common duct 1 to 2 cm. in diameter.

The presence of complete obstruction with continuous absence of bile from the feces and of urobilinogen from the urine has strongly favored the diagnosis of cancer involving the common duct (in the head of the pancreas, the ampulla of Vater or the common duct) or both hepatic ducts. When a cancer obstructs the common duct and has caused well-marked jaundice, it usually does not take long to produce complete obstruction, judged by the continued absence of urobilinogen from the urine with the Wallace and Diamond² test or a very low figure (0 to 0.3 mg. daily) with the Watson³ test.

One case (Case 1) of complete obstruction of the common duct was diagnosed as a cancer when it was stone. This mistake was not important except for the prognosis, since, in either event, surgery was required.

There was a great difference in the importance of the errors in the various groups. The error was most serious in Case 6, in which a patient with acute hepatitis was operated on for obstructive jaundice and died of bronchopneumonia, and was found to have a healing subacute yellow atrophy. This case was encountered six years ago; this mistake has not been repeated, and we have had several opportunities to restrain sur-

geons from exploring other patients at an early stage of the disease.

The determination of the cause of the jaundice in the first day or two of the disease is not essential since these are not emergency cases. In acute deep jaundice a short period of study is especially needed to avoid operating early with a diagnosis of complete or partial obstruction without adequate knowledge of the liver function or the surgical risk and course of the jaundice and without making the best diagnosis possible. A good rule in acute deep jaundice with brown stools is to avoid surgical treatment. The disease is obviously not due to external obstruction, but chiefly or entirely to damage of the liver cells (acute hepatitis, cirrhosis with acute necrosis and so forth). The risk of operating for severe or acute diffuse hepatitis at the height of the jaundice is extremely great. This is seen when the mortality of ordinary gall-bladder operations, from 2 to 5 per cent, is compared with that of about 35 per cent in operations on cases of cirrhosis and with one of nearly 100 per cent in operations on cases of acute yellow atrophy or severe acute hepatitis. In acute jaundice it was often a serious question how long to wait to watch the course of the disease. In acute cases without obvious infection and pain (acute hepatitis, necrosis in cirrhosis, obstruction by stone or hemolysis), the danger lies entirely on the side of early operation in cases with a wrong diagnosis. In chronic cases there is no reason to hurry a difficult diagnosis. Most patients with obstruction due to stone preserve good liver function for a long time, and other cases are either unsuitable (cirrhosis) or unsatisfactory (cancer) for surgery.

Too many diagnoses of cirrhosis were made when latent cancer was present, chiefly because the patient was a steady drinker and had a deficient diet and enlarged liver. The large majority of steady drinkers (over 90 per cent) never develop cirrhosis. Various cases of cancers were called cirrhosis, but no case of cirrhosis was called cancer. The best differentiation is achieved through the history and physical examination, but ascites may occur in both diseases and a palpable spleen may be absent in both.* Liver-function tests usually show some damage in both. This is more marked in well-developed diffuse cirrhosis than when nodules of cancer are scattered through a normal liver, on account of good compensation of the latter.

It is easy to confuse portal cirrhosis with the toxic cirrhosis that follows an attack of subacute yellow atrophy of the liver (Mallory⁵) when the acute attacks of the latter are not striking or

occurred so long ago that they have been forgotten. Erroneous diagnosis of cirrhosis, such as calling pigment cases portal, is of minor importance, since the treatment is similar for both—namely, medical.

There was 1 proved case of primary cancer of the liver (hepatoma) in the 41 cases of cirrhosis that came to autopsy. This is rarely discovered clinically, but is chiefly diagnosed pathologically.

Over half the proved errors—namely, 8 out of 14—were associated with cancer. One case (Case 1) was diagnosed as cancer because of complete biliary obstruction; cancer, however, was absent.

Cancer was overlooked in 7 cases. Of these, 4 (Cases 3, 4, 10 and 11) were called cirrhosis, 2 (Cases 5 and 12) were called infections of the liver (cholangitis with multiple small abscesses), and 1 (Case 13) was diagnosed as chronic passive congestion of the liver with possible infarcts in a patient with decompensated rheumatic mitral and aortic disease of long standing. These 7 cancers were difficult to find clinically. In 1 case primary cancer of the duodenum (Case 3) was missed by the roentgen ray. Cancer was primary in the bile passages in 2 cases, in the common duct in 1 (Case 5) and in the hepatic duct in 1 (Case 4). In 4 cases it was secondary—arising in 2 from tiny foci in the breast (Case 10) and esophagus (Case 12), in 1 (Case 11) from a latent cancer of the body of the pancreas and in 1 (Case 13) from a cancer of the stomach in a patient too weak for examination. These 7 cases of latent cancer within the liver or bile passages were extremely serious, with no opportunity for palliative surgical treatment, which in some cases was useless and in others was impossible because of the poor condition of the patient. Fever and leukocytosis in late cancer may simulate cholangitis and liver abscess. Probably an error in diagnosis can be avoided by a more frequent consideration of the possibility of cancer.

Multiple lesions were sometimes confusing. The symptoms of one lesion overshadowed those of another, as in Case 2, in which an obvious genitourinary infection covered the signs of a latent but extensive infection of the biliary tract. In Case 13, a patient with a chronic valvular heart disease showed well-marked symptoms, whereas the cancer of the stomach and liver were only vaguely suspected. In Case 9, the cholecystitis was easily diagnosed but the portal cirrhosis was latent.

Ease of Diagnosis

There was a great difference in the ease of diagnosis of the different diseases. The easiest

*The methods of diagnosis will be discussed in a later paper

to diagnose was toxic hepatitis in which there was a history of exposure to arsenic, einchophen, chloroform, carbon tetrachloride, gold thiosulfate or some other drug and in which no mistakes in diagnosis were made. Patients with toxic cases may have multiple diseases such as syphilis and asphenamine hepatitis, with alcoholic cirrhosis or cancer.

The disease next easiest to diagnose was complete obstruction, which was apparent on the basis of absence of bile in the bowel, determined not only by the color of the stools but better still by the complete absence of urobilinogen from the urine on repeated tests. All but 1 of these cases were cancerous.

Hemolytic jaundice had so many distinctive features that with careful study the diagnosis was usually easy. In chronic familial cases, the history, lack of pain, anemia, low-grade icterus, splenomegaly, small spherocytes, increased fragility of the red cells, presence of reticulocytes, lack of bile in the urine (usually), an excess of bile pigment in the feces and an indirect van den Bergh's reaction in the blood are distinctive. The presence of bile in the urine does not rule out hemolytic jaundice, since in some cases there is accompanying liver damage, apparently due to anoxemia (anemia, heart disease, pneumonia and so forth).

The sudden appearance of jaundice in patients with chronic myocardial insufficiency should make one suspect pulmonary infarct as a cause of the jaundice, even without local signs (Keefer and Resnik⁶).

The diagnosis of gall-bladder disease is relatively easy with modern methods,—the history and physical examination combined with Graham tests, biliary drainage and so forth,—as was also the diagnosis of acute pancreatitis with the additional help of early tests of the urinary diastase. Some patients were too sick for thorough examination, and this proved to be a source of error, as in Case 13.

Diagnosis of cancer of the liver was easy following previous operation for cancer of the stomach, bowel, prostate, pancreas and so forth or by biopsy of a lymph node, but the most difficult cases for diagnosis were those of small or latent cancer of the liver and common or hepatic ducts, which were not always distinguished from cirrhosis and cholangitis.

There are several small groups of cases in which no error in diagnosis was made that is worth mentioning.

Only 8 cases were classified as simple fatty liver; in 1 of these an alcoholic patient developed pneumonia and died. The autopsy showed a

large, soft, fatty liver without cirrhosis. In the other proved cases the fatty livers were complicated by cirrhosis. Unproved cases with two or more of several clinical signs—a much enlarged liver, jaundice, ascites, an enlarged spleen, varices, a low serum albumin, low prothrombin, edema, hemorrhages and poor liver function—were classified as fatty portal cirrhosis.

There were only 4 cases of acute pancreatitis with jaundice, all correctly diagnosed and all associated with gallstones. The diagnosis was relatively easy with the combination of jaundice, severe epigastric pain, vomiting, leukocytosis and, especially, marked increase of urinary diastase (in dilutions of 1:300, 1:1600, 1:2200 and 1:7500, respectively). No diagnosis of chronic pancreatitis was made, and no case was discovered at operation or autopsy.

Syphilis of the liver was proved in only 1 case (0.6 per cent) in the group of 175 jaundiced patients who came to operation or autopsy, and was not diagnosed again in the total series of 500 cases. A man of seventy had been explored thirty-five years previously at another hospital for an abdominal tumor, which proved to be a gumma of the liver with adhesions to the stomach. Treatment was inadequate. When he entered this hospital because of dull pain in the right upper quadrant of the abdomen, the jaundice was slight (icteric index 13), the liver was large, firm, irregular and tender, a blood Hinton reaction was negative, there was no ascites, and liver-function tests were almost normal. Peritoneoscopy was unsatisfactory because of omental adhesions to the liver. The reported incidence of syphilis of the liver has gradually lessened in recent years, probably as a result of earlier and better treatment.

Weill's disease (spirochetosis icterohemorrhagica) was not diagnosed or found post mortem in this series. It is evidently rare in this region, but the apparent rarity may be due in part to the fact that the clinical picture and laboratory methods are not well known. If earnestly looked for by means of proper bacteriologic procedures in cases of acute infection or catarrhal jaundice, cases will occasionally be recognized.*

SUMMARY AND CONCLUSIONS

The proved errors in diagnosis in 175 cases of jaundice that came to operation or autopsy was 14 (8 per cent).

The known errors, with one exception, were in the chronic group, and over half the errors were associated with the diagnosis of cancer, almost always in overlooking small or latent tumors.

*Three cases were found on other medical services at the Boston City Hospital in the last five years.

It is evident that latent cancer should be considered much oftener in doubtful chronic cases. There was a tendency to make too many diagnoses of portal cirrhosis in alcoholic patients with an enlarged liver. Various cancers were called cirrhosis, but no case of cirrhosis was called cancer.

Complete obstruction of the external bile ducts was due to cancer in 96 per cent of the proved cases, and partial obstruction was benign in 91 per cent.

The essential need is to separate medical from surgical cases of jaundice. This is far more important than is the diagnosis of the specific disease of the liver; for example, it is far more important to differentiate hepatitis, the treatment of which is essentially medical, and complete obstruction, in which it is essentially surgical, than to decide just which kind of cirrhosis or complete obstruction is present.

Cases of jaundice are rarely emergencies, and it is best not to hurry the diagnosis in most acute or chronic cases, especially in the absence of serious infection (cholangitis, abscess of the liver, empyema of the gall bladder, perforation or peritonitis), and not to trust to early impressions, which are often reversed by the course of the illness and the laboratory tests. It is especially necessary not to make the early diagnosis of acute deep jaundice a basis for early surgery, which in this series had a high mortality in the wrongly diagnosed cases. A period of study, with the giving of plenty of glucose and water, protein and vitamins, is essential in order to watch the course of the disease and to see which element predominates—damage to the liver cells, external obstruction or hemolysis.

If unexplained jaundice appears in chronic heart

disease, pulmonary infarct or hemolytic jaundice should be considered.

The ease of diagnosis of jaundice was approximately in the following order. The diseases easiest to diagnose were toxic and infectious hepatitis, complete external obstruction and hemolytic jaundice. Those moderately difficult to diagnose were fatty liver, acute pancreatitis, gall-bladder disease with partial external obstruction and cirrhosis. The most difficult to diagnose were multiple lesions, cases in which the patients were extremely sick and had incomplete examination and tumors of the liver and bile passages.

The differentiation of hepatocellular and obstructive jaundice and of stone from cancer in the common duct has become easier in the last ten to twenty years, but the difficulty of discovering various latent cancers causing jaundice remains.

Syphilis of the liver is less common than in the past, there having been only 1 proved case. No cases of Weil's disease or chronic pancreatitis were diagnosed or found.

MEDICAL PROGRESS

INDUSTRIAL HYGIENE

IRVING R. TABERSHAW, M.D.,* AND MANFRED BOWDITCH†

BOSTON

FOR the first time in the history of the United States, its manpower has been found to have quantitative limits. Since this commodity cannot be rapidly expanded, human resources must be husbanded; and since industrial hygiene is concerned with the preservation and improvement of the health of the worker, it has assumed a greater importance than heretofore. Conspicuous advances have been made not only in the prevention of specific occupational hazards, but also in the development of the public-health viewpoint in industry with the worker as the chief recipient of its benefits.

The application of newer knowledge in industrial hygiene has been constantly expanded under the stimulus of federal funds, which have since 1936 been aiding state industrial-hygiene activities. At the present time, there are approximately forty-seven units in thirty-eight states with about three hundred active workers.¹ Co-operative arrangements between these state units and other agencies responsible for worker health have been effective in spreading the recent gains in industrial hygiene.

SPECIFIC OCCUPATIONAL HAZARDS

The war has introduced a host of new chemicals of relatively unknown toxicity, besides accelerating the use of the numerous substances about whose toxicity much is known. Modern industry rests on a chemical base, and its constant development continuously creates new problems in industrial hygiene. Some of these are of temporary nature, but many will continue into the postwar world.

The Pneumoconioses

The pneumoconioses are still a fruitful source of medical investigation, since many points about them are still to be defined. The roentgenologic picture has been thoroughly reviewed by Pendergrass,² who has admirably summed up the difficulties and variations in the x-ray interpretation

of occupational disease of the thorax. It has been customary to think that the only disabling pneumoconioses are those due to silica and asbestos. Recent investigations, however, create the belief that the list will have to be expanded to include such silicates as talc and mica, and the literature abounds in cases of pneumoconioses from various minerals and earths.^{3,4}

Pinro et al.⁵ presented 15 cases of talc pneumoconiosis, including 5 autopsies, and in 13 of these the disability was directly attributable to the pneumoconiosis. Talc dust varies greatly mineralogically, and the highest incidence occurs in those workers exposed to talc with a high percentage of tremolite.⁶ Mica, another silicate, has given rise to an incidence of lung fibrosis of 11.4 per cent in miners of this mineral.³

Certain dusts such as coal and aluminum have not only been called harmless but are stated to have an antidotal effect. More recent investigations, however, indicate that these substances are not entirely harmless and may in fact cause some degree of pulmonary fibrosis. Anthracosis is rather frequent, as recent surveys have proved.^{7,8} The dangers to the lung from aluminum have been discussed in the German literature. It is stated that aluminum dust must be included in the list of pneumoconiosis-producing substances, although it remains to be proved whether it produces specific lesions.^{9,10} On the other hand, Crumlie and Blaisdell¹¹ report encouraging results from the symptomatic treatment of silicosis with aluminum dust and believe that it is an effective preventive. Silica is soluble to about 200 parts per million, and a small amount of metallic aluminum is stated to reduce this solubility to about 6 parts per million.

The study of the pathology of silicosis has continued. It has always been defined as a local disease of the lungs and thoracic lymph nodes. Recently a case came to autopsy that also showed systemic dissemination of silicotic nodules in the liver and spleen.¹²

Engineering methods of dust control have progressed to the stage that, in most industries, no worker need be exposed to a hazardous concentration of any pneumoconiosis-producing dust.

A number of new pulmonary syndromes have

The articles in the medical progress series of 1941 have been published in book form (*Medical Progress Annual*, Volume III, 678 pp., Springfield, Illinois: Charles C. Thomas, 1942, \$5.00).

*Physician, Division of Occupational Hygiene, Massachusetts Department of Labor and Industries.

†Director, Division of Occupational Hygiene, Massachusetts Department of Labor and Industries.

recently been described, and a fairly definite one, called "bagassosis," has been reported from the English literature. This lung disease is due to dust created by the crushing of broken sugar cane after the sugar has been extracted. Many exposed to this fine dust become sensitized and after several months develop dyspnea, cough, weakness and anorexia. The illness is severe and prolonged, but recovery ultimately takes place. The x-ray picture is similar to that of an inflammatory condition. Cases have recently been reported as having occurred in Louisiana, where a similar process is in operation.^{13, 14}

Another interesting lung disease has recently been reported in persons working in beryllium-recovery plants.^{15, 16} This pulmonary condition is characterized by dyspnea, cough and low-grade fever. The illness usually lasts about three months, and the x-ray picture suggests a diffuse inflammatory inhalation reaction. Practically all the affected workers recovered, but there have been a few fatalities. A group of cases similar to these have occurred recently among workers engaged in making electrical equipment and lamps.¹⁷ This condition is characterized by dyspnea and cough, weakness and loss of weight. The illness runs a more chronic course. One autopsy demonstrated the pathological findings of sarcoidosis. The x-ray picture is consistent with this diagnosis.

Lead

Lead, historically the most ubiquitous hazard to industrial health, is today being met with ever more frequently, and often in quite new roles. Although the usual industrial uses, as in foundries, paint making and storage-battery manufacture, continue to contribute their quotas of lead poisoning, many salvage operations coming to the fore, such as the oxyacetylene cutting of steel, which has been previously covered with lead paint, are proving highly dangerous.¹⁸ Fatal cases of encephalopathy occurring from inhaling fumes from storage-battery boxes burned as fuel have been reported.¹⁹ Such engineering aids as ventilation and wet mining methods have, however, helped to cut down the high incidence of lead poisoning in a number of industries.²⁰ The factors involved in the industrial exposure have received further attention, and the standard of 1.5 mg. per 10 cu. m. of air has been well substantiated as the upper limit of tolerance.

Experimentally, investigation has been going on regarding the behavior of lead in body tissues. The behavior of lead in the organism as a whole is dependent on the mechanism of its storage in the body, and means of identification in body tissues

have been perfected by Fairhall and others. The dropping mercury electrode and the development of radioactive lead as an indicator give promise of greater advances to come.²¹⁻²⁵

The therapy of lead poisoning is still not entirely clarified. In the past, ascorbic acid was suggested as a means of increasing the lead excretion,²⁶ but clinical observation has not proved that this vitamin has any effect on increasing the excretion of lead from the body.²⁷ The value of milk is somewhat controversial, but there is growing evidence that a person with a positive calcium balance retains less lead. Although milk cannot be considered the keystone of any preventive or therapeutic regime, it is of value in workers exposed to this hazard.

The physical signs and symptoms of lead poisoning have been thoroughly reviewed in articles by Kehoe²⁸ and Ashe.²⁹ Lead poisoning is primarily a clinical syndrome. Diagnosis is helped by study of the excretion, but the final diagnosis depends on an interpretation of clinical symptomatology, which affects chiefly the gastrointestinal and neuromuscular systems. Elimination of ingested lead is accomplished spontaneously, even without "de-leading." Gross changes in the acid base balance or calcium-phosphorus metabolism of the body are not affected if the lead exposures are kept within tolerance limits.³⁰

Control of the lead hazard has been aided in several states by the development of a health-department laboratory service similar to the Wassermann service offered by many states. Lead-free kits are distributed to physicians for the transmission of samples through the mails. This technic has not been adopted universally as yet, but has promise of further development as the medical profession becomes aware of the increasing incidence of lead poisoning.^{31, 32}

Miscellaneous Chemicals

An ever greater variety of miscellaneous toxic chemicals are finding use in industry. The two groups that have been especially studied because of their widespread application and particular necessity in wartime are those compounds that are used as solvents and those used in the making of munitions. The general use of benzol as a solvent has decreased somewhat as manufacturers have become increasingly aware of its toxic qualities. Some of its industrial uses are, however, still widespread; but fortunately many of these processes are carried out in closed systems, and hence no fumes are liberated under usual operating conditions.

The group of compounds known as chlorinated hydrocarbons are extensively used as degreasers

and as solvents. Carbon tetrachloride, although still widely used, has yielded in many instances to trichloroethylene. This latter substance, while less toxic, can cause serious effects and there is an unjustified complacency about its use.³³ The maximum allowable limit in workroom air is 200 parts per million, twice the figure hitherto accepted for carbon tetrachloride, since it is excreted fairly rapidly as trichloroacetic acid after detoxification in the body.³⁴ The symptoms of an excess inhalation of this substance are dullness, nausea, vomiting and coma. Reports in the literature still demonstrate the menace of carbon tetrachloride, which in acute poisoning gives rise to liver and kidney damage, coma and death; it is urged that the maximum allowable limit of this compound be revised drastically downward, since numerous cases of nausea and headache have occurred among workers exposed to less than 100 parts per million, the figure until recently thought to be safe.³⁵⁻³⁷

Ethylene dichloride, also a chlorinated hydrocarbon, is now used as a rubber solvent. Its toxicity is not completely defined, but apparently it too can cause nausea, vomiting and liver damage. Experimentally, it produces an irritation of the eyes in low concentrations. The present maximum figure of 200 parts per million may have to be revised downward.

Toluene has in many instances replaced benzol as a solvent. Although less toxic, it nevertheless can produce hepatomegaly, macrocytosis, a moderate secondary anemia and an absolute lymphocytosis. These changes may occur without any symptomatology. Hence, power ventilation is often necessary where toluene is used.³⁸

Munitions making is still quite hazardous to health, but ventilation procedures have greatly reduced these dangers. No special advance has been made in the medical knowledge of poisoning by trinitrotoluol (TNT), the maximum allowable limit for which has been set at 1.5 mg. per 10 cu. m. of air. Tetryl, a common explosive, is a potent source of dermatitis, and there is some evidence that it may be a systemic toxin. The dermatitis is characteristic, as is the yellow staining of hair and skin.³⁹ Detonators and "boosters" in munitions making, such as lead azide and mercury fulminate, are toxic when inhaled or absorbed. Fortunately, exposures to both these substances are well controlled, since they are most dangerous from the explosive standpoint.

The hazards associated with welding have been more clearly defined. Metal-fume fever, which occurs when zinc and other metallic oxides are inhaled in sufficient quantities, has been shown to be a well-defined syndrome.⁴⁰ It is characterized by chills, fever and leukocytosis several hours after the exposure, clearing up without sequelae

within a day or so. This exposure, as well as those to carbon monoxide, nitric oxide fumes, fluorides and other materials used in the welding fluxes, may usually be controlled by adequate power ventilation.⁴¹

Mercury and Radium

Since December, 1941, no mercury-carroled fur has been used in the making of felt hats. This has resulted in a decrease in the incidence of chronic mercurialism. Occasional cases are still reported from other industries, and mild cases have been known to occur among physicians and chemists exposed to mercury during laboratory procedures. This hazard is not generally recognized, but since mercurialism may result either from ingestion, inhalation of vapor or absorption through the skin, it is not uncommon where mercury is carelessly handled.

The best guide in chronic industrial poisoning is determination of the urinary excretion, since little or no mercury is normally found in the urine except in persons with a recent amalgam filling or in cases where a mercurial antiseptic has been used.⁴² Standards for atmospheric contamination have been evolved, and the American Standards Association has accepted 1 mg. per 10 cu. m. of air as the maximum allowable limit.⁴³ The mining of mercury is still hazardous, but the incidence of mercurialism has been kept down by the use of a new chemical spray in the mines. This consists of a lime-sulfur mixture with a suitable wetting agent. When sprayed on the working surfaces of the mine, it reduces the volatilization and has proved effective in conjunction with good house keeping.⁴⁴

The necessity for employing self-luminous compounds on the dials of instruments used in combat vehicles has intensified the industrial use of radioactive substances. The expansion in terms of number of workers has increased over fifty-fold, but the hazard of radium poisoning has fortunately this time been recognized and extensive measures have been taken to prevent it. A number of states have promulgated codes designed to prevent the ingestion or inhalation of abnormal amounts of radium. The development of extremely sensitive physical methods of determining the amount of radium stored in the body has helped greatly as a guide to prevention. One tenth of a microgram of radium has been established as the maximum permissible storage limit. So far, no cases of radium poisoning have been reported, and it is hoped that the preventive measures now instituted will obviate the occurrence of cases similar to those that followed the last war.⁴⁵⁻⁴⁹

DERMATOSES

Dermatitis continues to be one of the major problems confronting the industrial physician and, in terms of morbidity, is the greatest single factor contributing to absenteeism from illness. Dermatitis as a result of contact with the cutting oils used in machining operations is still the most frequent type. No one method of control is adequate, but effective preventive measures center in personal protective devices and proper methods of cleansing the skin. Protective clothing and protective creams are helpful in minimizing contact, and these, together with hot water, a good soap and frequent bathing, greatly reduce the hazard. Harsh abrasive mixtures and strong solvents must be avoided. The use of clean oil helps to keep down the incidence of oil pimples, but sterilization of reused oil, either by chemicals or heat, is not indicated, since infection is produced by organisms normally present on the skin.⁶⁰

Dermatoses due to a host of sensitizing and allergic agents are of common occurrence, and almost any substance used in industry may cause a rash. Such conditions cannot be adequately prevented by pre-employment patch testing; measures of control must rather be in the nature of job transfer, cleanliness and skin-protective devices. Burns produced by the action of strong acids and alkalis can usually be prevented by proper work methods and protective clothing. Prevention of the defatting effects of strong solvents, with drying, fissuring and dermatitis, lies mainly in the use of mechanical aids in manufacturing, in protective clothing and in the restoration of the fat content of the skin.

Dermatitis due to chlorinated naphthalenes and diphenyls, waxes used in the insulation of electrical cables, is most troublesome in the installation of these cables in fighting ships. Control is effective only through proper hygienic methods. A cleansing mixture of butyl stearate and sulfonated castor oil, which removes the wax from the skin, has been suggested and seems effective.⁶¹

Anthrax, an infection entering usually through the skin, is still of frequent occurrence, cases continuing to be noted among wool sorters, tannery workers and others engaged in the transport of these materials. Control lies in prompt attention to minute abrasions in workers potentially exposed to this hazard, of which it is essential that they be made aware. Methods of treatment, including serum and sulfonamides, are effective if promptly applied. Penicillin has been reported to be effective in 1 case.⁶²

PUBLIC-HEALTH ASPECTS

Industrial hygiene includes in its scope numerous activities related to the general health of the

worker. These have quite rightly come to the fore in the wartime program, since it is recognized that specific occupational disease accounts for no more than 5 per cent of the workers' disability from illness and that the general sicknesses to which mankind is heir account for the rest. Hence, in keeping the worker on the job, it is most important to attack directly all problems that affect morbidity and mortality, including those due to a hazardous working environment.

In many states a program of tuberculosis case finding in industry has been undertaken by means of a mass survey. This has been aided by the development of a photofluorographic unit, a number of which have been placed at the disposal of state industrial-hygiene divisions by the United States Public Health Service.⁶³ A venereal-disease program has been outlined and is gradually making progress, although it is less readily accepted by industry than are some other public-health measures.^{64, 65} Problems of sanitation and community health that affect the industrial environment have also received attention.

Probably the most significant advances have been those in the field of nutrition, and numerous developments have brought attention to this phase of public health so important to the worker. The special problems of in-plant feeding, outfeeding, nutritional requirements, food costs, vitamin supplements and so forth have been integrated into programs that are finding widespread acceptance in industry.⁶⁶⁻⁶⁸

Although hampered by the paucity of physicians, nurses and equipment available, many industries have adopted pre-employment and periodic examinations and have established medical departments with adequate equipment and staff. Developments are under way in the provision of medical and nursing care to small industries through visiting nurses' associations and other agencies.

The great influx of women into the nation's factories has caused their place in industry to be carefully studied by the United States Department of Labor, the United States Public Health Service and the state industrial-hygiene units. Standards have been promulgated for the effective employment of women, taking into account their physical characteristics.⁶⁹

Education in industrial health has by no means been neglected, and an active program is being formulated by the United States Public Health Service. The problem of absenteeism and its causes has received careful analysis, and progress has been made toward reducing this defect in the all-out war effort.

CASE 29521

PRESENTATION OF CASE

A sixty-nine-year-old retired schoolteacher was admitted to the hospital because of pain in the epigastrium and left shoulder of three hours' duration.

The patient was in excellent health until ten or twelve years before admission, at which time she began to have epigastric distress without any real pain. The distress was described as "acidity." She had occasional gaseous eructations but no vomiting. She was given a Sippy powder after each meal, which relieved the burning. She had continued to take the powder.

Ten years before entry she had a "typical story of coronary thrombosis for which she was given bed rest and morphine." Eight years prior to admission she became a vegetarian. There was a 20 or 30 pound loss in weight following this. The epigastric distress continued and was relieved by the Sippy powder.

Two or three weeks before entry, there was increase in the severity of the symptoms and for the first time she developed epigastric pain, which increased on the day of admission. After taking the Sippy powder, she suddenly became extremely sick and vomited "brownish, bloody material." The pain disappeared but she remained weak. She had noodles for supper, following which she became nauseated, went to the bathroom and fell down unconscious, striking her forehead. There was no vomiting or bowel movement at that time. It was not known how long she remained unconscious. On becoming conscious she vomited brownish material followed by bright-red blood. "Later" she had a black tarry bowel movement. Either before the vomiting or after it, she complained of burning epigastric pain, which radiated to the back and to the left shoulder and was accompanied by marked dyspnea. Morphine, administered by her physician, relieved the pain.

Physical examination on admission showed a

thin, acutely ill woman sitting up in bed. She was cyanotic and breathed in a rapid, shallow manner. She had periods of drowsiness, but between these she was fairly alert. There was slight dullness over the right base; the breath sounds were normal, and there were no rales. The heart was enlarged to the left. The sounds were of fair quality, and a soft apical systolic murmur was heard. The abdomen was distended, tympanitic and "firm," but there was no spasm, tenderness or masses. Peristalsis was normal. Pelvic and rectal examinations were negative.

The blood pressure was 154 systolic, 80 diastolic, on the right, and 130 systolic, 70 diastolic, on the left. The temperature was 99°F., the pulse 90, and the respirations 38.

Examination of the blood showed a red-cell count of 4,000,000, with 13.7 gm. of hemoglobin. The white-cell count was 16,000, with 97 per cent neutrophils. The urine was normal, with a specific gravity of 1.022. The stools were tarry, with a ++++ guaiac test.

X-ray examination showed no definite air below the diaphragm. There was a peculiar shadow behind the heart, which could represent air within the mediastinum or disease within the lung. A repeat x-ray examination on the following day showed areas of atelectasis at both bases and probably a moderate amount of fluid in the left pleural cavity. Films of the abdomen showed considerable gas and fecal material in the colon but no definite evidence of intestinal obstruction. During the course of examination she had an episode of "bradycardia with arrhythmia" associated with fainting. This lasted one or two minutes and did not recur. She continued to vomit dark-brown, guaiac-positive material for the next two days. The pain persisted and was worse with respiration. She was given intravenous fluids.

On the third hospital day the temperature rose to 104°F., and the pulse to 140, but the respirations remained around 40. Examination showed dullness over the left chest from the fifth interspace down posteriorly, with diminished breath sounds, tactile fremitus and vocal fremitus. Grocco's triangle was present, as was an area of bronchial breathing at the right base near the spine. There was a questionable friction rub in the left axilla. X-ray examination of the chest revealed a considerable amount of fluid in the left pleural cavity. A swallow of barium showed a large diverticulum in the lower esophagus. No free air could be seen under the diaphragm. The stomach contained a considerable amount of fluid, and the single swallow of barium dropped through the retained fluid and food. Examination was discontinued. A chest tap yielded 200 cc. of blood-

*On leave of absence

tinged, nonodorless fluid, which showed 1500 red cells and 5000 white cells per cubic millimeter, with 90 per cent polymorphonuclears and 10 per cent lymphocytes. A culture of the fluid showed many colonies of nonhemolytic streptococci and few of colon bacilli. The patient was given 5 gm. of sodium sulfadiazine. The following day she was distended and had some tenderness but no spasm. Another 350 cc. of fluid was withdrawn through a tap in the ninth interspace, without any improvement in the dyspnea. The fluid was brownish, cloudy and foul smelling.

The temperature slowly fell, but the pulse and respirations remained more or less stationary. The blood pressure was 140 systolic, 85 diastolic, in both arms. Despite oxygen therapy, the patient became steadily more cyanotic and died on the fifth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. WILLIAM B. BREED: I do not believe that this woman had coronary occlusion at any time. I believe that she had some congenital defect in the diaphragm. She may have had an ulcer in or about a hiatus hernia. Certainly she had some gastritis in that area, which would explain a good deal of the story later on. I think that there was a rupture of some part of the gastrointestinal tract into the left pleural cavity. Just where it was—in the stomach or in the colon—I do not as yet know. Let us go through the data and see how firmly such a diagnosis stands.

The "acidity"—a symptom that might have responded well to Sippy powders—could perfectly well have been due to a small hiatus hernia or gastritis. Regarding the story of coronary thrombosis, let it be remembered that symptoms due to hiatus hernia are often confused with those of coronary heart disease; and we have no evidence, except the patient's own statement, that she ever had a coronary occlusion. The disease process that I have already mentioned could perfectly well have produced the symptoms described. We have no evidence at hand that she had a bad heart, and no electrocardiogram to indicate old scarring or recent coronary disease. The heart sounds were said to have been good, and the heart was said to have been enlarged to the left. Too much emphasis should not be placed on this clinical observation in the presence of disease in the left pleural cavity. Two or three weeks before she came in she certainly had gastrointestinal bleeding, which could have been caused by a hiatus or diaphragmatic hernia, or by an ulcer in that region. Ulcers occasionally do occur in the region of a hiatus hernia. We know that gastritis may be present about a diaphragmatic hernia, and that a patient may bleed from either of these conditions. I

have never personally known or read of a case in which a hiatus hernia perforated into the pleural cavity. I am presupposing that she had a defect in the diaphragm. I do not know how much of the gastrointestinal tract might have herniated through from time to time. There may have been a perforation, let us say, of the colon. We know that the stomach does not contain colon bacilli. We know that there were a few colon bacilli found in the left pleural cavity along with nonhemolytic streptococci. She had no evidence of chronic anemia or of blood loss. She had some leukocytosis, which could be explained by an infectious process in the left pleural cavity. She had occult blood in the stool two or three days after the initial hemorrhage, which does not necessarily mean she was still bleeding.

I should like to ask a few questions about the x-ray examination. In two places it is stated that no definite air was seen below the diaphragm. I should like to have comment on that. I should also like to have explained the statement: "The stomach contained a considerable amount of fluid, and the single swallow of barium dropped through the retained fluid and food. Examination was discontinued."

DR. LAURENCE L. ROBBINS: I do not know why it was discontinued unless the patient's condition was poor. Probably the reason why the statement about no free air beneath the diaphragm was made is that there was a question of perforated hollow viscus. I am not at all sure that the films were taken in the correct position to determine whether there was free air beneath the diaphragm. Assuming that they were, there is no visible free air. There is a process in the left lower lung field that apparently consists of fluid within the pleural cavity; this markedly increased in amount in twenty-four hours. There probably is consolidation in the left lower lobe. One shadow definitely bothers me, and that could be a hernia.

DR. BREED: It could be part of the stomach?

DR. ROBBINS: Yes; but I am not sure that it is. I do not know what the fluoroscopist thought. His examination was probably not sufficient to rule out a hernia. The diverticulum that was described is this dense shadow just below the bifurcation of the trachea, and again we have to take the fluoroscopist's word that it is a diverticulum, which is most likely. We have evidence of a large amount of fluid and other material in the stomach.

DR. BREED: What about the swallow that dropped down through the fluid? Either it means something or it should not have been put in.

DR. ROBBINS: It is merely an indication that there was foreign material in the stomach and

that the patient was not adequately prepared for a gastric examination.

DR. BREED: Certainly you see no barium above the diaphragm in either of these films.

DR. ROBBINS: No.

DR. BREED: You speak of a ruptured viscus. Are you thinking about stomach, esophagus or colon—the same things I have mentioned?

DR. ROBBINS: Yes.

DR. BREED: You would not like to add anything more?

DR. ROBBINS: No. I do not believe that the x-ray examination was complete.

DR. BREED: I take it that on the first examination the left chest was clear, since it is not mentioned in the record. Perhaps Dr. Beckman knows about this case. Do you?

DR. WILLIAM BECKMAN: Yes.

DR. BREED: Then there was quite a sudden change in the examination of the left chest?

DR. BECKMAN: Yes.

DR. BREED: That is very striking and certainly leads one to suspect that the foul-smelling fluid that was removed after twenty-four hours contained more colon bacilli than did the fluid obtained at the original tap. If so, then one would certainly look below the pylorus for the source of this fluid. As I have already mentioned, the normal stomach is peculiarly free from colon bacilli, nor does the duodenum contain many colon bacilli. If we could be assured that the foul-smelling odor of this fluid was due to the colon bacillus, we should have to assume that it was coming from the large or small intestine. Of course the patient may have had vascular disease, but I am inclined to doubt it. One must always consider such a condition with a sudden change in the chest, especially in view of the fainting spell during the x-ray examination. I can get nothing from the x-ray examination, however, that makes me change my initial impression from reading the case over. I still believe that there was a rupture of some portion of the gastrointestinal tract, presumably below the pylorus, into the pleural cavity through a congenital lesion in the diaphragm. Whether the patient also had an ulcer, I do not know. There is no evidence one way or the other.

I am doubtful about the coronary thrombosis and I do not believe that evidence of an old coronary occlusion was found. The patient presumably died of sepsis in the pleural cavity—a rather unusual type of empyema—and possibly cardiac collapse, which was not due, however, to any specific heart disease.

DR. HELEN PITTMAN: If there was rupture of a hollow viscus into the pleural cavity, how about air in the pleural cavity? The x-ray films do not appear to show such a finding.

DR. ROBBINS: Air is not necessarily present. For example, a perforation of a peptic ulcer of the esophagus shows little air in the pleural cavity.

DR. BREED: I am not interested in the diverticulum of the esophagus. I should like to add that I do not believe the patient had cancer of the stomach or of the lower end of the esophagus.

DR. MARIAN ROPES: We were impressed with the story of ulcer symptoms for the ten years before entry and did think at first that the hemorrhage came from the ulcer and that the ulcer had perforated into the abdomen. But it soon became apparent that that was not true. We did not properly connect the findings in the left pleural cavity with the process in the gastrointestinal tract.

CLINICAL DIAGNOSES

Bleeding peptic ulcer.

Empyema, left.

Coronary thrombosis, old.

DR. BREED'S DIAGNOSES

Empyema, due to perforation of gastrointestinal tract (presumably below the pylorus).

Diaphragmatic hernia.

ANATOMICAL DIAGNOSES

Peptic ulcer of esophagus, with perforation into left pleural cavity.

Empyema, left.

Myocardial infarct, old.

Diverticulosis of duodenum, jejunum and sigmoid.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The autopsy showed an empyema in the left pleural cavity composed of 600 cc. of turbid, somewhat hemorrhagic fluid. The abdomen was negative. We were unable to find anything in the stomach or duodenum to account for the long-standing ulcer symptoms. At first we were at a loss to explain the cause of the empyema; then Dr. Sniffen found a good-sized hole at the lower end of the esophagus. There was a peptic ulcer of the lower end of the esophagus that accounted for the long-standing ulcer symptoms and had perforated into the left pleural cavity. In the mediastinum was an abscess 3 or 4 cm. in diameter.

The patient had evidence of old coronary thrombosis. The left descending branch of the coronary artery was completely occluded, and we found an anterior healed myocardial infarct.

DR. BREED: The diaphragm was intact?

DR. CASTLEMAN: Yes.

DR. ROBBINS: There was no hiatus hernia? Is it not rather rare to find peptic ulcer of the esophagus without hiatus hernia?

DR. CASTLEMAN: I do not know. It is rather difficult at autopsy to be sure of a slight hiatus hernia. If one did exist, it would probably have been reduced at the time of autopsy.

CASE 29522

PRESENTATION OF CASE

A seventy-three-year-old retired lawyer was admitted to the hospital because of weakness and tiredness.

The patient was in good health until about six months before entry, when, while working in his garden, he felt unusually tired and weak. He continued his activities, but at a slower pace, until eight weeks prior to admission, when he felt extremely weak and went to bed, where he stayed except for a daily trip to the bathroom. He had no fever, chills, night sweats or headaches. In the following four weeks he noticed a sore spot near the tip of the sternum on swallowing. At times there was a sensation of pressure on the chest and an occasional dry cough. His appetite became poor but his bowel movements remained the same as before. One month prior to admission, examination by his family physician was entirely negative except for a small right indirect inguinal hernia. The temperature was 101°F., the pulse 100, and the blood pressure 140 systolic, 70 diastolic. The urine was acid, with the slightest possible trace of albumin. The sediment contained a few white cells but no red cells. The hemoglobin was 60 per cent. The patient was placed on sulfadiazine, 1 gm. four times a day. Two days later the family physician thought that there were possible rales at the left base and an enlarged spleen. The temperature was 99.4°F. In the next two days the cough completely disappeared, the temperature became normal, and the pulse was 96. He had received 40 gm. of sulfadiazine, which was then discontinued. He was placed on iron and vitamin B tablets but refused to take them or to see his physician. He remained in bed. The substernal pain persisted. It was described as a steady, nonradiating pain that felt like "fifteen men on a dead man's chest"; it was not relieved by food or change of position but sometimes went away spontaneously. The patient refused all solid foods although he said that they caused no discomfort. A friend, however, stated that "solid foods seemed to catch on the way down." The patient subsisted on liquids and semisolids, taking them at odd hours instead of the usual mealtimes. There was occasional nausea but no vomiting, hematemesis, bloody or tarry stools and no numbness or tingling of the extremi-

ties. Two days before admission he developed a fever of 102°F. The next day his physician noticed marked pallor and weight loss since the last visit.

Physical examination on admission showed a well developed, rather emaciated, extremely pale man in no distress. The skin was pale and dry; the tongue was normal. The mucosa of the posterior part of his mouth was covered in areas by patches of white exudate with no surrounding inflammatory reaction. The teeth were in poor condition. The pharynx was covered with a thin mucous discharge. The heart and lungs were normal. There was a small right inguinal hernia. Vibration sense was diminished in the legs, but neurologic examination was otherwise normal.

The blood pressure was 126 systolic, 56 diastolic. The temperature was 101.2°F., the pulse 118, and the respirations 24.

Examination of the blood showed a red-cell count of 980,000, with a hemoglobin of 3 gm. per cent. The white cell count was 1400. Only 86 cells could be seen in the smear. Of these 22 were neutrophils, 28 large lymphocytes, 16 small lymphocytes and 20 monocytes. The red cells were large and well stained. There was some anisocytosis. No reticulocytes were seen. The urine had a pH of 5.5 and a specific gravity of 1.016. There was a + test for albumin. One or two white cells were seen in the sediment. The stools were guaiac negative. A blood Hinton test was negative. The hematocrit was 13 per cent. The mean corpuscular volume was 133 cubic microns, the mean corpuscular hemoglobin 31 micromicrograms, and the mean corpuscular hemoglobin concentration 23 per cent. The nonprotein nitrogen was 23 mg. per 100 cc. Gastric analysis showed no free acid and a combined acidity of 8 units. At the end of thirty minutes the free acid was 5, and the combined acid 25.

X-ray films of the chest showed no definite evidence of consolidation or shift of the mediastinum. A gastrointestinal series revealed no definite abnormality of the esophagus or stomach. There were at least three large diverticula of the second and third portions of the duodenum. The duodenal cap showed a pressure defect on the superior surface, which was interpreted as being probably of no clinical significance.

From the time of admission the patient had a persistent fever, the rectal temperature reaching 102°F. daily. During this period he coughed continually but raised no sputum. He was placed on iron and liver, without response. On the third hospital day he had two severe shaking chills. The temperature soared to 103°F., and the respirations rose to 30. There was no chest pain or increased

cough. Examination showed dullness, bronchial breathing, increased spoken and whispered voice, and rales over the left lower lung field. The white-cell count was 700, but no white cells could be found in the smear. He was given intravenously 4 gm. of sulfadiazine in 1000 cc. of 5 per cent dextrose in water and 500 cc. of whole blood. He remained alert. The temperature gradually rose to 104°F., and he died on the fifth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. JOHN W. NORCROSS*: This patient was a seventy-three-year-old man with progressive anemia, leukopenia and intermittent chest pain of about six months' duration. Before going into a detailed differential I should like to consider a few points in the history.

The initial complaints were fatigue and tiredness, which of course could have been entirely due, and probably were, to the anemia. The patient also complained of pressure on his chest. Any man with severe anemia, particularly a man of seventy-three, is entitled to angina pectoris, and I think that this must be considered as a possible cause of the pain that he had in the chest. But it was not typical angina, since, as later described, it was nonradiating and steady; angina at times, however, can be almost constant. I also want to point out that the patient had a small amount of albuminuria. So far as we know from the history, the hemoglobin was 60 per cent before he received sulfadiazine. Furthermore, the family doctor thought that the spleen was enlarged, but nowhere else is there any mention of this, and we have to assume that numerous physical examinations made on this man after he entered the hospital did not show a palpable spleen. There are many negative factors mentioned later in the history that are of importance. There was no vomiting, hematemesis, bloody or tarry stools or paresthesias. When he entered the hospital there was no distress, emphasizing the intermittency of the chest pain. The note is made that the vibration sense was diminished. We are not told how much, but we must remember that in a man of seventy-three, owing to the probable presence of arteriosclerosis, this observation is of little clinical importance. The fact that no lymph nodes were felt may be significant. The laboratory notes show that he had a severe macrocytic, hypochromic anemia. Later I shall say more about the blood smear, which Dr. Castleman kindly let me have. The patient had free acid in his gastric analysis. I assume that the test meal was used in doing this analysis, since if histamine had been given there probably would have been more than 5

units of free acid present. At any rate he did not have achlorhydria.

I should now like to see the x-ray film of the chest.

DR. GEORGE W. HOLMES: I do not see anything definitely wrong in the chest.

DR. NORCROSS: Can you see anything in the bones that might be abnormal?

DR. HOLMES: No. The shadow of the right auricle is possibly a little prominent, but it is well within normal limits. For a man of his age he shows surprisingly little evidence of arteriosclerosis. There is no tortuosity of the aorta, and no visible calcification in the wall. The vessels around the root of the lung are large, but perhaps these are of no great importance. These films show some barium in the esophagus, but we shall have to take the word of the man who did the fluoroscopy that there were no varices. I cannot rule them out from this one film. Diverticulums are scattered along the duodenal loop, but unless there was some question of disease in the pancreas, I should not think they had any particular bearing on the case. The distance between the duodenal loop and the diaphragm is rather short, and one might expect the liver to be small rather than large, although that is not a definite finding.

DR. NORCROSS: On the film showing the spine do you see anything to make you worry about the bones?

DR. HOLMES: No.

DR. NORCROSS: The patient had a persistent fever, cough and apparently a terminal pneumonia. With regard to a detailed differential diagnosis, one condition that must be considered in any man of this age is an overwhelming infection, which can cause the blood picture given in the abstract. Miliary tuberculosis likewise can do this. In addition, a worn-out bone marrow could lead to an anemia and leukopenia of this degree. Although it is not so stated in the history, the smear showed a normal number of platelets, an observation that is against a diagnosis of bone-marrow depletion. The duration of six months is also against it. We might even consider the possibility that one of the diverticulums ruptured and caused a localized peritonitis. In a man of this age the signs as well as the symptoms may be extremely confusing and such a patient can have an abscess in the abdomen without much to show for it on physical examination. Here again, I think that this is extremely unlikely, but should be put into a differential diagnosis. Blood loss either extrinsic into the bowel or intrinsic in the form of a hemolytic process seems unlikely. Blood loss would not account for the extreme leukopenia, and there is ample evidence that the patient did

*Physician, Lahey Clinic

not lose blood from the gastrointestinal tract. From a hemolytic point of view, particularly a hemolytic process coming from a drug or toxic chemical of one kind or another, we should have to assume that he had agranulocytosis in addition to a hemolytic anemia to account for this blood picture. Of course hemolysis leading to such a severe anemia would be accompanied by jaundice, which would be visible to the examiner. This apparently was not the case.

Severe pernicious anemia must be considered. The vibratory change is not significant, but it is important that free hydrochloric acid was demonstrated in the gastric analysis. In my opinion, true pernicious anemia does not have even this amount of free acid in the gastric contents. Furthermore, there was no response to liver therapy. I do not know over how long a period he received liver, but he was in the hospital for five days and at least in that time he did not respond, which is strongly against pernicious anemia. Furthermore, the platelets were normal in the smear and certain other changes in the blood were not characteristic of pernicious anemia.

Carcinoma with metastases is a possibility. We do know that one can have widespread metastases in the bone that do not show by x-ray examination. The type of chest pain could come from metastatic disease in the spine, sternum or ribs. The type of change in the blood, however, is usually different, there usually being more of a myeloid, leukemoid picture, which was not present in this case. Agranulocytosis of course does not explain the anemia. Aplastic anemia, or more correctly hypoplastic anemia, does not explain it, because in this disease the platelets are of necessity reduced along with the other elements. Leukemia, lymphoma and Hodgkin's disease could cause this picture, but again we have no evidence of enlarged spleen, liver or nodes, and with what evidence we have, one would have to be brave to make any one of these diagnoses.

There is one condition that I think is more likely—namely, multiple myeloma with widespread bone-marrow involvement that was not sufficiently localized in any one place to show by x-ray study. The type of pain from which he suffered may be said to be characteristic of, or at least completely compatible with, this diagnosis. The remissions of the pain are also typical. Usually patients with multiple myeloma do not have much change in the platelets and may on occasion have just as severe an anemia and leukopenia. The latter is unusual, of course, but this is an unusual case.

In connection with this point, I should like to make some comments on the smear. I might say that I do not agree entirely with the differential given in the history. According to my interpretation, there were 37 per cent neutrophilic cells, 1 per cent being myelocytes. Most of these cells were perfectly satisfactory neutrophils. Forty-eight per cent were lymphocytes, of which only 5 per cent were normal, all the rest being atypical in one or more ways. In addition to these lymphocytes, 12 per cent were characteristic of cells found in patients suffering from multiple myeloma, 2 per cent being typical plasma cells, and 10 per cent so-called "myeloma cells." There were also 3 per cent blast forms. In addition there was rouleaux formation. I do not want to say too much about this, as it was not outstanding, but in areas of the smear that were thin and would not ordinarily have rouleaux formation there was a considerable amount of it.

The weakness, fatigue and various other things are amply explained by this diagnosis. The patient did not have much albumin in the urine. We do not know whether Bence-Jones protein was present. There are many patients with myeloma, however, who have no more albumin than this, and this albumin may have been Bence-Jones protein. The absence of palpable lymph nodes and enlarged spleen is perfectly characteristic. I should obviously like to see some x-ray evidence to help me here, but I do not believe that the lack of it rules out the diagnosis. I should also like to know about the total protein and the sedimentation rate, as well as the findings of a bone marrow biopsy, but I assume they were not done. I believe that this case can fit in with the diagnosis of multiple myeloma, with terminal bronchopneumonia.

DR. WILLIAM A. BISHOP: I was much puzzled when I was called to see this patient outside the hospital. I obtained a sketchy and not too reliable history. He had a fever, and although I could not find anything definite in the lungs, I went on the hunch that he must have had an upper respiratory infection. The cough was considerably worse than is stated in the record, although it was unproductive. On that basis, I gave him sulfadiazine. He was a peculiar type of person, who really did not want to see me, and I was called only because the people in the house were anxious about him. So I met an unresponsive, resistant patient from whom it was difficult to get a good history. But, as stated in the record, he had had a definite six-month period of feeling tired. When I first saw him he was pale, but not so markedly

as when he entered the hospital. I saw him three times and was told not to come again. They had no telephone, but I finally got a message to him telling him to stop taking the sulfadiazine and to begin the iron, liver and vitamins. Since the temperature had fallen to normal on the third day,

cough at that time, and of course the severe anoxia was evident.

DR. BENJAMIN CASTLEMAN: Dr. Beckman, would you like to tell us about your impression?

DR. WILLIAM BECKMAN: I did not have much to say of this patient. I saw him once with the med-

FIGURE 1. *Photomicrograph of the Wall of the Esophagus Showing Plasma-Cell Infiltration.*

I thought that only a day or two more of the sulfonamides was necessary. The thing that he chiefly complained of was pain, or the pressure, as he called it, of "fifteen men on a dead man's chest," at the lower end of the sternum. I do not believe that this was angina, since the pain did not radiate. Then I was struck by the fact that it was painful for him to swallow, and entertained the thought that there might have been something in the esophagus. That was about the picture when I left him, and I was frankly quite at sea. Eight days later I was again called. The temperature was 102°F.; the patient looked worse, being much paler, and had lost weight, with the story that he had continued to refuse food except liquids. He also refused medicine, saying that it hurt him to take it. I thought that I could hear something in the lung bases and sent him to the hospital on the following day with a diagnosis of probable bronchopneumonia. He had fever and

students, and I must say that I did not even come close to the diagnosis. I thought that he had aplastic anemia and suggested giving liver in capsules. It was atypical pernicious anemia, with the thought that he might get a response before he succumbed to the obvious pulmonary sepsis that he had at the time.

CLINICAL DIAGNOSES

Aplastic anemia.
Lobar pneumonia: left lower lobe.
Generalized arteriosclerosis.

DR. NORCROSS'S DIAGNOSES

Multiple myeloma.
Terminal bronchopneumonia.

ANATOMICAL DIAGNOSIS

Plasma-cell leukemia, with involvement of the bone marrow, spleen, lymph nodes, esophagus, lungs and kidneys.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The autopsy on this man showed an unusual esophagus. Practically the whole esophageal wall, from the beginning to the cardia, was markedly thickened, measuring in places 4 to 5 mm., and was rigid, as if there were submucosal infiltration. It had a dirty, brown-black appearance. On gross examination we were unable to decide what it was. It certainly did not look like carcinoma of the esophagus, and there was no ulceration of the mucosa. The liver was about normal in size, and the spleen slightly enlarged, weighing 290 gm., but neither presented any gross abnormality. The kidneys were slightly enlarged and pale, which one might expect with anemia.

Microscopical examination, however, told the whole story. A section through the wall of the esophagus showed the infiltration that we were able to see in the gross. Practically all the cells were characteristic atypical plasma cells (Fig. 1). In one lymph node, a peripheral sinus was completely filled with plasma cells. Sections of the bone marrow and spleen, as well as those of the lungs and kidney, also showed numerous plasma cells. There were no isolated foci of myelomatous infiltration in the bones, the lesions being diffuse, which, as Dr. Norcross has stated, makes them difficult, if not impossible, to see in x-ray films. We were unable to find any myeloma casts in the tubules of the kidney.

I believe that the case should be classified as plasma-cell leukemia, with diffuse infiltration of the lungs, liver, spleen, kidneys and lymph nodes, as well as the bone marrow, rather than multiple

myeloma. Of course the two diseases are the same, but in the leukemic type the plasma cells get out into the peripheral blood in larger numbers than they do in the average case of multiple myeloma. Looking back in our records we found two similar cases—in men sixty-four and sixty-five years old respectively. One had a red-cell count of 1,500,000, and the other a count of 700,000; one had a white-cell count of 1500, and the other a count of 1200. These patients also complained of fatigue and were clinically diagnosed as having aplastic anemia.

DR. HOLMES: Are there any other cases with this type of esophagus?

DR. CASTLEMAN: I cannot recall one, but any kind of leukemia may produce this type of infiltration. Certainly the substernal pain was caused by the esophageal disease.

DR. HOLMES: Under the fluoroscopic examination, the esophagus should have failed to dilate when the patient swallowed. It ought to have been possible to see that the esophagus was rigid. From these films, however, I get the impression that this man was in poor condition and that the examination was incomplete.

DR. JOSEPH AUB: Abnormal white cells are more susceptible to sulfonamides than are normal cells. Livingston,* at the Huntington Memorial Hospital, showed that sulfonamides drop the white cell count enormously in leukemia.

DR. CASTLEMAN: You think that that might also apply to plasma cells?

DR. AUB: I wonder if it would.

1944—A YEAR OF DECISION

THE year on which we are embarking may well be a year of decision for this generation and for generations to come. With almost no decision on our part we have been forced into a test of power, limitless in its geographic scope; this year, if we are true to our destiny, we shall achieve the first of our final victories. The costs of this victory, and its dangers, are yet to be computed; but whether we shall come through it with a clear future or a confused and clouded one is a decision that soon must be made.

It has become a truism that we can win the war and lose the victory, as we lost it in 1918 and 1919 and in the twenty-odd years thereafter. We are also told that we are fighting and work-

ing and paying to preserve our old way and yet we know that many of the foundations of that way of life are not worth preserving. There is anything in this war that is worrisome, besides security, it is a new way of life, a better way of life for all of human kind. We are not ashamed to say that spiritual and intellectual values must be reckoned ahead of material ones.

To many Americans, still, the idea of progress suggests plenty of gasoline, endless rubbers, endless roads, and development of the plastics industry to keep pace with the new magic of electronics. These developments will probably be given peace and prosperity, but there has been a certain fiscal association with the word progress in our past history, that limits its meaning in a rather unfortunate manner.

The real problems that are going to make this a year of decision are those that can be solved only by clear-sighted planning and fact-finding. We are going to begin to be confronted with the necessity of a switch-back of industry to a peacetime basis, with a major unemployment problem. We are going to meet the vanguard of seven million young men, crippled and well, who will have to see the rewards of the victory they have won. We are going to decide whether we can afford to play ball with our allies, once the immediate danger is past, or whether we are going to scramble for the major part of the fruits of the victory—to see who can dominate the air routes, shipping lanes and the richest markets. We are going to see if we can play a mature role in international politics and world statesmanship, after the terms that we have professed—protecting, patronizing, helping without bullying and operating without assuming a leadership that has not been earned. This may be the year when we shall have to decide whether, as a nation, we have become of age—if we are mature enough to be granted a leadership in settling the most perplexing problems with which the world has ever been confronted.

FATIGUE LABORATORY

Fatigue Laboratory of the Harvard School of Business Administration was the result, more directly, of the wisdom and foresight of Wallace B. Donham who, during his term of office, appreciated the possibilities of research under the conditions with which industry is confronted. The laboratory was accordingly set up, in 1918, under the auspices of the Rockefeller Foundation, and continues to function with the aid of the National Research Council.

At present Professor Lawrence J. Henderson directs the establishment of the laboratory and is its wisest counsellor, under the successive directorships of Dr. Arlie V. Bock and Dr. D. B. Dill. Lieutenant Colonel Dill continues his interest during the present activities of the laboratory, but the active directorship has passed back into the hands of Dr. Bock for the duration of the war, with the practical functioning of the laboratory in the hands of Drs. R. C. Darling, J. P. Fortes and Robert E. Johnson.

Except for a small flame of pure research that is burning at the laboratory until better days of academic pursuits have returned, the work being conducted is done entirely for the needs of Scientific Research and Development and the Quartermaster Corps of the Army. Thus, in a cold room, with a minimum temperature of 50°F., various types of warm clothing, including electrically heated suits and shoes, are worn on the living subject; here also, stiffly reclining, lies "Oscar," the electric dummy, within whose patient frame is measured the amount of heat required to keep his body temperature up to human normal with the aid of various styles and types of garments. In another chamber, temperature and humidity are attained, and here, experiments are conducted on heat exhaustion, acclimatization, and the best types of clothing for these climatic conditions, with a three-and-a-half-day-an-hour march simulated on an electric treadmill. Still another chamber furnishes the barometric pressures of various altitudes.

Nutrition studies based on the standard field rations are being conducted, with a view to their balance, particularly regarding the vitamin B fractions; studies have been made under field working conditions on the protein requirements of the body, and it has been found that good health and nutrition can be maintained on a protein intake considerably below the traditionally accepted 70 gm. per day, with those that are provided being principally from vegetable sources.

In addition to its homework, the laboratory is constantly on call to send its investigators into the field wherever needed, to make their studies under actual living and working conditions. Its official reports run into volumes, and when, finally, the veil of secrecy can be lifted, it will be found that scientific progress has taken some tremendous steps in various directions during the war years.

Indefinite and inclusive as the term "fatigue" may be, the Fatigue Laboratory has long since outgrown its title.

MEDICAL EPONYM

PANDY REACTION

The paper "Über eine neue Eiweissprobe für die Cerebrospinalflüssigkeit [A New Albumin Test for the Cerebrospinal Fluid]" by Kalman Pandey (b. 1869) appears in the *Neurologisches Centralblatt* (29:915-919, 1910). A portion of the translation follows:

This test consists in adding a drop of cerebrospinal fluid to about 1 cc. of concentrated carbolic acid (1 part carbolic acid crystals plus 15 parts of distilled water). Wherever the two fluids come in mutual contact there appears after a few seconds a bluish white turbidity resembling a cloud of smoke—an indication that in the fluid in question there are easily precipitable proteins (globulins) in pathological quantity.

R. W. B.

CORRESPONDENCE

A WARTIME EMERGENCY DIABETIC COMA SERVICE

To the Editor: Early diagnosis and treatment of diabetic coma lessen mortality and recovery. With this in mind, the Coma Service has been organized at the Massachusetts General Hospital.

Through the co-operation of the hospital, a corps of diabetic nurses, a chemical technician and the medical staff, blood and urine analyses, as well as medical treatment and special nursing, will always be available, day and night, Sundays and holidays. Such a service would be desirable for all hospitals, but unfortunately on account of war conditions this is not feasible.

Any doctor who has a case of diabetic coma in or outside a hospital and cannot secure the laboratory and medical assistance that he believes indicated can feel at liberty to call on the Emergency Diabetic Coma Service at the New England Deaconess Hospital for consultation regarding treatment or admission of the patient.

BOOK REVIEWS

Biological Symposia. Edited by Jaques Cattell. Volume VIII. *Levels of Integration in Biological and Social Systems.* Edited by Robert Redfield. 4°, cloth, 240 pp. Lancaster, Pennsylvania: The Jaques Cattell Press, 1942. \$2.50.

The contributions to this interesting volume represent new frontiers of research for students of human society. The papers are all concerned with one or another aspect of the question, How are parts constituted into wholes throughout the range of life-forms?

An informative and critical introduction is written by Robert Redfield. Libbie H. Hyman, in "The Transition from the Unicellular to the Multicellular Individual," points out that the essential difference between a protozoan colony and a multicellular individual is polarization, the establishment of an axis along which there is both functional and morphological differentiation. "Intermediate Levels of Organismic Integration," by J. William Buchanan, sums up his position in the declaration that the organization of animals of the lower groups is characterized by an absence of centralization of the response mechanisms. In the chapter "Higher Levels of Integration" R. W. Gerard notes that the difference between lower and higher organisms is mainly in their transmissive mechanisms and in their adaptive amplification. Man as an org is selfish, individualistic and dominated by the old brain and its emotional attributes.

Man as a unit in the epiorganism is altruistic and operative, and depends on the functioning of his brain and its intellectual attributes. William Burrows, his paper "Synergistic Aspects of Bacterial Population," questions the validity of the concept that specific microetiology is the basis of much of modern bacteriology and suggests that diseases may be caused not by a single species of bacterium but by associated micro-organisms. H. S. Jennings concludes that the transition from the individual to the social level begins in the one-cell organisms; and advances there by several steps. Thomas Pa considers the problem of integration in infrasocial insect populations, with marked emphasis on the argument that population is as much a biologic unit as the organism and has the attributes of preproduction, death, metabolism, irritability, growth and differentiation, a heredity, an environmental adaptation and adjustment. The chapter by W. C. Allee, entitled "Social Dominance and Subordination Among Vertebrates," points to the fact that the dominance-subordination social pattern may be based on heredity, the physiologic state of the individual and psychological factors. A closer reciprocal understanding between the social and the biologic sciences is urged by I. Alfred E. Emerson in his chapter "Basic Comparisons of Human and Insect Societies," to the end that scientists shall not overlook the place of emotional force and money even in science. C. R. Carpenter gives an interesting and illuminating discussion on societies of monkeys and apes. In "The Societies of Primitive Man," A. Kroeber attempts to show that some measure of kinship of primitive man persists into higher civilization because kinship is biologically inescapable and perhaps equally inescapable psychologically. The concluding chapter "Modern Society," is by Dr. Robert E. Park, who discusses the "great society" from the distinguishing characteristics of size, complexity, speed, mechanism and freedom.

It seems to the reviewer that a careful reading of this instructive volume will give the reader a fair measure of intellectual balance in any further consideration of biological phenomena.

Starling's Principles of Human Physiology. Edited and revised by C. Lovatt Evans, D.Sc., F.R.C.P., F.R.S., LL.D. With chapters on the special senses revised by H. H. Huxley, M.D., Sc.D., F.R.S. Eighth edition. 8°, cloth, 121 pp., with 673 illustrations. Philadelphia: Lea and Febiger, 1941. \$10.00.

The author succeeds well in maintaining a proper balance in presenting the subject matter of physiology and its more important recent developments. The order adopted is in keeping with the courses given at University College. In this edition, the section covering the central nervous system has been entirely rewritten to conform to the newer knowledge in this field. The chapter on reproduction has been extensively revised, and a good deal of new matter has been added. The discussions on the endocrine organs, the vitamins and the urinary system and those sections concerned with biochemistry have been rewritten and rearranged. One will find many newly introduced figures of great teaching value. Although the book is essentially planned for the use of the student, the clinician can turn to it with considerable profit.

Boston City Hospital, and physician-in-chief, Waltham Hospital. 8°, cloth, 114 pp., with 11 charts. New York: The Commonwealth Fund, 1943. \$1.50.

This small work discusses the spectacular reduction in mortality due to some of the common diseases and seeks to ascertain the underlying causes of this decline.

Diagnosis of Uterine Cancer by the Vaginal Smear. By George N. Papanicolaou, M.D., Ph.D., Department of Anatomy, Cornell University Medical College; and Herbert F. Traut, M.D., Department of Obstetrics and Gynecology, Cornell University Medical College and the New York Hospital. 4°, cloth, 46 pp., with 11 color plates. New York: The Commonwealth Fund, 1943. \$5.00.

This volume describes a new, simple and inexpensive aid in the diagnosis of cancer of the uterus. The study is based on three years' experience in the Woman's Clinic at Cornell University.

Clinical Parasitology. By Charles F. Craig, M.D., M.A. (hon.), colonel, United States Army (retired); and Ernest C. Faust, M.A., Ph.D., professor of parasitology, Department of Tropical Medicine, Tulane University of Louisiana, consultant on tropical medicine and on epidemic diseases to the Secretary of War and to the United States Public Health Service. 8°, cloth, 767 pp., with 284 illustrations and 4 colored plates. Philadelphia: Lea and Febiger, 1943. \$9.00.

This new edition of a standard work has been brought up to date and new material relating to epidemiology in the field of human parasitology and on diseases transmitted to man by arthropods has been included. Four full-page color plates, two clinical tables and forty new figures have been added to the text. The table on the important malaria-transmitting mosquitoes of the world has been revised by Lt. Col. Paul F. Russell, Division of Preventive Medicine, Office of the Surgeon-General, Army of the United States. This work should prove valuable to medical and sanitary officers stationed in the tropics and the Orient.

Nutrition in Health and Disease. By Lena F. Cooper, B.S., M.A., M.H.E., chief, Department of Nutrition, Montefiore Hospital, New York City, dean, School of Home Economics, Battle Creek College, and supervising dietitian, United States Army (1918-1919); Edith M. Barber, B.S., M.S., editor of food column, New York *Sun*, and lecturer on history of cookery, Teachers College, Columbia University; and Helen S. Mitchell, B.A., Ph.D., chief nutritionist, Office of Foreign Relief and Rehabilitation Operations, State Department, and research professor in nutrition, Massachusetts State College. Ninth edition, revised. 8°, cloth, 716 pp., with 99 illustrations and 7 colored plates. Philadelphia: J. B. Lippincott Company, 1943. \$3.50.

This standard work on nutrition for use in schools of nursing has been thoroughly revised and brought up to date. Much new material has been added on the vitamins and a new chapter on food and nutrition problems in wartime. The table on the composition of foods has been revised and includes niacin, pyridoxine, pantothenic acid and biotin. A new feature of this edition is a glossary giving the concise definition of technical words and their pronunciation.

Gastro-Enterology. By Henry L. Bockus, M.D., professor of gastroenterology, University of Pennsylvania Graduate School of Medicine. Philadelphia: J. B. Lippincott Company, 1943. \$12.00.

stomach. 4°, cloth, 831 pp., with 134 illustrations, 21 tables. Philadelphia and London: W. B. S. Company, 1943. \$12.00.

This is the first volume of a system of diseases digestive tract and organs. The second volume, of the small and large intestines, and the third volume, of the liver, biliary tract, pancreas and second, of gastrointestinal disorders, will be published later. The purpose of the work is to include a discussion of every case and affection of the digestive tract. The author, drawn on his large experience in the Gastrointestinal Department of the Graduate Hospital of the University of Pennsylvania.

The Modern Treatment of Syphilis. By Joseph E. Murray, M.D., associate professor of medicine and adjunct professor of public-health administration, Johns Hopkins University, physician-in-charge, Syphilis Division, Johns Hopkins Clinic, and visiting physician, Johns Hopkins Hospital, Baltimore, and special consultant, United States Public Health Service. With the collaboration of Jarold E. Murray, M.D.; Harry Eagle, M.D., surgeon, United States Public Health Service, and lecturer in medicine, Johns Hopkins University; Paul Paget, M.D., associate in medicine, Johns Hopkins University; Mary S. Goodwin, M.D., instructor in pediatrics, Johns Hopkins University; Frank W. Reynolds, M.D., instructor in medicine, Johns Hopkins University. Second edition; second printing. 4°, cloth, 717 pp., with 109 illustrations and 12 tables. Springfield, Illinois: Charles C Thomas, 1943. \$7.50.

This authoritative work was first published in 1931 and the second edition in 1941. The second edition is completely revised to the extent that twenty-three of the original thirty-two chapters of the first edition have been completely rewritten and the other nine chapters have been extensively changed. The entire second edition is set from new type. A new chapter on the public aspects of the treatment of syphilis and a much more extensive discussion of infections in syphilis and its relation to other diseases have been added. The bibliography has been completely revised to about the same length as that in the first edition, with omission of older references to make room for the more recent ones. The second printing of the second edition has made possible the inclusion of a new chapter on venereal-disease control in the Army and Navy. In addition, the chapter on intensive arsenotherapy in syphilis has been thoroughly rewritten and brought up to date.

The Boy Sex Offender and His Later Career. By J. Doshay, M.D., Ph.D., psychiatrist, Children's Hospital, New York City. With a foreword by George W. Peck, M.D., associate professor of clinical psychiatry, University Medical College, consulting psychiatrist, Department of Correction, New York City, and consulting psychiatrist, New York Hospital. 8°, cloth, 206 pp., with 40 tables. New York: Grune & Stratton, 1944. \$4.00.

The author of this book has been extensively revised for over ten years examining thousands of patients in the clinics of the City of New York. His comments and conclusions are based on a relatively large number of investigations. New lights on certain phases of juvenile sex delinquency are brought out. A rather startling conclusion is that the so-called "born" boys commit just as many a violent offense as the "acquired" delinquents.
